particularly proatherogenic. Therefore Lp(a) is often measured in individuals with a normal lipid panel but with a history of premature cardiovascular disease and/or a strong family history of cardiovascular disease. Turbidimetric, nephelometric, RIA, and ELISA methods are all currently used for Lp(a) measurement. Most of these assays, except for ELISA, are based on the use of polyclonal antibodies. Sandwich-type ELISAs are usually based on the use of a combination of monoclonal and polyclonal antibodies to apo B and apo(a). The immunoreactivity of antibodies directed to the repeat kringle 4 type 2 domain in apo(a) makes some Lp(a) assays vary as a function of apo(a) size. These assays tend to underestimate apo(a) concentration in samples with apo(a) of smaller size than the apo(a) present in the assay calibrator and to overestimate the apo(a) concentration in samples with larger apo(a). Traditionally, Lp(a) concentrations have been reported in terms of total Lp(a) particle mass or, alternatively, in terms of Lp(a) protein. If the purpose is to provide Lp(a) values that are independent of apo(a) size, it is recommended that the Lp(a) assay use antibodies directed to an apo(a) domain other than kringle 4 type 2, or to the apo B-100 component of Lp(a). This would allow the values to be expressed in nanomoles per liter. At present, Lp(a) measurements are not well standardized, but a value of approximately 30 mg/dL of total Lp(a) particle mass has traditionally been used as a cutoff, above which increased concentrations of Lp(a) are associated with increased risk of CHD. Because Lp(a) values vary among ethnic groups, reference intervals ideally should be population based. For example, African Americans generally have significantly higher Lp(a) concentrations than do whites.

Sources of Variation and Bias in Test Measurement

Concentrations of various lipoproteins and their constituent parts—lipids and apolipoproteins—vary within individuals (see [Chapter 4](#)). Analytical variations for such measurements are relatively small—generally approximately 2% to 3% CVs for cholesterol—but some direct measurements of LDL-C and HDL-C do not meet National Cholesterol Education Program (NCEP) guidelines for analytical performance (see [Table 23.10](#)) on dyslipidemic samples. In contrast, physiological variations are much larger and contribute to the vast majority of overall variation in lipid and lipoprotein concentrations. For this reason, a patient's usual lipid or lipoprotein concentration is not reliably established from a single measurement, and the NCEP Laboratory Standardization Panel has made several specific recommendations for reducing the effects of preanalytical factors and specimen-processing procedures on lipid and lipoprotein testing.

ADVANCED LIPID AND LIPOPROTEIN TESTING FOR CORONARY HEART DISEASE RISK ASSESSMENT

Despite the strong association of plasma lipid concentrations with CHD risk, it has been long recognized that half

of all myocardial infarctions occur among individuals with a normal lipid panel. Consequently, a wide variety of alternative or emerging biochemical markers and assays have been identified for better assessing cardiovascular risk. For example, LDL-P and HDL-P, which represent measurement of LDL and HDL particle number, respectively, can be measured by nuclear magnetic resonance (NMR) or by mass spectrometry and are positively related to CHD risk in case of LDL-P and negatively related for HDL-P. Similarly, the size of lipoproteins can be measured by a variety of physical techniques, and in the case of LDL, smaller-size LDL has been shown to be positively related to cardiovascular risk, particularly in patients with diabetes and metabolic syndrome. Several studies have shown that both lipoprotein particle number and size may be superior to LDL-C and HDL-C as cardiovascular biomarkers. Other alternative tests are based on other factors besides conventional lipids or apolipoproteins, such as oxidized lipids and the plasma concentration of the amino acid homocysteine. However, at this time, no overall consensus has been reached on how most of these advanced lipid and lipoprotein tests are best used, but as discussed later, hsCRP, a marker of inflammation, may be useful for deciding how to best treat patients at intermediate risk of CHD based on conventional risk markers.

High-Sensitivity C-Reactive Protein

CRP was first discovered in 1930 and was subsequently shown to be an acute phase reactant. It is routinely monitored as an indication of infection and autoimmune disease (see [Chapter 18](#)).

Numerous epidemiologic studies have demonstrated that increased serum CRP concentrations are positively associated with risk of future CHD events ([Fig. 23.24](#)). These findings support the hypothesis that (1) inflammation, (2) atherothrombosis, (3) diabetes, and (4) hypertension are interrelated and share common pathogenic mechanisms.

Prospective epidemiologic studies have shown that a single hsCRP measurement is a strong predictor of (1) myocardial infarction, (2) stroke, (3) peripheral vascular disease, and (4) sudden cardiac death, even in individuals with no history of heart disease. It has also been shown in prospective studies that hsCRP can be used to more accurately classify patients at intermediate risk of CHD. National guidelines for the measurement of hsCRP as a marker of CHD risk have been issued jointly by the American Heart Association and the Centers for Disease Control and Prevention (AHA/CDC). The Canadian Cardiovascular Society guidelines included hsCRP in the risk assessment of CHD and as a secondary target for treatment. In addition, the AHA/ACC guidelines, following the 10-year risk assessment, added new risk markers such as hsCRP, coronary artery calcium, or ankle-brachial indices in the risk assessment tools.

Several pharmacologic agents that have demonstrated cardioprotective ability, such as aspirin and statins, lower the risk of CHD that is associated with increased hsCRP

Fig. 23.24 (A) Relative risk of cardiovascular events with increase in low-density lipoprotein (LDL) and C-reactive protein (CRP). (B) Probability of event-free survival decreases with increases in CRP and LDL levels. LDL-C, LDL cholesterol.

concentration. As a consequence, hsCRP is now often used in intermediate-risk individuals with low to normal lipids, but because of increased inflammation are at higher risk so that intervention with a statin can be implemented.

Methods have been developed to detect the low concentrations of CRP required for prediction of vascular risk, refer to as hsCRP. Of various techniques used to lower the limits of detection of CRP assays, the most successful approach has been to amplify the light-scattering properties of the antigen-antibody complex by covalently coupling latex particles to a specific antibody—a procedure that is easily automated on standard laboratory instrumentation. Many commercial hsCRP assays with low detection limits (<0.3 mg/L) are available, some with within-laboratory analytical imprecision of less than 10%.

Although it is an acute phase reactant, hsCRP exhibits a relatively low degree of intraindividual variability in clinically stable patients. It has been recommended to have two hsCRP measurements taken 2 or more weeks apart, with the average value used to estimate vascular risk. Furthermore, because hsCRP values are unaffected by food intake and exhibit almost no circadian variation, fasting specimens are not required.

Data from several large US and European cohorts indicate that the distribution of circulating hsCRP concentrations appears comparable among men and women not using postmenopausal hormone replacement therapy (HRT), with the 50th percentile for both genders seen at approximately 1.5 mg/L. Concentrations of hsCRP are higher in women who use oral HRT than in women who do not. Reference intervals of less than 1, 1 to 3, and greater than 3 mg/L, which correspond to approximate tertiles of the CRP distribution in healthy adults, are recommended for classification of individuals into low, moderate, and high cardiovascular risk groups in primary prevention settings.

REVIEW QUESTIONS

- Which of the following formulas shows the correct calculation for indirectly measuring LDL-C (Friedewald formula)?
 - LDL-C = HDL-C + (Triglyceride/5)
 - LDL-C = Total cholesterol – (HDL-C) – (Triglyceride/5)
 - LDL-C = Total cholesterol + HDL-C + (Triglyceride/5)
 - LDL-C = HDL-C – (Triglyceride/5)
- The protein component of a lipoprotein is referred to as:
 - terpene.
 - apolipoprotein.
 - prostaglandin.
 - phospholipid.
- The lipoprotein that contains a carbohydrate-rich protein covalently bound to apo B-100 and a special protein motif called the “kringle” domain is:
 - LDL.
 - HDL.
 - chylomicron.
 - lipoprotein(a).
- What lipoprotein transports mostly cholesteryl esters through the blood?
 - LDL
 - VLDL
 - Chylomicrons
 - Lipoprotein(a)
- The enzyme that is critical for hydrolysis of triglycerides on chylomicrons for their conversion to chylomicron remnants is:
 - cholesterol oxidase.
 - glycerol kinase
 - lipoprotein lipase.
 - HMG-CoA reductase.
- The rate-limiting enzyme in cholesterol biosynthesis that is inhibited by statin drugs is:
 - cholesterol oxidase.
 - glycerol kinase
 - lipoprotein lipase.
 - HMG-CoA reductase.

7. Which of the following lipid metabolic pathways has a role in transferring hepatically derived lipids, particularly triglyceride, to peripheral cells for energy metabolism?
 - a. Exogenous pathway
 - b. Endogenous pathway
 - c. Intracellular cholesterol transport pathway
 - d. Reverse cholesterol transport pathway
8. The formation of mixed micelles containing unesterified cholesterol, fatty acids, monoglycerides, phospholipids, and bile acids is referred to as:
 - a. emulsification.
 - b. denaturation.
 - c. esterification.
 - d. saturation.
9. With regard to lipids, a carboxyl ($-\text{COOH}$) with a long side chain (R) containing an even number of carbon atoms that is important in human nutrition and metabolism is a type of lipid referred to as a(n):
 - a. acylglycerol.
 - b. ester.
 - c. fatty acid.
 - d. terpene.
10. In the laboratory analysis of triglycerides, the initial step in all methods is:
 - a. phosphorylation of glycerol catalyzed by glycerokinase.
 - b. oxidation of cholesterol by cholesterol oxidase.
 - c. hydrolysis of triglyceride by lipase.
 - d. reduction of phenol and H_2O_2 by peroxidase.

Electrolytes and Blood Gases

Mark A. Cervinski, Mark D. Kellogg, Mitchell G. Scott

OBJECTIVES

1. Define the following terms:
 - Anion
 - Blood gas
 - Cation
 - Colligative properties
 - Electrolyte
 - Electrolyte exclusion effect
 - Osmolality
 - Oxygen dissociation curve
 - Oxygen saturation
 - pH
 - Partial pressure
 - Co-oximetry
 - Sweat chloride test
2. For each of the following electrolytes, state and describe the biochemistry, physiological functions, localization, clinical significance, method of analysis, and potential analytical interferences:
 - a. Bicarbonate
 - b. Chloride
 - c. Potassium
 - d. Sodium
3. Compare direct and indirect ion-selective electrode testing, including uses of and interferences in each method.
4. Discuss the measurement of sweat chloride, including reasons for performing, details of the phases of testing, and specimen requirements.
5. Describe the following methods of electrolyte/blood gas measurement, including which analytes are measured with each technique, the principle of the method, specimen requirements, and possible interferences:
 - a. Coulometry-amperometry
 - b. Osmometry
 - c. Potentiometry
 - d. Sweat testing
 - e. Tonometry
6. List and describe the four colligative properties of a solution.
7. State the formula that demonstrates the relationship between total concentration of CO_2 , bicarbonate, and hydrogen ion concentration.
8. State the Henderson-Hasselbalch equation and explain each of its components.
9. List the three essential properties of arterial blood required for adequate oxygen delivery to tissues.
10. For blood gas determinations, describe each of the following:
 - a. Specimen requirements
 - b. Preferred anticoagulant
 - c. Collection technique
 - d. Specimen transport conditions
11. List the analytical problems that arise in the analysis of pH, $p\text{O}_2$, and $p\text{CO}_2$ with inappropriate specimen collection or transport.
12. Diagram a generic blood gas analyzer; state and describe the methods or calculations used to measure pH, $p\text{O}_2$, and $p\text{CO}_2$, including noninvasive and continuous monitoring methods.

KEY WORDS AND DEFINITIONS

Anemic hypoxia Hypoxia (a reduced supply of oxygen to the tissues) resulting from a decrease in the amount of hemoglobin or number of erythrocytes in the blood.

Blood gases $p\text{CO}_2$ and $p\text{O}_2$ (partial pressures of carbon dioxide and oxygen), usually in whole blood.

Colligative properties Properties of solutions that depend on the number of particles in the solution; examples include (1) osmotic pressure, (2) boiling point elevation, (3) freezing point depression, and (4) vapor pressure lowering.

Cystic fibrosis (CF) Inherited disorder of a transmembrane conductance regulator protein (CFTR) that leads to chronic pancreatic and obstructive pulmonary disease.

Cystic fibrosis transmembrane conductance regulator (CFTR) A transmembrane protein produced by the CFTR gene.

Electrolytes Charged low-molecular-mass molecules present in plasma and cytosol, usually ions of (1) sodium, (2) potassium, (3) calcium, (4) magnesium, (5) chloride, (6) bicarbonate, (7) phosphate, (8) sulfate, and (9) lactate.

Electrolyte exclusion effect Electrolytes are excluded from the fraction of total plasma volume that is occupied by solids, which leads to underestimation of electrolyte concentration by some methods.

Hemoglobin (Hb) An oxygen-carrying, heme-containing protein abundant in red blood cells.

Henderson-Hasselbalch equation Equation that defines the relationship between pH, bicarbonate, and the partial pressure of dissolved carbon dioxide gas:

$$\text{pH} = \text{pK} + \log \left(\frac{c\text{HCO}_3^-}{\alpha + p\text{CO}_2} \right)$$

Ion-selective electrode (ISE) A type of special-purpose, potentiometric electrode consisting of a membrane selectively permeable to a single ionic species. The potential produced at the membrane-sample solution interface is proportional to the logarithm of the ionic activity or concentration.

Osmolal gap A difference between the observed and calculated osmolalities in serum analysis. The formula for calculated osmolality is $1.86 \times \text{Na (mmol/L)} + \text{glucose (mmol/L)} + \text{blood urea nitrogen (mmol/L)} + 9$; or $1.86 \times \text{Na (mmol/L)} + \text{glucose (mg/dL)}/18 + \text{urea (mg/dL)}/2.8 + 9$.

Osmometry Technique for measuring the concentration of dissolved solute particles in a solution.

Osmotic pressure The pressure required to stop osmosis through a semipermeable membrane between a solution and pure solvent.

Oximetry A technique used to determine the oxygen saturation of arterial blood.

Oxygen dissociation curve The sigmoidal curve obtained when SO_2 of blood is plotted against $p\text{O}_2$.

Oxygen saturation (SO_2) The fraction (percentage) of functional hemoglobin that is saturated with oxygen.

Oxyhemoglobin Hemoglobin that contains bound O_2 .

P_{50} $p\text{O}_2$ for a given blood sample at which the hemoglobin of the blood is half saturated with O_2 ; P_{50} reflects the affinity of hemoglobin for O_2 .

Partial pressure The substance (mole) fraction of gas times the total pressure; e.g., the partial pressure of oxygen, $p\text{O}_2$, is the fraction of oxygen gas times the barometric pressure.

pH The negative logarithm of hydrogen ion activity.

Pilocarpine iontophoresis Noninvasive method that uses electricity to force the drug pilocarpine into the skin for the purpose of inducing localized sweating at the site of iontophoresis.

Point-of-care testing (POCT) Clinical testing that occurs next to the patient, usually with a handheld device and an unprocessed specimen collected immediately before testing.

Sweat chloride The concentration of chloride in sweat; increased sweat chloride is characteristic of cystic fibrosis.

Water homeostasis The body process that maintains a balance of water intake and output.

Maintenance of **water homeostasis** is paramount to life for all organisms. In humans, the maintenance of water homeostasis in various body fluid compartments is primarily a function of the four major electrolytes: Na^+ , K^+ , Cl^- , and HCO_3^- . These electrolytes also have a role in acid-base balance and heart and muscle function, and serve as cofactors for enzymes. Abnormal electrolyte concentrations may be the cause or the consequence of a variety of medical disorders. Because of their physiologic and clinical interrelationships, this chapter discusses determination of (1) electrolytes, (2) osmolality, (3) sweat testing, (4) **blood gases** and **pH**, and (5) oxygen hemodynamics.

ELECTROLYTES

Electrolytes may be classified as *anions*, negatively charged ions that move toward an anode, or *cations*, positively charged ions that move toward a cathode. Important physiologic electrolytes include Na^+ , K^+ , Ca^{2+} , Mg^{2+} , Cl^- , HCO_3^- , H_2PO_4^- , HPO_4^{2-} , SO_4^{2-} , and some organic anions, such as lactate. At physiologic pH, proteins in serum are usually anions, and albumin accounts for most of the difference between the commonly measured cations (Na^+ , K^+) and anions (Cl^- , HCO_3^-), also known as the anion gap. Hydrogen ion (H^+) concentration is routinely measured as pH, but its concentration is so low relative to other ions (10^{-9} vs. 10^{-3} mol/L) that

its role as an electrolyte is negligible for clinical purposes. The major electrolytes (Na^+ , K^+ , Cl^- , HCO_3^-) occur primarily as free ions, whereas significant amounts (>40%) of Ca^{2+} , Mg^{2+} , and trace elements are bound by proteins, mainly albumin. Determination of body fluid concentrations of the four major electrolytes (Na^+ , K^+ , Cl^- , and HCO_3^-) is commonly referred to as an *electrolyte profile*.

SPECIMENS FOR ELECTROLYTE DETERMINATION

Serum and *plasma* are the usual specimens analyzed for electrolytes. Capillary blood, collected in microsample tubes or capillary tubes, or applied directly from a finger stick to point-of-care devices, are also common. Arterial or venous heparinized whole blood specimens obtained for blood gas and pH determinations may also be used with direct **ion-selective electrodes (ISEs)**. Differences in values between serum and plasma and between arterial and venous samples have been documented, but only the difference between serum and plasma K^+ can be considered clinically significant. Heparin, either lithium or ammonium salt, is required if plasma or whole blood is assayed. The use of plasma or whole blood has the advantage of shortening turnaround time as compared with serum, as these samples do not require sample clotting prior to analysis. Plasma or whole blood provides a

distinct advantage in determining K^+ concentrations, which are invariably higher in serum, depending on platelet count. Grossly lipemic blood can be a source of analytical error (see the section “Electrolyte Exclusion Effect”), and ultracentrifugation of lipemic serum or plasma is required prior to analysis via indirect-ISE methods. Hemolysis of red blood cells will cause erroneously high K^+ results in serum, plasma, and whole blood samples (pseudohyperkalemia); however, it is usually detected in serum and plasma due to its characteristic color. Hemolysis is, however, usually undetected when whole blood is analyzed. Pseudohyperkalemia may also develop in unhemolyzed specimens that are not promptly processed as K^+ will leak out of red blood cells when whole blood is stored at 4°C (for more details on preanalytical errors, refer to [Chapter 3](#)).

Urine collection for Na^+ , K^+ , or Cl^- assays should be done without the addition of preservatives. Body fluid aspirates, feces, or gastrointestinal (GI) fluid samples may also be submitted for electrolyte analysis.

SODIUM

Sodium is the major cation of extracellular fluid. Because it represents approximately 90% of the ≈ 154 mmol of inorganic cations per liter of plasma, Na^+ is responsible for almost one half the osmotic strength of plasma. It therefore plays a central role in maintaining the normal distribution of water and osmotic pressure in the extracellular fluid compartment (ECF).

Sodium is freely filtered by renal glomeruli. Seventy to 80% of the filtered Na^+ load is actively reabsorbed in the proximal tubules, with Cl^- and water passively following in an iso-osmotic and electrically neutral manner. Another 20% to 25% is reabsorbed in the loop of Henle, along with Cl^- and more water. In the distal tubules, interaction of the adrenal hormone aldosterone with the coupled Na^+ - K^+ and Na^+ - H^+ exchange systems results directly in the reabsorption of Na^+ , and indirectly of Cl^- , from the remaining 5% to 10% of the filtered load. It is the regulation of this latter fraction of filtered Na^+ that primarily determines the amount of Na^+ excreted in the urine. These processes are discussed in detail in [Chapter 35](#).

Specimens

Serum, plasma, and urine may be stored at 4°C or may be frozen. Erythrocytes contain only 1/10 of the Na^+ present in plasma, so hemolysis does not cause significant errors in serum or plasma Na^+ values. Lipemic samples should be ultracentrifuged, and the infranant analyzed unless a direct ISE is used (see the section “Electrolyte Exclusion Effect”).

Fecal and GI fluid specimens require preparation before assay. Because significant electrolyte loss in feces only occurs in diarrhea, only liquid stool samples may be justified for analysis. Immediately after collection, liquid stool specimens should be clarified of particulate matter by filtration through gauze or filter paper and by centrifugation. If not analyzed immediately, fecal and GI fluids should be stored frozen to prevent microbial growth.

Reference Intervals

A typical reference interval for *serum* or plasma Na^+ is 135 to 145 mmol/L. The interval for premature newborns at 48 hours is 128 to 148 mmol/L, and the value for umbilical cord blood from full-term newborns is ≈ 127 mmol/L.

Urinary sodium excretion varies with diet, but for an adult male consuming 7 to 14 g of NaCl per day, an interval of 120 to 240 mmol/L is typical. A large diurnal variation in Na^+ excretion has been noted, with the rate of Na^+ excretion during the night being only 20% of the peak rate during the day. The Na^+ concentration of cerebrospinal fluid is 136 to 150 mmol/L. Mean fecal Na^+ excretion is less than 10 mmol/L.

POTASSIUM

Potassium is the major intracellular cation with an average concentration in tissue cells of ~ 150 mmol/L, and in erythrocytes, the concentration is ~ 105 mmol/L. High intracellular concentrations are maintained by the Na^+ , K^+ adenosine triphosphate (ATP)ase pump, which continually transports K^+ into the cell against a concentration gradient. Diffusion of K^+ out of the cell into the ECF and plasma occurs whenever pump activity is decreased because of (1) depletion of metabolic substrates such as glucose; (2) competition for ATP between the pump and other energy-consuming activities of the cell; or (3) slowing of cellular metabolism (as occurs with refrigeration). The importance of these considerations on sample integrity for analysis of K^+ is discussed later.

The body requirement for K^+ is satisfied by an average dietary intake of 2.4 to 4.4 g/d (60 to 120 mmol/d). Potassium absorbed from the GI tract is rapidly distributed, with a small amount taken up by cells, and most excreted by the kidneys. Potassium filtered through the glomeruli is almost completely reabsorbed in the proximal tubules and is then secreted in the distal tubules in exchange for Na^+ under the influence of aldosterone. Aldosterone enhances K^+ secretion and Na^+ reabsorption in the distal tubules by a Na^+ - K^+ exchange mechanism. The kidneys respond to K^+ loading with an increase in K^+ output, so that urine collected during or after a period of high K^+ intake may have K^+ concentrations as high as 100 mmol/L. In contrast, the tubular response to conserve K^+ is very slow in the initial stages of depletion. Unlike the prompt response to conserve Na^+ in deficit states, it can take up to 1 week for the tubules to reduce K^+ excretion to 5 to 10 mmol/d from the typical 50 to 100 mmol/d.

Factors that regulate distal tubular secretion of K^+ include intake of Na^+ and K^+ , mineralocorticoid concentration, and acid-base balance. Because renal conservation mechanisms are slow to respond, K^+ depletion can be an early consequence of restricted K^+ intake or loss of K^+ by extrarenal routes such as diarrhea. A diminished glomerular filtration rate is typical of renal failure, and the consequent decrease in distal tubular flow rate is an important factor in the hyperkalemia associated with renal failure.

Specimens

Comments made earlier on specimens for Na^+ analysis are generally applicable to those for K^+ analysis, with some caveats. Potassium concentrations in plasma and whole blood are 0.1 to 0.7 mmol/L lower than those in serum, and most reference intervals for serum K^+ are 0.2 to 0.4 mmol/L higher than those for plasma K^+ . The extent of this difference depends on the platelet count, because additional K^+ in serum is primarily a result of platelet rupture during clotting. This variability in the amount of additional K^+ in serum makes plasma the specimen of choice.

Specimens for determining K^+ concentrations in serum or plasma must be collected by methods that minimize hemolysis, because the release of K^+ from as few as 0.5% of erythrocytes can increase K^+ values by 0.5 mmol/L. An increase in K^+ of 0.6% has been estimated for every 10 mg/dL of plasma **hemoglobin** caused by hemolysis. Thus slight hemolysis ($\text{Hb} \approx 50$ mg/dL) can be expected to raise K^+ values by $\approx 3\%$, marked hemolysis ($\text{Hb} \approx 200$ mg/dL) by 12%, and gross hemolysis ($\text{Hb} > 500$ mg/dL) by as much as 30%. The use of correction factors based on a hemolysis index has been suggested for estimating K^+ in hemolyzed samples, but their use has been questioned. Regardless, it is imperative that if the laboratory chooses to report K^+ concentrations on hemolyzed samples that the presence of hemolysis is noted with a comment that results are falsely elevated, whether an estimate of the extent of elevation is provided or not. It is important to remember that if K^+ concentrations are determined by ISE on whole blood specimens, hemolysis is not readily visible. When hemolysis is suspected, as in the case of an unexpected increase in K^+ , a portion of the specimen should be centrifuged and the plasma visually inspected.

Clinically significant preanalytical errors can occur for K^+ determinations if blood samples are not processed quickly. Maintenance of the intracellular-extracellular K^+ gradient depends on the activity of the energy-dependent Na^+/K^+ -ATPase. If a whole blood specimen is maintained at 4°C versus 25°C before separation, glycolysis is inhibited and the energy-dependent Na^+/K^+ -ATPase cannot maintain the Na^+/K^+ gradient. An increase in plasma K^+ will occur as a result of K^+ leakage from erythrocytes and other cells. The increase of K^+ in serum is on the order of 0.2 mmol/L by 1.5 hours at 25°C , and is as high as 2 mmol/L after 4 hours at 4°C .

A falsely decreased K^+ value can be observed if an unseparated sample is stored at 37°C , because glycolysis occurs and K^+ shifts intracellularly. Even at room temperature, extreme leukocytosis can initially cause falsely decreased K^+ concentrations. The extent of this decrease depends on leukocyte count, temperature, and glucose concentrations, but has been reported to be as much as 0.7 mmol/L at 37°C . In addition to causing pseudohypokalemia, samples from leukemic patients with very high white blood cell counts ($>300 \times 10^9$ cells/L) can result in a pseudohyperkalemia due to WBC rupture. Taken together, the recommendation for reliable K^+ determinations is to collect blood with heparin and

to maintain it near 25°C , and then to separate the plasma within minutes by high-speed centrifugation. In practical terms, separation within 1 hour when samples are maintained at room temperature is unlikely to introduce great error.

Finally, skeletal muscle activity causes K^+ efflux from muscle cells into plasma and can cause a marked elevation in plasma K^+ values. A common example occurs when an upper arm tourniquet is not released before beginning to draw blood after a patient has repeatedly clenched their fist. This combination of tourniquet induced venostasis and muscular activity can artificially raise plasma K^+ values as much as 2 mmol/L.

Reference Intervals

Reported reference intervals for the serum of adults vary from 3.5 to 5.1 mmol/L and from 3.7 to 5.9 for newborns. For plasma, a frequently cited adult interval is 3.3 to 4.9 mmol/L. Urinary excretion of K^+ varies with dietary intake, but a typical range observed is 42 to 86 mmol/L for males and 33 to 70 mmol/L for females. In severe diarrhea, GI loss may be as much as 60 mmol/L.

METHODS FOR THE DETERMINATION OF SODIUM AND POTASSIUM

Sodium and potassium may be determined by (1) atomic absorption spectrophotometry (AAS), (2) flame ionization spectrophotometry (FES), (3) electrochemically with an ion-selective electrode, or (4) spectrophotometrically. Although AAS, FES, or spectrophotometric methods have been used for Na^+ and K^+ analyses in the past, most laboratories now use ISE methods. For example, in 2017, of the laboratories reporting proficiency data for Na^+ and K^+ to the College of American Pathologists (CAP), 98% were using ISE methods.

Ion-Selective Electrodes

ISEs measure Na^+ and K^+ using the principle of potentiometry. Potentiometry is the determination of change in electromotive force (E , potential) in a circuit between a measurement electrode (the ISE) and a reference electrode, as the selected ion interacts with the membrane of the ISE. ISE composition varies with the analyte measured; Na^+ ISEs are fitted with glass membranes and K^+ electrodes with liquid ion-exchange membranes incorporating valinomycin. In electrolyte analyzers and automated instruments, the system is calibrated with solutions containing defined amounts of Na^+ and K^+ . The potentials of the electrodes in the presence of the calibrators are determined, and the $\Delta E/\Delta \log$ concentration responses are stored in microprocessor memory for calculating unknown concentration when E of the unknown is measured.

Frequent calibration of the electrodes' response or slope factors, initiated by the user or by microprocessor-controlled uptake of calibrator, is typical of most current ISE systems. Some of the available ISE systems also check the potential

of one of the calibrators or of a third calibrator, immediately prior to the measurement of each patient specimen, to compensate for electrode drift and/or noise.

Two types of ISE methods, indirect ISE and direct ISE, are in use and must be distinguished. With *indirect ISE methods*, the sample is first mixed with a large volume of diluent of low ionic strength prior to introduction into the measurement chamber. Indirect ISE is most commonly used on automated, high-throughput clinical chemistry systems. Indirect methods were developed early in the history of ISE technology, when dilution was necessary to present a small sample in a volume large enough to adequately cover a large electrode and to minimize the concentration of protein at the electrode surface. With *direct ISE methods*, the sample is presented to the electrodes without dilution. Direct ISE methods became possible with electrode miniaturization and are available on a few automated laboratory instruments. Direct ISE electrodes are primarily used in blood gas analyzers and point-of-care devices where whole blood is directly presented to the electrodes.

Errors observed in the use of ISEs fall into three categories. First are errors caused by lack of selectivity. For instance, many Cl^- electrodes lack selectivity against other halide anions such as I^- or SCN^- from the metabolism of sodium nitroprusside. Second are errors introduced by repeated protein coating of the ISE membranes, or by contamination of the membrane or salt bridge by ions that compete or react with the selected ion and thus alter the electrode response. Such errors in ISE measurements necessitate periodic changes of the membrane as part of routine maintenance. Finally, the **electrolyte exclusion effect**, which applies only to indirect methods and is caused by the solvent-displacing effect of lipid and protein in the sample, results in falsely decreased values.

Spectrophotometric Methods

Spectrophotometric methods are based on Na^+ or K^+ specific enzyme activation. However, the higher cost of these methods and the fact that few problems exist with ISE methods have resulted in “niche” use of spectrophotometric analysis, primarily with smaller instruments used in physicians’ offices, and more recently “isolation” laboratories for patients with emerging infectious diseases.

Kinetic spectrophotometric assays for Na^+ are based on activation of the enzyme β -galactosidase by Na^+ to hydrolyze *o*-nitrophenyl- β -D-galactopyranoside. The rate of production of *o*-nitrophenol (the chromophore) is measured at 420 nm.

Spectrophotometric K^+ assays rely upon the K^+ activation of pyruvate kinase for the conversion of phosphoenolpyruvate to pyruvate, which is then reduced to lactate by lactate dehydrogenase, in the process of oxidizing NADH to NAD^+ .

ELECTROLYTE EXCLUSION EFFECT

The major plasma electrolytes, Na^+ , K^+ , Cl^- , and HCO_3^- , have minimal protein binding and are carried in the water phase of plasma. The composition of plasma is approximately 93% water and 7% solids such as proteins and lipids. When the fixed volume of plasma (e.g., 10 μL) is pipetted for dilution into a buffer of low ionic strength before indirect ISE analysis, only 9.3 μL of *plasma water* that contains the electrolytes is added to the diluent. However, when we report plasma electrolyte concentrations, we report the values in mmol/L of total plasma volume, not in plasma water volume. Thus in the absence of increased plasma protein or lipid concentrations, a reported Na^+ concentration of 140 mmol/L of plasma volume would equal a Na^+ concentration in plasma water of 150 mmol/L ($140 \times [100/93]$). This negative “error” or bias in plasma electrolyte analysis has been recognized for many years.

All electrolyte reference intervals are based on the assumption that plasma is reliably ~93% water and reflect concentrations in total plasma volume and not in water volume. Even though it is the electrolyte concentration in plasma water that is physiologically relevant (the Na^+ concentration of normal saline is 150 mmol/L), it was assumed that the volume fraction of water in plasma is sufficiently constant that this difference could be ignored. This electrolyte exclusion effect, however, becomes problematic when pathophysiologic conditions are present that alter the plasma water volume, such as hyperlipidemia or hyperproteinemia. In these settings, falsely low electrolyte values are obtained whenever samples are diluted before analysis.

In certain settings, such as ketoacidosis with severe hyperlipidemia or multiple myeloma with severe hyperproteinemia, the negative exclusion effect may be so large that laboratory results lead clinicians to believe that electrolyte concentrations are normal or low, when in fact the concentration in the water phase may be high or normal, respectively, leading to pseudohyponatremia (Fig. 24.1).

In severe hypoproteinemia, the effect works in reverse, resulting in falsely high (2% to 4%) Na^+ or K^+ values. As with the indirect ISE, the original method for measuring plasma electrolytes, flame photometry, also required dilution of the sample prior to analysis, and as such is also subject to pseudo-hypo- and hypernatremia.

Direct ISE methods do not require sample dilution, and as there is no dilution, ion activity is directly proportional to the concentration in the water phase, not the concentration in the total plasma volume. Therefore direct ISE methods are free of electrolyte exclusion effects. To make results from direct ISEs equivalent to those from indirect ISEs (and flame photometry), direct ISE methods operate in what is commonly referred to as the “flame mode.” In this mode, the directly measured concentration in plasma water is multiplied by the average water volume fraction of plasma (0.93). Although the actual water volume fraction of plasma may vary widely, as long as the activity of the specific ion is constant, the concentration of the ion in the water phase becomes *independent* of

Fig. 24.1 Predicted influence of water content on sodium measurements for a 100 mmol/L NaCl solution by direct ion-selective electrode (ISE) versus flame emission photometry or indirect ISE. Blue areas represent the volumes of nonaqueous components that are suspended in the solution. In plasma these consist of lipids or proteins. (Modified from Apple, F. S., Koch, D. D., Graves, S., & Ladenson, J. H. [1982]. Relationship between direct-potentiometric and flame-photometric measurement of sodium in blood. *Clinical Chemistry*, 28, 1931–1935.)

the relative proportions of water and total solids if the ion is not bound by proteins. Most clinical chemists and physicians have reached the conclusion that direct ISE methods for electrolyte analysis are the methods of choice. However, results from direct ISE methods will continue to be converted to total plasma volume concentrations by use of the “flame mode,” as greater than 80% of laboratories continue to use indirect ISE methods.

Chloride

Chloride is the major extracellular anion and, similar to Na^+ , is significantly involved in the maintenance of water distribution, osmotic pressure, and anion-cation balance in the ECF. In contrast to its high ECF concentrations (≈ 103 mmol/L), the concentration of Cl^- in the intracellular fluid of erythrocytes is 45 to 54 mmol/L, and in the intracellular fluid of most other tissue cells, it is only ≈ 1 mmol/L. In gastric and intestinal secretions, Cl^- is the most abundant anion.

Chloride ions are almost completely absorbed from the intestinal tract. In the kidneys, they are filtered from plasma at the glomeruli and are passively reabsorbed, along with Na^+ , in the proximal tubules. In the thick ascending limb of the loop of Henle, Cl^- is actively reabsorbed by the chloride pump, which promotes passive reabsorption of Na^+ . Loop diuretics such as furosemide inhibit the chloride pump. Chloride concentrations are not homeostatically controlled, and passively reflect the concentration of the major ions sodium and bicarbonate. In addition, chloride concentrations fall, to maintain the electroneutrality of body fluids when pathological levels of other anions (e.g., ketoacids and lactate) are present.

Specimens

Chloride is most often measured in serum or plasma, urine, and sweat. Fecal determination of Cl^- may also be useful for the diagnosis of congenital hypochloremic alkalosis with

hyperchloridorrhea (increased Cl^- in stool). Chloride is stable in serum and plasma, and hemolysis does not significantly alter serum or plasma Cl^- concentration because the erythrocyte concentration of Cl^- is approximately half of that in plasma.

Reference Intervals

Reported reference intervals for Cl^- in the serum or plasma vary from 98 to 107 mmol/L to 100 to 108 mmol/L. Urinary excretion of Cl^- varies with dietary intake, but an interval of 110 to 250 mmol/24 hours is typical.

METHODS FOR DETERMINATION OF CHLORIDE IN BODY FLUIDS

Chloride is determined largely by ISE, with some laboratories performing coulometric-amperometric titration for sweat chloride testing.

Ion-Selective Electrode Methods

Chloride ISEs are composed of solvent polymeric membranes incorporating quaternary ammonium salt anion exchangers. Although they are by far the most common methods for measuring Cl^- in clinical laboratories, these electrodes may suffer from membrane instability and lot-to-lot inconsistency in terms of selectivity to other anions. Anions that tend to be problematic include other halides and organic anions (e.g., SCN^-), which can be particularly problematic because of their ability to solubilize in the polymeric organic membrane of these electrodes.

SWEAT CHLORIDE

Sweat Collection

Sweat collection is a two-step procedure involving (1) localized sweating stimulated by iontophoresis of the cholinergic drug pilocarpine nitrate into an area of the skin, and (2) collection of sweat from the stimulated area into gauze or plastic microbore tubing. Iontophoresis uses a small electric current to deliver pilocarpine into the sweat glands from the positive electrode, and an electrolyte solution at the negative electrode completes the circuit. There are two methods for **pilocarpine iontophoresis** and sweat collection: using filter paper or gauze, or using plastic microbore tubing. The filter paper/gauze method, sometimes referred to as the Gibson-Cooke method, is the original method. Iontophoresis is achieved with electrodes over reagent-soaked gauze, followed by collection of sweat from the collection site into clean gauze. Alternatively, electrodes attached to pilocarpine-containing agar disks can be used for stimulation, with sweat collected into plastic capillary tubing. The inner flexor surface of the forearm is the preferred site for sweat testing. Sweat stimulation can be performed on the inner thigh; however, this site yields lower sweat volume.

Sufficient Sample Collection

The CFF requires 75 mg or 15 μL of sweat, if collected by Gibson-Cooke or Macroduct methods, respectively. CFF accredited centers are required to monitor the rate of their

“quantity not sufficient” (QNS) specimens and must review sample collection steps, should the QNS rate exceed the mandated acceptable limits. On average, the percentage of insufficient samples should not exceed 5% for patients older than 3 months of age, and 10% for patients less than 3 months of age. Insufficient sweat samples can be the result of several factors such as age, race, and skin condition. Collecting an adequate amount of sweat can be more challenging in patients younger than 1 month of age. For this reason, it is recommended that sweat testing in asymptomatic individuals be performed when the infant is at least 2 weeks of age, is more than 36 weeks’ gestation at birth, and weighs more than 2 kg. To increase the chances of an adequate sample volume, two sites can be stimulated at one patient encounter. If the laboratory collects sweat from two sites (bilateral testing), the collection is considered QNS only when both sites are inadequate.

Quality of Sweat Collection and Analysis

Sweat collection is a manual process with many opportunities for error. Most errors result in QNS collections (QNS by CFF guidelines). Quality of sweat collection can be maintained by having a sufficient test volume to maintain competency, and limiting the testing personnel to a few well-trained individuals. The CFF recommends following CLSI-C34-A2 guidelines for sweat collection and analysis.

The Centers for Disease Control and Prevention does not list sweat as a potentially infectious material unless it is visibly contaminated with blood. However, laboratory personnel should practice the same standard precautions they would use with any other body fluid. All equipment used in iontophoresis should be disinfected between patients in accordance with procedures consistent with the institution’s infection control policies. Disinfectants must not contain bleach, which could contaminate the sweat sample.

It is important to have the patient physically prepared for the sweat collection. The patient should be physiologically and nutritionally stable, well hydrated, free of acute illness, and not receiving mineralocorticoids. The patient should avoid using lotions on the skin prior to sweat collection. Possible adverse events during sweat collection include redness and itching at the stimulation site. Pilocarpine urticaria associated with sweat testing is rare but has been reported. Burns to the patient’s skin after iontophoresis are extremely rare but can occur.

Reference Intervals for Sweat Chloride

For all individuals, including newborns with a positive newborn screen for CF, a sweat chloride concentration of less than 30 mmol/L indicates that CF is unlikely. This is a recent change to the previous practice of reporting separate reference intervals for infants up to and including 6 months of age. The following reference intervals are recommended for all patients regardless of age.

- ≤29 mmol/L: CF unlikely
- 30 to 59 mmol/L: intermediate
- ≥60 mmol/L: indicative of CF

The functional upper limit for sweat chloride is 160 mmol/L. A sweat chloride concentration greater than 160 mmol/L represents specimen contamination or analytical error. A sweat chloride concentration less than 30 mmol/L alone is insufficient to rule out the diagnosis; the value should be interpreted in regard to the clinical presentation and with the knowledge that “normal” concentrations have been associated with CF. Some mutations of the CF gene are associated with intermediate or normal sweat chloride concentrations. For example, according to the Cystic Fibrosis Foundation (CFF) registry, 3.5% of CF patients had sweat chloride concentrations less than 60 mmol/L, and 1.2% had concentrations less than 40 mmol/L. Clinical practice regarding follow-up of intermediate sweat chloride results varies widely. The CFF recommends a repeat sweat chloride test within 2 months of the intermediate result.

Reasons for Falsely Elevated Chloride in Sweat

There are numerous physiological conditions in addition to CF that may increase sweat chloride concentrations (see the CLSI document C34-A3). However, the most common cause of falsely elevated sweat chloride is evaporation. The 2007 CFF guidelines for sweat testing were established with the goal of reducing preanalytical variations in sweat testing. Testing procedures should minimize the opportunity for evaporation and contamination of the sweat sample. Sweat samples should be analyzed soon after collection on the same day. However, the laboratory can store the sweat samples if necessary. If sweat is collected into gauze, it should be reweighed promptly and can be stored with a tightly fitting lid up to 72 hours at 4°C. If sweat is collected in microbore tubing coils, it should be transferred to a 0.2 mL microcentrifuge tube with a tight-fitting cap and may be stored for up to 72 hours. The sweat should not be stored or transported in the microbore tubing.

Quantitative Analysis of Sweat Chloride Coulometric-Amperometric Titration

Sweat chloride concentration is determined by coulometric titration as this method can measure chloride concentrations as low as 10 mmol/L, and is the most precise method for measuring Cl^- over the entire range of concentrations found in sweat. ISEs are not used to measure sweat chloride, as they lack precision at the chloride concentrations found in normal subjects.

Coulometric-amperometric determinations of Cl^- (also called the *Cotlove chloridometer technique*) depend on the generation of Ag^+ from a silver electrode at a constant rate, and on the reaction of Ag^+ with Cl^- in the sample to form insoluble silver chloride (AgCl):

After the stoichiometric point is reached, excess Ag^+ in the mixture triggers shutdown of the Ag^+ generation system. A timing device records elapsed time between the start and stop of Ag^+ generation. Because the time interval is proportional to the amount of Cl^- in the sample, the concentration of

Cl^- can be determined by comparing the time elapsed against a calibration curve.

This method is subject to interferences by other halide ions, by CN^- and SCN^- ions, by sulfhydryl groups, and by heavy metal contamination. Maintenance of the systems is crucial for proper operation.

Sweat chloride ion concentration is used to confirm the diagnosis of **cystic fibrosis (CF)**. CF is caused by dysfunction of the **cystic fibrosis transmembrane conductance regulator (CFTR)**. Functional abnormalities in CFTR result in impaired electrolyte transport in secretory and absorptive epithelia, including the reabsorptive duct of the sweat gland. This leads to high salt loss via the sweat gland in patients with CF. In 1989, the CFTR gene was identified as the genetic basis of CF and over 1900 mutations in the 168 kb gene are known today. However, genetic testing is not always definitive, as the majority of mutations are not associated with clinical symptoms. Quantitative analysis of chloride in sweat remains the gold standard for CF diagnosis.

Sweat Conductivity Screening

Sweat conductivity is not diagnostic for CF but might be used as a screening test for CF. Compared to sweat chloride analysis, sweat conductivity is easier to perform and requires a smaller sample (minimum of 6 μL). Sweat conductivity is measured by comparing electrical conductance of sweat to that of NaCl standard solutions. Sweat conductivity is expressed as mmol/L (equivalent NaCl), a unit that represents the molar concentration of a solution of NaCl that has the same conductivity as the sweat sample at the same temperature, not the actual sodium or chloride concentration in the sweat sample. The CFF has approved the Macroduct Sweat-Chek (Wescor) for screening at clinical sites, such as community hospitals, using sweat conductivity ≥ 50 mmol/L as a cutoff for referral to an accredited CF care center.

BICARBONATE (TOTAL CARBON DIOXIDE)

Total carbon dioxide is used here to describe the quantity that is measured most often in automated clinical chemistry analyzers by acidification of a serum or plasma sample and measurement of carbon dioxide released by the process, or by alkalization and measurement of total bicarbonate. Under certain conditions of collection and specimen handling, total carbon dioxide values determined in this manner will be almost identical to values for the calculated concentration of total carbon dioxide obtained in blood gas analysis (see the later section in this chapter on blood gas methods).

Specimens

The same sample types used for Na^+ or K^+ may be assayed. Given a specimen in a vacuum-draw tube, the concentration of total CO_2 is most accurately determined when the assay is done as promptly as possible

after collection and centrifugation of the blood in a fully filled, unopened tube. Ambient air contains far less CO_2 than does plasma, and gaseous dissolved CO_2 will escape from the specimen into the air, with a consequent decrease in the CO_2 value of up to 2 to 3 mmol/L in the course of 1 hour. In practical terms, the logistics of high-volume processing and automated analysis of specimens almost ensures that most CO_2 measurements are done on specimens that have lost some dissolved gaseous CO_2 , simply because preservation of anaerobic conditions is not practical between the time plasma is placed on an instrument and the time it is sampled. Thus the term *bicarbonate* may be preferable to *total CO_2* .

Methods for Determination of Serum or Plasma Total Carbon Dioxide

Methods for total CO_2 measurement with modern automated instruments may be electrode based or enzymatic. In indirect electrode-based methods, the plasma sample is acidified to convert the various forms of CO_2 present in the sample to gaseous CO_2 . The amount of gaseous CO_2 released after acidification is determined by a $p\text{CO}_2$ electrode in the reaction chamber of the CO_2 module. *Direct ISE methods* for total CO_2 are no longer common on automated analyzers due to problems with specificity.

In *enzymatic methods* for CO_2 , the specimen is first alkalized to convert all CO_2 and carbonic acid to HCO_3^- . The enzymatic reactions are as follows:

The decrease in absorbance at 340 nm, as NADH is oxidized to NAD^+ , is proportional to the total CO_2 content. The enzymatic method is more common than the electrode-based method, with approximately 80% of laboratories utilizing an enzymatic method.

Reference Intervals

The reference interval for total carbon dioxide in adults is 22 to 28 mmol/L but can be method and instrument dependent. The reference interval for CO_2 also varies with age, with pediatric patients exhibiting lower values due to a higher respiratory rate.

POINTS TO REMEMBER

- Sodium, potassium, and chloride concentrations in biological fluids are predominantly quantified using ion-selective electrodes.
- Sweat chloride concentrations are quantified utilizing coulometric-amperometric titration, and elevated concentrations are used to diagnose cystic fibrosis.
- Indirect ion-selective electrodes used for measuring serum/plasma sodium concentrations are prone to the electrolyte exclusion effect in samples containing high concentrations of lipids and/or proteins.
- Total serum/plasma CO_2 concentrations will decrease when samples are uncapped and exposed to room air.

PRINCIPLES OF OSMOTIC PRESSURE AND OSMOSIS

Osmometry is a technique for measuring the concentration of solutes that contribute to the osmotic pressure of a solution. Osmotic pressure governs the movement of solvent (water in biological systems) across semipermeable membranes that separate two solutions. Examples of biologically important selective membranes are those enclosing the glomeruli and capillary vessels that are permeable to water and to essentially all *small* molecules and ions, but not to large protein molecules. Differences in the concentrations of osmotically active molecules that cannot cross a membrane cause those molecules that can cross the membrane (such as water in the descending loop of Henle) to move to equalize the concentrations on both sides of the membrane. The force driving this movement of solute and permeable ions is known as **osmotic pressure**. As a simple example, consider an aqueous solution of sucrose placed within a sac made up of a membrane permeable only to water, with an open vertical glass tube attached to the sac. If the sac is placed into a beaker of distilled water, water will move from the beaker across the membrane into the sucrose solution. The pressure of this solvent movement will cause the sucrose solution to rise up the tube. At equilibrium, the gravitational pressure of the column of solution in the tube equals the osmotic pressure and prevents further net movement of water from the beaker. The height of the rise of the sucrose solution in the glass tube is a measure of the *osmotic pressure* of the sucrose solution. This is the pressure that would have to be exerted on the sucrose side of the membrane to prevent the flow of water across the membrane.

If the sucrose solution in the above example was replaced with a solution of NaCl at the same molarity, the solution in the glass tube would reach equilibrium at a point almost twice as high as that observed with sucrose. This is because NaCl dissociates into two ions per molecule and would thus have twice as many osmotically active solutes (osmoles) for the same molar concentration as the sucrose solution. In reality, the number of active particles in a solution of NaCl is less than this (~0.93 for NaCl), as explained later in this chapter. The total number of individual solutes present in a solution per given mass of solvent, regardless of their chemical nature (i.e., nonelectrolyte, ion, or colloid), determines the total osmotic pressure of the solution. In blood plasma, for example, nonelectrolytes such as glucose and urea and, to a much lesser extent, proteins contribute to the osmotic pressure.

Colligative Properties

In addition to the osmotic pressure being raised when a solute is dissolved in a solvent, the *vapor pressure* of the solution is *lowered* below that of the pure solvent. As a result of the change in vapor pressure, the *boiling point* of the solution is *raised* above and the *freezing point* of the solution is *lowered* below that of the pure solvent.

These four properties of solutions—(1) increased osmotic pressure, (2) lowered vapor pressure, (3) increased boiling point, and (4) decreased freezing point—are called **colligative properties**. All are directly related to the total number of dissolved solutes per mass of solvent. For example, a 1-molal (mol/kg) aqueous solution boils at a temperature 0.52°C higher than and freezes at a temperature 1.858°C lower than pure water. The vapor pressure of this solution is 0.3 mm Hg lower than the vapor pressure of pure water, which is 23.8 mm Hg at 25°C. The term *osmolality* expresses concentrations relative to *mass* of the solvent (1 osmolal solution is defined to contain 1 Osmol/kg H_2O), whereas the term *osmolarity* expresses concentrations per volume of solution (1 osmolar solution is defined to contain 1 Osmol/L). Osmolality (Osmol/kg H_2O) is a thermodynamically more exact expression because solution concentrations expressed on a weight basis are temperature independent, whereas those based on volume vary with temperature. Although the term *osmolarity* is often used in the medical literature, *osmolality* is what the clinical laboratory measures.

An electrolyte in solution dissociates into two (in the case of NaCl) or three (in the case of CaCl_2) dissolved ions; therefore the colligative effects of such solutions are multiplied by the number of dissociated ions formed per molecule. However, because of incomplete electrolyte dissociation and associations between solute and solvent molecules, many solutions do not behave as the ideal case, and a 1-molal solution may give an osmotic pressure lower than theoretically expected. The osmotic activity coefficient is a factor used to correct for deviation from the “ideal” behavior of the system:

$$\text{Osmolality} = \frac{\text{Osmol}}{\text{KgH}_2\text{O}} = \Phi nC$$

where Φ = osmotic coefficient, n = number of solutes into which each molecule in the solution potentially dissociates, and C = molality in mol/kg H_2O .

Glucose has an osmotic coefficient of 1.00, whereas the Φ for sodium chloride is 0.93 at the concentrations found in serum—thus the derivation of $1.86 \times \text{Na}^+$ (mmol) in the formula to calculate plasma osmolality (NaCl potentially contributes two osmotically active ions times $0.93 = 1.86$). Ethanol has an osmotic coefficient of 0.83. The total osmolality or osmotic pressure of a solution is equal to the sum of the osmotic pressures or osmolalities of all solute species present. The electrolytes Na^+ , Cl^- , and HCO_3^- , which are present in relatively high concentrations, make the greatest contributions to serum osmolality. Nonelectrolytes such as glucose and urea, which are present normally at lower molal concentrations, contribute less, and serum proteins contribute less than 0.5% of the total serum osmolality because even the most abundant protein is present at millimolar concentrations.

Determination of Plasma and Urine Osmolality

Determination of plasma and urine osmolality can be useful in the assessment of electrolyte and acid-base disorders. Comparison of plasma and urine osmolalities can determine the status of water regulation by the kidneys in settings of severe electrolyte disturbances, as might occur in diabetes insipidus or the syndrome of inappropriate antidiuretic hormone (SIADH). The major osmotic substances in plasma are Na^+ , Cl^- , glucose, and urea; thus expected plasma osmolality can be calculated from the following empirical equation:

$$\begin{aligned} \text{mOsmol/kg} = & 1.86 [\text{Na}^+ (\text{mmol/L})] \\ & + \text{glucose} [\text{mmol/L}] \\ & + \text{urea} [\text{mmol/L}] \\ & + 9 \end{aligned}$$

or

$$\begin{aligned} \text{mOsmol/kg} = & 1.86 [\text{Na}^+ (\text{mmol/L})] \\ & + \text{glucose} [\text{mg/dL}] / 18 \\ & + \text{urea N} [\text{mg/dL}] / 2.8 \\ & + 9 \end{aligned}$$

The 9 mOsmol/kg added to the previous equation represents the contributions of other osmotically active substances in plasma, such as K^+ , Ca^{2+} , and proteins, and 1.86 is two times the osmotic coefficient of Na^+ , reflecting the contributions of both Na^+ and Cl^- . Some versions of this equation do not include the plus 9 mOsmol/kg factor.

The reference interval for plasma osmolality is 275 to 300 mOsmol/kg. Comparison of measured osmolality versus calculated osmolality can reveal the presence of an **osmolal gap**, which can be important in determining the presence of exogenous osmotic substances. Comparison of calculated and measured osmolalities can also confirm or rule out suspected pseudohyponatremia caused by the electrolyte exclusion effect. Virtually all clinical laboratories use freezing point depression osmometers for the measurement of osmolality because of its simplicity and the fact that vapor pressure osmometers will not detect volatile substances such as methanol, ethanol, or isopropanol. Furthermore, freezing point depression, unlike vapor pressure, is independent of changes in ambient temperature.

Freezing Point Depression Osmometer

The components of a freezing point depression osmometer, often simply referred to as an osmometer (Fig. 24.2) are as follows:

1. A thermostatically controlled cooling bath or block maintained at -7°C
2. A rapid stir mechanism to initiate (or “seed”) freezing of the sample
3. A thermistor probe connected to a circuit to measure the temperature of the sample (The thermistor is a glass bead attached to a metal stem whose resistance varies rapidly and predictably with temperature.)
4. A galvanometer that displays the current from the thermistor, and that is used as a guide when the measuring potentiometer is used
5. A measuring potentiometer

In most instruments, components 4 and 5 are replaced by a light-emitting diode (LED) display that indicates the time course of the freezing curve and the final result.

During analysis, the sample, in which the thermistor probe and the stirring wire are centered, is lowered into the bath and, with gentle stirring, is super-cooled to a temperature several degrees below its freezing point (-7°C). When the LED display (or galvanometer) indicates that sufficient super-cooling has occurred, the sample is raised to a point above the liquid in the cooling bath, and the wire stirrer is changed from a gentle rate of stir to a short but vigorous rate, which initiates freezing of the super-cooled solution. This freezing occurs only to the slush stage, with about 2% to 3% of the solvent solidifying. The released heat of fusion initially warms the solution, and then the temperature plateaus and remains stationary, indicating the equilibrium temperature at which both freezing and thawing of the solution are occurring. At the end of the equilibrium temperature plateau, the galvanometer again indicates decreasing temperature as the sample freezes further toward a complete solid. An example of the calculation to obtain osmolality is as follows: if the observed freezing point is -0.53°C , then

$$\text{mOsmol/kg H}_2\text{O} = \frac{-0.53}{-1.86} \times 1000 = 285$$

where -1.86°C is the molal freezing point depression of pure water.

Fig. 24.2 Block diagram of a freezing point depression osmometer. 1, Cooling fluid; 2, stirring rod; 3, thermistor; 4, galvanometer; 5, potentiometer with direct readout. The test tube is shown above the liquid in the cooling bath (solid line) and inside the cooling liquid (dashed line).

POINTS TO REMEMBER

- Dissolved solutes will result in a solution with an increased osmotic pressure, lowered vapor pressure, increased boiling point, and decreased freezing point.
- Freezing point depression osmometers are the most commonly used technique to measure osmolality in the clinical laboratory.
- Comparison of plasma and urine osmolality can be useful for the assessment of water balance and disorders such as diabetes insipidus and the syndrome of inappropriate antidiuretic hormone.
- A gap between the measured and calculated osmolality can reveal the presence of unmeasured osmolytes.

BLOOD GASES AND pH

The detection and clinical management of respiratory and metabolic disorders often depends on rapid and accurate measurements of the **partial pressures** of oxygen (pO_2) and carbon dioxide (pCO_2) in blood. Measures to support life in patients with cardiopulmonary impairment depend largely on assisted ventilation using mixtures of gases that are tailored in response to blood gas results. Modern instruments for blood gas determination are simple to operate and, with meticulous maintenance and quality control, are capable of

rapid, reliable data. Details of the pathophysiology of blood gases in relation to respiration and acid-base disorders are discussed in detail in [Chapter 36](#).

Nomenclature for this area of analysis has been recommended by the CLSI, but alternative nomenclatures exist and are in common use, as summarized in [Box 24.1](#).

BEHAVIOR OF GASES

Determination of gas pressures in blood depends on the application of certain physical principles ([Table 24.1](#)). The partial pressure (tension) of a gas dissolved in blood is by definition equal to the partial pressure of the gas in an imaginary ideal gas phase in equilibrium with the blood. The partial pressure of a gas is the same in erythrocytes and plasma; thus the partial pressure of a gas is the same in whole blood and plasma. The partial pressure of a gas in a gas mixture is defined as the substance fraction of gas (mole fraction) times the total pressure.

Various spaces where gases are present include the ambient environment (room air), the bronchial tree and alveoli of the patient, and the measuring chamber of a laboratory instrument. In all these spaces, atmospheric (barometric) pressure, $P(\text{Amb})$, is the prevailing pressure, and partial pressures of each of the gases present in these spaces must add up to the

BOX 24.1 Conversion Factors, Prefixes, Symbols, and Descriptors Used in Discussions of Gases Measured in Blood and Expired Air

Conversion Factors

1 mm Hg = 0.133 kPa

1 kPa = 7.5 mm Hg

kPa: 1 kilopascal = 1000 pascal. The pascal is the SI derived unit of pressure; it equals 1 Newton/m².

General Prefixes

P (or p): partial pressure or tension

Usage: pO_2 , pCO_2 , pH_2O

Alternative: pO_2

S: saturation fraction

Usage: SO_2

Alternative: sO_2

c: substance concentration

Usage: ctO_2 for concentration of total O_2

Usage: $ctCO_2$ for concentration of total CO_2

Usage: $cHCO_3^-$ for concentration of bicarbonate

d: dissolved gas, used with substance concentration (c)

t: total, used with substance concentration (c); thus

$$ctCO_2 = cHCO_3^- + ctCO_2$$

Specimen origin is indicated by lower case letters. Whole blood and plasma are distinguished by capitals.

a: arterial B: blood

v: venous P: plasma

c: capillary

Usage: $pO_2(aB)$, for partial pressure of O_2 in arterial blood

Prefixes Associated With External Respiration

V : volume of air or blood (unit, L)

$\dot{V}$: volume rate (unit, L/min)

F : substance fraction, also called mole fraction

E : expired air

I : inspired air

A : alveolar air

Usage: $\dot{v}(A)$, alveolar ventilation; $\dot{v}(B)$, cardiac output; $FO_2(I)$, fraction of O_2 in inspired air; $pO_2(A)$, partial pressure of O_2 in alveolar air; and $pCO_2(E)$, partial pressure of CO_2 in expired air.

Other Descriptors

BTPS: Body Temperature (37°C or 310.16 K) and ambient Pressure, fully Saturated ($pH_2O = 47$ mm Hg or 6.25 kPa)

STPD: Standard Temperature (0°C or 273.16 K) and standard Pressure (760 mm Hg or 101.08 kPa) of Dry gas

Amb: ambient atmosphere (unit is atm, atmosphere)

B: barometric (atmospheric)

BTPS: Usage: $P(\text{amb})$, $P(\text{Amb})$

SVP: Saturated Vapor Pressure, the vapor pressure of water.

SVP_T means SVP at a specified temperature [e.g., $SVP_{37^\circ C} = 47$ mm Hg; $pH_2O(\text{saturated})$]

ATPS: Ambient Temperature and Pressure, Saturated with water vapor

^aThis list is not complete but is presented to facilitate interpretation of terms used in the text and to illustrate various forms that may be encountered in the literature.

From Maas, A. H. (1991). IFCC reference methods for measurement of pH, gases and electrolytes in blood: reference materials. *European Journal of Clinical Chemistry and Clinical Biochemistry*, 29, 253–261.

TABLE 24.1 Physical Principles Applied in Blood Gas Measurements

Boyle's law: The volume of an ideal gas at a constant temperature varies inversely with the pressure exerted to contain it.	$V \propto 1/P$
Charles' (Gay-Lussac's) law: The volume of an ideal gas at a constant pressure varies directly with its absolute temperature.	$V \propto T$
Avogadro's hypothesis: Equal volumes of different ideal gases at the same temperature and pressure contain the same number of molecules.	$n_i/V_i = n_j/V_j$
Dalton's law: The total pressure exerted by a mixture of ideal gases is the sum of the partial pressures of each of the gases in the mixture.	$P = \sum P_i$
Henry's law: The amount of a sparingly soluble gas dissolved in a liquid is proportional to the partial pressure of the gas over the liquid.	$c = \alpha \times P$

value of $P(\text{Amb})$, which will vary with altitude and barometric pressure. Measurements of partial pressure used for clinical management are always made at *Body Temperature* (37°C), at $P(\text{Amb})$, and in the presence of Saturated water vapor ($p\text{H}_2\text{O} = 47 \text{ mm Hg}$). Use of this *BTPS* convention (see [Box 24.1](#)) has the following practical effects:

1. It relates laboratory data for blood gases strictly to the geographic location of the patient, so that reference intervals become altitude dependent.
2. It assumes a standard body temperature of 37°C and that the measuring device also holds the sample of blood at exactly 37°C. It also implies that in circumstances such as *imposed* hypothermia, when a patient's temperature is not 37°C, blood gas values determined at 37°C might need to be corrected to the actual body temperature to obtain an estimate of blood gas partial pressures in the patient.
3. It recognizes that partial pressures of measured gases in the blood coexist with a constant and standard saturated vapor pressure (SVP), which is identical for both the calibration conditions of the instrument and the measurement conditions of the blood sample.

Boyle's and Charles' laws and Avogadro's hypothesis are combined in what is called the *general gas equation*:

$$P = (nRT)/V$$

where P = pressure in units of millimeters of mercury (mm Hg) or kilopascals (kPa); V = volume in liters in which an ideal gas is contained; T = temperature in degrees kelvin (0°C = 273.16 K); n = number of moles of gas; and R = gas constant.

The SI unit of P is the pascal (Pa). However, millimeters of mercury (also called *torr*) have continued to remain popular in some countries (see [Box 24.1](#) for conversion factors). Use of SI units does have a practical advantage in that 1 atm almost equals 100 kPa (1 atm = 101.325 kPa). Partial pressures expressed in kilopascals therefore are very close estimates of percentages of the gases in the mixture at 1 atm. Pressure, P (or p), may mean total pressure, as in the expression $P(\text{Amb})$ for the mixture of gases in ambient air, or partial pressure in

arterial blood, as in $p\text{O}_2(\text{aB})$. Numeric value and units of R differ depending on the units used for P , so that

$$R = 6236 \text{ mm Hg} \times \text{L} \times \text{K}^{-1} \times \text{mol}^{-1}$$

or

$$R = 8.31 \text{ kPa} \times \text{L} \times \text{K}^{-1} \times \text{mol}^{-1}$$

It is important to note that $p\text{O}_2$ is related only to the concentration of dissolved O_2 (cdO_2) in the blood and $p\text{CO}_2$ to the concentration of dissolved CO_2 (cdCO_2) in the blood (see Henry's law; [Table 24.1](#)). The total concentration of O_2 in blood (ctO_2) is the sum of concentrations of dissolved O_2 and of O_2 bound to hemoglobin, with cdO_2 being a small component of tO_2 (see the later section on hemoglobin saturation). The total concentration of CO_2 (ctCO_2) is defined operationally as the sum of concentrations of dissolved CO_2 , carbonic acid, HCO_3^- , undissociated bicarbonate, and carbonate ion.

Dalton's law of partial pressures governs the calibration and control of blood gas instruments. *Dalton's law* (see [Table 24.1](#)) may be written for room air as follows:

$$P(\text{Amb}) = p\text{O}_2 + p\text{CO}_2 + p\text{N}_2 + p\text{H}_2\text{O} + pX$$

where pX is the partial pressure of any other gas in the air sample.

Consider a calibrator gas certified to contain 15% O_2 (L/L or mol/mol) and 5% CO_2 , the remainder being N_2 . The mole fractions (or F) of the gases in the dry mixture are 0.15, 0.05, and 0.80, respectively. This mixture, after saturation with water vapor at 37°C (to mimic a patient's blood or alveolar air), is introduced into a blood gas instrument's measuring chamber (held at 37°C to mimic a patient's body temperature) for the purpose of calibrating the instrument for subsequent measurements of gases in patients' samples. If the local barometric pressure, $P(\text{Amb})$, on this occasion is 747 mm Hg, then humidified calibrator gas is present in the chamber at ambient, barometric pressure, such that

$$P(\text{Amb}) = 747 \text{ mm Hg} = p\text{O}_2 + p\text{CO}_2 + p\text{N}_2 + p\text{H}_2\text{O}$$

To set the instrument to the $p\text{O}_2$ and $p\text{CO}_2$ of the calibrator gas, the $p\text{H}_2\text{O}$ at 37°C, which is equal to the SVP of water, 47 mm Hg must be included. Therefore,

$$\begin{aligned} 747 \text{ mm Hg} - p\text{H}_2\text{O} &= p\text{O}_2 + p\text{CO}_2 + p\text{N}_2 \\ &= 747 - 47 \\ &= 700 \text{ mm Hg} \end{aligned}$$

If $P(\text{Amb})$ corrected for $p\text{H}_2\text{O}$ represents the sum of partial pressures for the dry gases whose mole fractions we know, we can calculate the exact $p\text{O}_2$ and $p\text{CO}_2$ values for the calibrator gas, under circumstances of measurement, and then enter these calibrator values into the instrument.

The law of partial pressure is also applied in defining gas mixtures used to determine $p\text{O}_2(0.5)$ or P_{50} and other derived quantities, and to control instrumentation with tonometered samples. *Henry's law* predicts the amount of dissolved gas in a liquid in contact with a gaseous phase (see [Table 24.1](#)).

The coefficient for O_2 in blood, αO_2 , is 0.00140 (mmol/L)/mm Hg. Therefore, when arterial $p\text{O}_2$ is normal ($\approx 100 \text{ mm Hg}$), the concentration of dissolved O_2 in arterial blood, cdO_2 , is 0.140 mmol/L, which is a very small proportion of the ctO_2

content in blood (≈ 9 mmol/L), the bulk of which is O_2 bound by hemoglobin. Increasing the O_2 fraction of inspired air to 100% or increasing the pressure of inspired air, as in a hyperbaric chamber, forces more O_2 into a solution. The $cdCO_2$ can be calculated in the same way: αCO_2 at $37^\circ C$ in plasma = 0.0306 mmol/L/mm Hg. Thus at a pCO_2 of 40 mm Hg, the $cdCO_2 = 40 \times 0.0306 = 1.224$ mmol/L. In the determination of blood gases, pCO_2 is determined along with blood pH. As will be subsequently explained, these two parameters in conjunction with the Henderson-Hasselbalch equation permit the calculation of HCO_3^- , as follows:

$$\log cHCO_3^- = pH - pK' + \log [pCO_2 \times \alpha CO_2 (P)]$$

The antilog is then taken to derive $cHCO_3^-$.

APPLICATION OF THE HENDERSON-HASSELBALCH EQUATION IN BLOOD GAS MEASUREMENTS

Carbon dioxide and water react to form carbonic acid, which in turn dissociates to hydrogen ions and HCO_3^- .

Thus the total concentration of CO_2 ($ctCO_2$), the concentration of bicarbonate ($cHCO_3^-$), the concentration of dissolved CO_2 ($cdCO_2$), and the H^+ ion concentration (cH^+) are interrelated.

This relationship and its effect on pH are described by the **Henderson-Hasselbalch equation** below. In plasma a small proportion of the $cdCO_2$ includes undissociated (dissolved) carbonic acid. The amount in plasma can be expressed as $cdCO_2 = \alpha \times pCO_2$, where α represents the solubility coefficient of CO_2 .

$$pH = pK' + \log \frac{cHCO_3^-}{\alpha \times pCO_2}$$

pK' in the equation above is the negative log of the apparent overall (combined) dissociation constant for carbonic acid. It is *apparent* because concentrations are used rather than activities and *overall* because both the $cdCO_2$ and the concentration of carbonic acid are used. K' (and thus pK') depends not only on the temperature but also on the ionic strength of the solution.

For blood at $37^\circ C$, the normal mean value is $pK(P) = 6.103$, and the normal mean solubility coefficient for CO_2 gas is $(0.0306 \text{ mmol}) \times (L^{-1}) \times (\text{mm Hg}^{-1})$. When pK' and α for normal plasma at $37^\circ C$ are inserted, the Henderson-Hasselbalch equation takes the following form:

$$pH = 6.103 + \log \frac{cHCO_3^-}{0.0306 \times pCO_2}$$

where pCO_2 is reported in millimeters of mercury and $cHCO_3^-$ is reported in millimoles per liter.

By measuring any two of the three parameters, pCO_2 , pH, or $cHCO_3^-$, and by using the Henderson-Hasselbalch equation with the above values for pK' and α , the other parameter may be calculated. Although used as constants, pK' and α must be recognized as means and are susceptible to biological variation. Changes in ionic strength of $\pm 20\%$ cause changes in pK' between 6.08 and 6.12. Variations in pK' of plasma also occur with temperature (pK will decrease by 0.0026 per

$1^\circ C$ increase and will decrease slightly with increasing pH). For most clinical purposes, these variations of pK' can be ignored. However, in pathologic cases with markedly deviant ionic strength, the change in pK' may be significant. The value of α is affected by the presence of increased ions or proteins in solution (value decreases) or lipids (value increases); for instance, in lipemic plasma, the value of α may be 0.033 or higher. Thus, parameters calculated on the assumption that pK' and α are invariant may have error under certain pathologic circumstances. Several authors suggest caution in using calculated HCO_3^- values from blood gas analyzers in extremely ill patients, as the calculated and measured tCO_2 values can differ by greater than 10% in adult and greater than 20% in pediatric ICU patients, respectively.

OXYGEN IN BLOOD

The total O_2 content (ctO_2) of a blood sample is the sum of the concentrations of hemoglobin-bound O_2 and of dissolved O_2 . At a blood ctO_2 of 9 mmol/L, the O_2 associated with hemoglobin as **oxyhemoglobin** (O_2Hb) is 8.86 mmol/L. The O_2Hb is defined as erythrocyte hemoglobin with O_2 reversibly bound to Fe^{2+} of its heme group.

Hemoglobin A (Hb A, the normal adult gene product) reversibly binds O_2 via the heme- Fe^{2+} moiety and binds biological effectors at other allosteric sites. Methemoglobin (MetHb), carboxyhemoglobin (COHb), sulfhemoglobin (SulfHb), and cyanmethemoglobin, collectively termed dyshemoglobins, are forms of hemoglobin that are not capable of reversible O_2 binding because of chemical alterations of the heme moiety. Another group of abnormal hemoglobins, collectively referred to as *hemoglobin variants* or *hemoglobinopathies*, have genetically determined changes in their amino acid sequence that can alter their O_2 affinity. More than 900 hemoglobin variants have been described, of which only a small fraction are clinically significant (for details see [Chapter 28](#)).

Uptake of O_2 by blood in the lungs is governed primarily by the pO_2 of alveolar air and by the ability of O_2 to diffuse freely across the alveolar membrane into blood. At the pO_2 normally present in alveolar air (≈ 102 mm Hg) and with a normal membrane and normal hemoglobin A, more than 95% of hemoglobin will bind O_2 . At a $pO_2 > 110$ mm Hg, more than 98% of normal hemoglobin A binds O_2 . When all hemoglobin is saturated with O_2 , further increases in the pO_2 of alveolar air simply increase the concentration of cdO_2 in the arterial blood. Delivery of O_2 by blood to tissues is governed by the large gradient between pO_2 of arterial blood and that of the tissue cells, and by the dissociation of O_2Hb in the erythrocytes at the lower pO_2 of the blood-tissue cell interface.

Three properties of arterial blood are essential to ensure adequate O_2 delivery to tissues:

1. Arterial pO_2 must be sufficiently high (≈ 90 mm Hg) to create a diffusion gradient from arterial blood to the tissue cells. The pO_2 at the venous end of the capillaries is typically ~ 30 to 45 mm Hg; thus the normal arteriovenous difference in pO_2 is 50 to 60 mm Hg. Low arterial pO_2 (*hypoxemia*) results in tissue O_2 starvation (*hypoxia*).

2. The O₂-binding capacity of blood must be normal (i.e., the concentration of hemoglobin capable of binding and releasing O₂ must be normal). Decreased Hb concentration will cause so-called **anemic hypoxia**.
3. The hemoglobin must be able to bind O₂ in the lungs yet release it at the tissue. In other words, the affinity of hemoglobin for O₂ must be normal. Too great an affinity of hemoglobin for O₂ may cause “affinity-based” tissue hypoxia, in which O₂ is not released at the capillary-tissue interface. There are approximately 100 high-affinity hemoglobin variants described to date; however, individually they are all rare. Hemoglobin F, while not a hemoglobin variant, has a higher affinity for oxygen than hemoglobin A, the normal adult hemoglobin.

HEMOGLOBIN OXYGEN SATURATION

Before the factors that affect Hb affinity for O₂ are discussed, it is important to define the concept of hemoglobin **oxygen saturation (SO₂)**:

$$SO_2 = \frac{\text{Oxygen Content}}{\text{Oxygen Capacity}}$$

This is the fraction (percentage) of functional hemoglobin that is saturated with oxygen and is essentially an indirect means of estimating the *p*O₂. However, at least three different approaches exist for determining oxygen “saturation,” and although each is distinct, they are often used interchangeably to determine “oxygen saturation.” These three terms—hemoglobin oxygen saturation (SO₂), fractional oxyhemoglobin (FO₂Hb), and estimated oxygen saturation (O₂Sat)—have distinct definitions described in CLSI C46-A2. Ambiguous use of these terms occurs because in healthy subjects with normal amounts of normal hemoglobin, the values for all three entities are very similar. However, these assumptions can lead to erroneous conclusions in seriously ill patients and those with dyshemoglobins or hemoglobin variants.

Spectrophotometric methods are used to determine O₂Hb and HHb, and SO₂ is calculated according to

$$SO_2 = \frac{cO_2Hb}{cO_2Hb + cHHb}$$

where *c*O₂Hb is the concentration of oxyhemoglobin, *c*HHb is the concentration of deoxyhemoglobin, and the sum of oxyhemoglobin and deoxyhemoglobin represents all hemoglobin capable of reversibly binding O₂. SO₂ is usually expressed as a percent in the United States, but it may also be expressed as a decimal fraction of 1.00.

SO₂ most often is determined by simple pulse **oximetry** and cannot determine COHb, MetHb, or SulfHb concentrations. These devices measure absorbance at 660 and 940 nm for which O₂Hb and HHb have unique absorbance patterns. Pulse oximeters are appropriate for monitoring HbO₂ saturation, and they serve this purpose extremely well. However, use of SO₂ in the initial evaluation of a patient with dyshemoglobins can be very misleading. For instance, in a comatose patient with 15% COHb, the SO₂ by simple pulse oximetry might read 0.95, whereas the fraction of oxyhemoglobin in

reality would be only 0.80. Thus it seems reasonable to assess for the presence of dyshemoglobins before SO₂ is used for clinical purposes. The reference interval for SO₂ from healthy adults is 0.94 to 0.98 (94% to 98%).

Another expression of oxygen “saturation” is fractional oxyhemoglobin (FO₂Hb), which is calculated as

$$FO_2Hb = (cO_2Hb / cHHb + cCOHb + cMethHb + cSulfHb)$$

This value requires determination of all hemoglobin species and can be performed on a co-oximeter present in modern blood gas analyzers. These instruments prepare a hemolysate from whole blood by sonication, and spectrophotometrically determine the total amount of hemoglobin and the percent of each of the aforementioned species. This is accomplished by using monochromatic light at 6 to 128 fixed wavelengths between 535 and 670 nm and measuring absorbance at each of the wavelengths. Newer co-oximeters use a diode array and 128 wavelengths. Because each species of hemoglobin has its own absorbance pattern, an integrated software algorithm calculates the percent of each one. The reference interval for FO₂Hb is 0.90 to 0.95 (90% to 95%).

Finally, using empirical equations, the integrated software in blood gas instruments can estimate the oxygen saturation from measured pH, *p*O₂, and hemoglobin. This value should be clearly referred to as *estimated oxygen saturation*, but it frequently is reported and referred to as “O₂Sat.” If calculated values such as “O₂Sat” are reported, they should be interpreted with reservation because the algorithm assumes normal hemoglobin affinity for O₂, normal 2,3-diphosphoglycerol (2,3-DPG) concentrations, and the absence of dyshemoglobins. Such calculated estimates have been found to vary by as much as 6% saturation from measured values.

Decreases in arterial FO₂Hb may indicate a low arterial *p*O₂ or an impaired ability of hemoglobin to bind O₂. The amount of O₂ that the blood can carry is determined by three major factors: (1) the *p*O₂, which reflects how much O₂ is dissolved in the blood; (2) the amount of normal hemoglobin available in erythrocytes; and (3) the affinity of available hemoglobin for O₂. Decreases in *p*O₂ indicate a reduced ability of O₂ to diffuse from alveolar air into the blood. This may be due to hypoventilation or to increased venoarterial shunting that is secondary to cardiac or pulmonary insufficiency, resulting in an increased fraction of blood that has not reached equilibrium with alveolar air. Hypoventilation and increased shunting are also characterized by an increased *p*CO₂. Decreases in total hemoglobin concentration can result from a decreased number of erythrocytes that contain a normal concentration of hemoglobin (normochromic anemia) or a decreased mean cell concentration of hemoglobin in the erythrocytes (hypochromic anemia). Decreased FO₂Hb hemoglobin can also occur as a result of poisonings that convert part of the hemoglobin into the species COHb, MetHb, or SulfHb, which cannot properly bind or exchange O₂. Clinically it is important to distinguish between arterial hypoxemia (decreased arterial *p*O₂ and decreased FO₂Hb caused by decreased availability of O₂) and cyanosis (decreased FO₂Hb caused by abnormally high concentrations of reduced hemoglobin or chemically

altered hemoglobin incapable of carrying O_2). Note that in the setting of cyanosis, measurement of SO_2 or an estimated SO_2 ("O₂Sat") could be normal if cyanosis is due to the presence of MetHb or COHb.

Hemoglobin-Oxygen Dissociation

The degree of association or dissociation of O_2 with hemoglobin is determined by pO_2 and the affinity of hemoglobin for O_2 . When the SO_2 of blood is determined over a range of pO_2 and is plotted against pO_2 , a sigmoidal curve called the *O₂ dissociation curve* is obtained. The *shape* of the curve is affected by the increasing efficiency with which HHb molecules bind more O_2 once some O_2 has been bound (*cooperativity*; see also Chapter 28). The *location* of the curve relative to the pO_2 required to achieve a particular concentration of SO_2 in the blood is a function of the affinity of hemoglobin for O_2 .

The affinity of hemoglobin for O_2 depends on five factors: temperature, pH, pCO_2 , 2,3-DPG concentration, and the presence of dyshemoglobins such as COHb and MetHb. Dissociation of O_2 in relation to 2,3-DPG concentration and abnormal hemoglobin proteins, such as fetal hemoglobin (Hb F), thalassemias, and other hemoglobinopathies, are discussed in Chapter 28.

The graph in Fig. 24.3 shows the effect of plasma pH on the O_2 dissociation curve (the Bohr effect). Similar graphs can be made for variations of pCO_2 , temperature and 2,3-DPG concentration.

Determination of P_{50}

P_{50} is defined as the pO_2 at which the hemoglobin of the blood is half saturated with O_2 . The measured value of P_{50} differs from the standard value of P_{50} by some amount determined by the extent that pH differs from 7.40, pCO_2 differs from 40 mm Hg, temperature differs from 37°C, and 2,3-DPG differs from 5.0 mmol/L. The value of P_{50} therefore becomes a measure of change of hemoglobin affinity because of the factors that affect it.

Clinical Significance

Increased values for P_{50} indicate displacement of the O_2 dissociation curve to the right (i.e., decreased affinity of the hemoglobin for O_2). The chief causes are hyperthermia, acidemia, hypercapnia, high concentrations of 2,3-DPG, and the presence of a hemoglobin variant with decreased O_2 affinity. The physiologic effects of decreased affinity of hemoglobin are small. The affinity is still sufficient to bind adequate amounts of O_2 in the lungs, and the low affinity facilitates dissociation of O_2 Hb at the peripheral tissues. Indeed, in anemia, low affinity (as a result of increases in 2,3-DPG) is a desirable compensatory mechanism. The compensatory responses in healthy individuals to alter the P_{50} can be remarkable. For instance, in fully acclimatized (70 days) high-altitude climbers (Mt. Everest), full cognition was maintained without supplemental oxygen at an altitude of 8400 m and an average $P(a)O_2$ of only 25 mm Hg.

Low values for P_{50} signify displacement of the O_2 dissociation curve to the left (i.e., increased affinity of hemoglobin). The main causes are hypothermia, acute alkalemia, hypocapnia, low 2,3-DPG, and variant hemoglobin. The physiologic consequence of increased affinity of hemoglobin for O_2 is less efficient dissociation of O_2 Hb at the peripheral tissue and lower tissue pO_2 .

DETERMINATION OF pCO_2 , pO_2 , AND pH

The instruments used for determination of pCO_2 , pO_2 , and pH are highly automated. Proper specimen collection and handling are critical for accurate determinations.

Specimens

Whole blood is the most likely specimen for a clinical laboratory to receive for gas analysis. Differences in measured blood gas values between arterial and venous blood are most pronounced for pO_2 . pO_2 is generally ≈ 60 mm Hg lower in venous blood after O_2 is released in the capillaries, whereas pCO_2 is 2 to 8 mm Hg higher in venous blood. pH generally is only 0.02 to 0.05 pH units lower in a venous sample.

Proper specimen collection is critical to obtaining accurate results for blood analysis for gases and pH. Placement of indwelling catheters with heparin locks for short- and long-term intravenous therapies is common. Failure to flush the catheter properly has unpredictable effects on measured quantities and is often indicated by bizarre, nonphysiologic results.

Arterial or venous specimens are collected anaerobically with lyophilized (balanced) heparin anticoagulant in 1 to 3 mL sterile syringes. Lyophilized heparin is preferable to liquid heparin because liquid heparin, which has atmospheric pO_2 and pCO_2 values, dilutes the sample, with the effect being greatest when the syringe is not completely filled. An increasing ratio of liquid heparin to blood can have an increasingly marked effect on measured pCO_2 and the parameters calculated from it. Sample dilution with 10% volume of liquid heparin having an atmospheric pCO_2 of 0.25 mm Hg has been shown to lead to a 10 to 20 mm Hg decrease in measured blood pCO_2 .

Anaerobic technique for collection means no exposure of blood to atmospheric air. The pCO_2 of air is about 0.25 mm Hg; this is much less than that of blood (≈ 40 mm Hg). Thus the CO_2 content and pCO_2 of blood exposed to air will decrease, and blood pH, which is a function of pCO_2 , will rise. The PO_2 of atmospheric air (≈ 155 mm Hg) is ≈ 60 mm Hg higher than that of arterial blood and ≈ 100 mm Hg higher than that of venous blood. Therefore blood from patients' breathing room air that is exposed to atmospheric air gains O_2 , and blood with $pO_2 > 150$ mm Hg, as occurs in patients undergoing O_2 therapy, loses O_2 . Blood can also be exposed to air simply from the air in the needle and the syringe hub dead space. Error will be minimal if the resulting bubble is ejected immediately after drawing by holding the syringe tip up and expelling the bubble(s). The potential effect of small bubbles on blood gas results was clearly demonstrated in

Fig. 24.3 (A) Oxygen dissociation curves for human blood with different plasma pH but constant pCO_2 of 40 mm Hg, a 2,3-diphosphoglycerol (2,3-DPG) concentration in erythrocytes of 5.0 mmol/L, and temperature at $37^\circ C$. (B) A Hill plot. Conditions are the same as in A. The coefficients given in this chart form the basis for the correction of measured pO_2 . (C) The effect of $pH(P)$ to shift the dissociation curve is called the *Bohr effect*; the coefficient above for $\Delta \log pO_2 / \Delta pH(P)$ applies to conditions when the pCO_2 is 40 mm Hg, and changes in $pH(P)$ are due to changes in concentrations of noncarbonic acids and bases. If, however, the changes in $pH(P)$ are being caused by changes in pCO_2 , then the absolute value of the coefficient is greater (i.e., $\Delta \log pO_2 / \Delta pH(P) = -0.49$). The coefficients for the Bohr effect are specified for pO_2 of whole blood but use the pH of plasma, $pH(P)$. The coefficient for DPG effect is based on the DPG concentration in the erythrocytes, cDPG(E). $c^* = 1$ mmol/L.

one study in which a 100 μL bubble of room air was added to ten 2 mL blood samples with pO_2 values between 25 and 40 mm Hg. In these samples, pO_2 increased an average of 4 mm Hg in only 2 minutes, whereas pCO_2 decreased 4 mm Hg. Before analysis, mixing of the sample by vigorously rolling the syringe between the palms should be done to establish a homogeneous sample.

Arterialized capillary blood is sometimes an acceptable alternative to arterial blood when an arterial cannula is not available, or when repeated arterial puncture must be avoided. Freely flowing cutaneous blood originates in the arterioles and corresponds closely to arterial blood in composition. However, arterialized capillary blood is not acceptable when systolic blood pressure is less than 95 mm Hg. Capillary

puncture should be preceded by warming of the selected skin puncture site for 10 minutes to achieve vasodilation and adequate blood flow. For collection from the finger of a child or an adult or from an infant's heel, warming may be accomplished by immersing the arm or leg in water warmed to 42°C. The first blood drop to appear should be wiped away, and subsequent free-forming drops should be taken up in a capillary collection tube containing lyophilized heparin. Only free-flowing blood provides a satisfactory sample, and collecting the drops as soon as they form minimizes aerobic exposure. *Transport and analysis* of specimens should be prompt. However, delayed analysis of up to one hour will have a minimal effect on reported values from most samples. The pH of freshly drawn blood decreases on standing at a rate of 0.04 to 0.08 pH unit/h at 37°C, 0.02 to 0.03/h at 22°C, and less than 0.01/h at 4°C. The decrease in pH is accompanied by a corresponding decrease in glucose and an equivalent increase in lactate. $p\text{CO}_2$ increases by ≈ 5 mm Hg/h at 37°C, by 1 mm Hg/h at 22°C, and by only ≈ 0.5 mm Hg/h at 2 to 4°C. The primary cause of these changes is glycolysis by leukocytes, platelets, and reticulocytes. In freshly drawn blood with a normal $p\text{O}_2$ that is maintained anaerobically, cell respiration causes $p\text{O}_2$ to decrease at a rate of ≈ 2 mm Hg/h at room temperature. Adverse effects of glycolysis and respiration on pH, ctCO_2 , $p\text{O}_2$, and $p\text{CO}_2$ of blood can best be prevented by analysis within 30 to 60 minutes after collection. If analysis must be delayed longer than 30 minutes, the syringe should be immersed in a mixture of ice and water until analysis. Under these conditions, changes are negligible because glycolysis is inhibited. With today's blood gas instrumentation, introduction of a chilled sample carries little risk of low-temperature effect on measurements, because thermal equilibration to 37°C is rapid and complete.

The aforementioned small changes in values that can be expected with delays in analysis are true *only* when the white blood cell (WBC) count is normal or only slightly elevated. Glycolysis and the resulting effects on pH, $p\text{O}_2$, and $p\text{CO}_2$ increase dramatically with markedly elevated WBC, such as occurs in leukemia. Experiments have shown that $p\text{O}_2$ decreases by 20 mm Hg in just two minutes and by 40 mm Hg in only 5 minutes with WBC values greater than 100,000/ μL as observed in patients with "blast crisis." Indeed, for samples with these types of WBC values, it is very difficult to overcome this effect. Even after the sample is immersed in ice, thermal equilibrium takes several minutes, allowing significant $p\text{O}_2$ loss before the contents reach 4°C. The only alternative to obtaining accurate blood gas values on such patients is immediate analysis performed at the point of care.

Instrumentation

A schematic diagram characteristic of a typical instrument is shown in Fig. 24.4. Electrochemical principles and structural features of electrodes are discussed in Chapter 10.

Operation of a traditional blood gas instrument begins with the operator presenting a blood specimen at the sample probe. The sample is taken through the probe by a peristaltic pump that loads the chamber with 60 to 150 μL of sample.

The sample then resides in the chamber long enough to allow thermal equilibration and completion of measurements. On completion of measurement, the pump pushes the sample to waste.

Because electrodes are not stable over long periods of time, frequent calibration of pH, $p\text{CO}_2$, and $p\text{O}_2$ is required. The instrument (see Fig. 24.4) is designed so that a manually actuated or a microprocessor actuated valve (self-calibrating) admits calibrator gases, standard buffers, or a sample to a small chamber (C) maintained at $37^\circ\text{C} \pm 0.1^\circ\text{C}$. Most instruments contain a barometer so that barometric pressure $P(\text{Amb})$ is always known to the microprocessor during calibration. Almost all manufacturers now produce small, portable, stand-alone, and easy-to-operate instruments designed for "satellite lab" operations; several handheld devices that use disposable electrodes are also available. Readers are referred to Chapter 17 for a discussion of **point-of-care testing**.

Maintenance of Instrumentation

Sophistication of contemporary equipment and availability of high-quality calibrator materials have made reliable and accurate determination of blood pH and gases primarily a matter of meticulous maintenance, adherence to the manufacturer's recommended procedures, control of the equipment, and proper collection and handling of specimens. Software programs of the instrument's microprocessor often provide display warnings and diagnostic routines that alert the operator and assist in troubleshooting. The manufacturer's suggested maintenance schedule should be considered a minimum guideline, with reliance on experience to indicate maintenance frequency.

Cleanliness of the sample chamber and path is especially important. Automatic flushing to cleanse the sample chamber and path after each blood sample measurement is a feature of most instruments without disposable electrodes. Despite proper flushing, however, complete or partial clogging of the chamber, the path, or both may occur. Fibrin threads and small clots may be present in the specimen or may form while the sample resides in the warm chamber. If allowed to remain, they can affect subsequent measurements or calibrations by interfering with contact of blood, buffers, or gases with electrode membranes. Visibility of the path through the heat sink is helpful for detecting clogs, dirt, and bubbles. Bubbles that fail to rinse out can be a particular problem if they settle on an electrode.

Quality Assurance and Quality Control

Elements of good quality assurance of blood gas and pH measurements include (1) proper maintenance of the instrument, (2) use of control materials, (3) verification of electrode linearity, (4) checking of barometer accuracy, and (5) accurate measurement of temperature.

Minimum calibration and quality control (QC) frequency is mandated by federal law in the United States (Clinical Laboratory Improvement Amendments [CLIA] '88). CLIA regulations require a one-point calibration every 30 minutes (or within 30 minutes of a patient sample) and a two-point

Fig. 24.4 Diagram of blood gas instrumentation. *B*, Constant temperature bath at 37°C; *C*, chamber; *CPU*, computer; *E* (electrodes), pH and gas standards are shown at top of diagram.

calibration every 8 hours. For QC, the minimum CLIA required frequency is one concentration of QC material every 8 hours, with the entire range of control concentrations covered in every 24-hour period. In many laboratories, however, the practical answer is to run three concentrations of QC for pH, pO_2 , and pCO_2 on every instrument in use, at least once per shift following completion of maintenance and troubleshooting procedures. Newer analyzers, particularly the smaller satellite laboratory and point-of-care instruments, frequently have an “auto quality control (QC)” feature or use “electronic QCs.” Auto QC consists of onboard QC material that is automatically analyzed by the instrument at designated intervals that fulfill regulatory requirements. Electronic QC, which is most common in devices with disposable electrode cartridges, consists of cartridges that verify the electronic specification of the instruments. For further discussion of these issues, see [Chapter 17](#) on point-of-care testing.

CLIA similarly mandated external quality assurance (proficiency testing) and set criteria for satisfactory interlaboratory performance as follows: pH, target value ± 0.04 ; pO_2 , target value ± 3 SD; and pCO_2 , target value $\pm 8\%$ or ± 5 mm Hg, whichever is greater.

Blood-Based and Fluorocarbon-Based Control Materials

Commercial blood-based control material usually consists of tanned human erythrocytes suspended in buffered medium and sealed in vials with a gas mixture of known O₂ and CO₂ content. Nonblood fluorocarbon materials with O₂-carrying properties similar to those of blood are also available. These products usually are made at three concentrations of pH, pCO_2 , and pO_2 . Unopened, these types of control materials have the advantages of a long refrigerated shelf life.

Aqueous Fluid Control Materials

These materials consist of a buffered medium with gas mixtures in sealed glass ampules. Immediately prior to opening the vial and introducing it into the instrument, the fluid is equilibrated with the gas by vigorous shaking by hand. The disadvantages of aqueous controls stem from their dissimilar matrix to blood. Lower viscosity and surface tension confer different washout characteristics and impair their ability to detect clogging. Greater electrical conductivity reduces their effectiveness in detecting inadequate grounding, and lower thermal coefficients make them slower to detect failures of

temperature control. Nevertheless, aqueous commercial controls are the most commonly used materials for quality control purposes.

Sources of Analytical Error

General causes of analytical error include calibration of the instrument with incorrect set points for pH buffers or calibrator gases, degraded calibration materials, failure of temperature control of the measurement chamber, and a dirty sample chamber or path. Incorrect calibration may arise from wrong entries made for buffer or gas values into the microprocessor, from incorrect manual calculations of $p\text{CO}_2$ and $p\text{O}_2$ values for calibrator gases, or from using gases that are dry because the humidification device is not working properly. Measurements of $p\text{O}_2$ are particularly sensitive to temperature error. To keep systematic error to 1% to 2%, the temperature control at 37°C must be within $\pm 0.1^\circ\text{C}$. Built-in barometers can be checked by contacting nearby meteorological stations or by verifying the pressure against a NIST-certified barometer placed in the laboratory. Gases other than O_2 present in a blood sample may affect performance of the $p\text{O}_2$ electrode. The anesthetic gases halothane and nitrous oxide have a direct effect, because both can be reduced at the polarized cathode in competition with O_2 . Under most circumstances, however, these effects are small and can be ignored.

Reference Intervals

Reference intervals for arterial blood $p\text{O}_2$, SO_2 , $p\text{CO}_2$, and pH are extensively described in [Chapter 36](#). Values for $p\text{O}_2$ and $p\text{CO}_2$ will decrease with increasing altitude, but compensatory mechanisms keep pH values the same.

$p\text{CO}_2$ values decrease with altitude above sea level at a rate of 3 mm Hg/km (5 mm Hg/mile). A physiologic change occurs with change in posture; $p\text{CO}_2$ is 2 to 4 mm Hg higher for a sitting or standing person than for one in the supine position. During pregnancy, $p\text{CO}_2$ falls gradually to a mean of about 28 mm Hg just before term.

TEMPERATURE CORRECTION OF MEASURED pH, $p\text{CO}_2$, AND $p\text{O}_2$

In the Henderson-Hasselbalch equation, pK' and α are used as constants for a temperature of 37°C. The temperature-controlled sample chamber of an instrument is specified to be $37^\circ\text{C} \pm 0.1^\circ\text{C}$, and it is at that temperature that all measurements of pH and partial pressure of gases are made. The body temperature of a febrile patient may be elevated to 40°C to 41°C , or a patient may be made hypothermic for certain surgeries and have a temperature as low as 23°C . Most blood gas instruments on keyboard entry of a patient's actual temperature can calculate and present temperature-corrected pH and $p\text{CO}_2$. Correction of pH and $p\text{CO}_2$ to the actual temperature of the patient is usually omitted in states of hyperthermia. However, significant disagreement exists with respect to hypothermic states.

The equation shown in [Table 24.2](#) illustrates the complexity of the calculation used to correct $p\text{O}_2$ to the patient's body

TABLE 24.2 Temperature Correction Formulas Recommended by the CLSI²³

pH	$p\text{H}(T) = p\text{H}(37^\circ\text{C}) - [0.147 + 0.0065 \times (p\text{H}(37^\circ\text{C}) - 7.40) \times (T - 37^\circ\text{C})]$
$p\text{CO}_2$	$p\text{CO}_2(T) = p\text{CO}_2(37^\circ\text{C}) \times 10^{[0.019 \times (T - 37^\circ\text{C})]}$
$p\text{O}_2$	$p\text{O}_2(T) = p\text{O}_2(37^\circ\text{C}) \times 10^{\left(\frac{5.49 \times 10^{-11} \times p\text{O}_2^{3.88} + 0.071}{9.72 \times 10^{-9} \times p\text{O}_2^{3.88} + 2.30} \right) \times (T - 37^\circ\text{C})}$

temperature. Complexity is unavoidable because at $p\text{O}_2 < 100$ mm Hg ($\text{SO}_2 \leq 0.95$), the hemoglobin-oxygen dissociation curve is shifted to the left by the decrease in temperature and by the concomitant rise in pH (see [Fig. 24.3](#)). For temperature corrections of $p\text{O}_2$ between 100 and 400 mm Hg, accurate formulas become even more complicated.

CONTINUOUS AND NONINVASIVE MONITORING OF BLOOD GASES

Obtaining arterial, venous, or capillary blood is an invasive procedure, and test results reflect conditions pertaining only to a single point in time. Repetitive sampling carries risks, including infection and vascular complications. In premature infants particularly, repeated sampling imposes an undesirable blood loss.

Extensive discussion of noninvasive and continuous modes of monitoring is beyond the purview of this text. However, laboratorians must be aware of them, because blood samples and standard analytical equipment remain the reference for monitoring the effectiveness of such devices.

The accuracy of transcutaneous $p\text{O}_2$ monitoring can vary widely, depending on whether the site of application reflects arterial, capillary, or venous blood flow. Because there is little difference between arterial and venous $p\text{CO}_2$, transcutaneous monitoring of $p\text{CO}_2$ is less problematic, and pulse oximeters can often serve as a surrogate for $p\text{O}_2$. Transcutaneous monitoring works best in areas of thin skin, hence its popularity in neonates and in settings of euolemia. In addition to monitoring $p\text{O}_2$ and $p\text{CO}_2$, new in-line devices that also monitor pH, electrolytes, glucose, and hematocrit have been introduced to the market.

POINTS TO REMEMBER

Blood gas instruments use the Henderson-Hasselbalch equation to calculate bicarbonate concentration and extremes of sample ionic strength; protein and lipid concentration may alter the accuracy of this calculated value.

The presence of bubbles in blood gas syringes has the potential to dramatically change the $p\text{O}_2$ and $p\text{CO}_2$ of blood gas samples.

Hemoglobin oxygen saturation (SO_2), fractional oxyhemoglobin (FO_2Hb), and estimated oxygen saturation may produce very dissimilar values in the presence of dyshemoglobins and hemoglobin variants.

Blood gas analyzers have more stringent requirements for the frequency of calibration and quality control assessment.

REVIEW QUESTIONS

- The most common method for measuring sodium and potassium is
 - flame emission spectrophotometry.
 - enzymatic methods.
 - atomic absorption spectrophotometry.
 - ion-selective electrode.
- Which of the following will shift the O_2 dissociation curve to the right?
 - Hyperthermia
 - Acute alkalemia
 - Hypocapnia
 - Low 2,3-DPG
- Which of the following present the least risk of erroneous blood gas values?
 - 30 minutes at ambient temperature
 - WBC $>100,000/\mu\text{L}$
 - Air bubbles in the sample
 - First drop from a capillary puncture
- The vapor pressure osmometer has fallen out of popular use due to several technical drawbacks. Which of the following are false regarding this instrument?
 - It does not include any volatile solutes in its measurement of serum osmolality.
 - It is sensitive to changes in ambient temperature.
 - It contains a thermistor, a galvanometer, and a measuring potentiometer.
 - It would be able to detect an increase in osmolality attributable to increased blood glucose.
- Recent developments in genetic testing, paired with advances in understanding genotype-phenotype correlations in cystic fibrosis, have broadened the testing options for this serious condition. Currently the gold standard test for the diagnosis of cystic fibrosis is:
 - sweat conductance.
 - sweat chloride.
 - immunoreactive trypsinogen.
 - assay to detect common mutations.
 - gene sequencing to detect common and novel mutations.
- Solutes change the behavior of the solvent to which they are added in predictable ways, conferring colligative properties to the solution, including
 - decreased osmotic pressure.
 - increased vapor pressure.
 - decreased boiling point.
 - decreased freezing point.
 - increased transmittance.
- The most common cause of falsely elevated sweat chloride testing results is
 - eczema.
 - improper gauze placement.
 - hypothyroidism.
 - postcollection evaporation.
 - analytic error.
- What is the expected effect on plasma K^+ concentration if a freshly drawn sample is stored on the bench for 1.5 hours prior to being centrifuged?
 - An increase in plasma K^+ of ~ 2 mmol/L
 - A decrease in plasma K^+ of ~ 0.2 mmol/L due to transcellular shift into RBCs
 - An insignificant increase in plasma K^+ of ~ 0.2 mmol/L
 - A decrease in plasma K^+ due to increased hemolysis
 - A decrease in plasma K^+ ~ 2 mmol/L due to transcellular shift into RBCs
- Hemolysis of a plasma sample will most likely affect which of the following, and why?
 - Sodium; it is present in equal amounts both intracellularly and extracellularly
 - Glucose; it moves out of cells into plasma
 - Insulin; it is the major intracellular anion and is present in high amounts in RBCs
 - Potassium; it is localized mainly within cells, particularly RBCs
- Which of the following equations is the correct Henderson-Hasselbalch equation?
 - $pK' + pH + \log [cHCO_3]/[cH_2CO_3]$
 - $pK' + pH + \log [cH_2CO_3]/[cHCO_3]$
 - $pH + pK' + \log [cHCO_3]/[cH_2CO_3]$
 - $pH + pK' + \log [cH_2CO_3]/[cHCO_3]$

Hormones

Timothy James Cole

OBJECTIVES

1. Define the following:
 - Amino acid–derived hormone
 - Autocrine system
 - Endocrine system
 - Endocrinology
 - Hormone
 - Hormone receptor
 - Incretin hormone
 - Paracrine system
 - Protein or polypeptide hormone
 - Steroid hormone
2. Describe the three classifications of hormones; include examples of each, chemical structures, characteristics, half-life, and tissues of origin.
3. List and describe three physiological functions of hormones; include the role of hormones in each category and give examples of hormones in each category.
4. Compare the two types of receptor-hormone interactions; include examples of each type, postreceptor actions, and the specific effects that each type of interaction produces in a cell.
5. Provide examples of feedback mechanisms in the endocrine system.
6. List and describe four techniques used to assess hormones; include basic principles, specimen requirements, and an advantage of each technique.

KEY WORDS AND DEFINITIONS

Autocrine A mode of hormone action in which a cell secretes a hormone that binds to autocrine receptors on that same cell, leading to changes in the cell.

Circadian rhythms Rhythmic repetition of certain phenomena in living organisms at about the same time each day.

Cyclic adenosine monophosphate (cAMP) A cyclic nucleotide that serves as an intracellular and, in some cases, extracellular “second messenger” mediating the action of many peptide or amine hormones.

Endocrine system The system of glands that release their secretions (hormones) directly into the circulatory system. In addition to the endocrine glands, included are the chromaffin and the neurosecretory systems.

Endocrinology The scientific study of the function and pathology of the endocrine glands.

Gonadotropin Any hormone that stimulates the gonads.

G-proteins Guanine nucleotide-binding proteins (G-proteins) are a family of intracellular proteins involved in transmitting chemical signals from outside the cell, and causing changes inside the cell. They communicate signals from many hormones, neurotransmitters, and other signaling factors.

G-protein–coupled receptors (GPCRs) A large superfamily of membrane receptors whose intracellular effects are mediated by G proteins.

Half-life In endocrinology, the time required for a hormone to fall to half its original concentration in the specified fluid or blood.

Homeostasis The maintenance of equilibrium of internal body functions in response to external changes.

Hormone A chemical substance that has a specific regulatory effect on the activity of a certain organ or organs on cell types.

Paracrine A type of hormone function in which hormone synthesized in and released from endocrine cells binds to its receptor in nearby cells of a different type and affects their function.

Phospholipase C- γ Any esterase that catalyzes the hydrolysis of the phosphoric ester bond of a membrane phospholipid, generating a phosphorylated alcohol and diacylglycerol.

Pituitary gland A small oval gland attached to the base of the vertebrate brain and consisting of an anterior and a posterior lobe (also known as the hypophysis and the pituitary body).

Receptor A molecular structure, normally a protein, within a cell or on the surface characterized by (1) selective binding of a specific substance and (2) a specific physiological effect that accompanies the binding; examples include (1) cell surface receptors for peptide hormones, neurotransmitters, antigens, complement fragments and immunoglobulins, and (2) cytoplasmic receptors for steroid and other lipid-derived hormones.

Second messenger Any of several classes of intracellular signaling molecules that translate electrical or chemical messages from the environment (first messengers) into cellular responses.

Zinc finger motif Found in nucleic acid-binding proteins that contain one or more zinc-binding domains (tandemly repeated, highly conserved stretches of 28 amino acids).

BACKGROUND

Hormones are chemical messengers synthesized and secreted by endocrine glands, organs, or isolated cells that have specific regulatory effects on the activity of target cells. As a component of the **endocrine system**, hormones are produced at one site in the body and, in general, exert their action(s) at distant sites. Some hormones exert actions locally (**paracrine**), and other hormones exert their action on their cell of origin, regulating their own synthesis and secretion (**autocrine**). Classic endocrine hormones include insulin, thyroxine, and cortisol; neurotransmitters and neurohormones are examples of paracrine hormones, and certain growth factors that stimulate synthesis and secretion of other hormones from the same cell are examples of autocrine hormones. Table 25.1 lists hormones that are commonly measured in the clinical laboratory. Hormones are classified as polypeptides or proteins, derivatives of amino acids, and steroids or other lipid derivatives.

Polypeptide or Protein Hormones

Adrenocorticotrophic hormone (ACTH), insulin, and parathyroid hormone (PTH) are examples of polypeptide or protein hormones. They are water soluble and circulate freely in plasma as the secreted complete molecule or as active or inactive fragments. The **half-life** of these hormones in plasma is relatively short (≤ 10 to 30 minutes), and their concentrations may vary dramatically, depending on specific physiological and pathological states. These hormones initiate cellular responses by binding to a vast array of cell surface membrane **receptors** on target cells and activate intracellular signal-transduction pathways that lead to a specific action or changes within the target cell. For example, insulin, when released from pancreatic β -cells, binds to cell-surface insulin receptors at target tissues, such as the adipose and muscle, to promote the uptake of glucose from the bloodstream.

Amino Acid–Derived Hormones

Thyroid hormone such as thyroxine and the catecholamines are examples of hormones that are derived from amino acids; in both of these cases they are derived from tyrosine. They are water soluble and circulate in plasma bound to specific transport proteins (thyroxine) or circulate freely (catecholamines). Thyroxine binds avidly to three specific binding proteins—transthyretin, thyroid-binding globulin, and albumin—and

has a half-life of approximately 7 to 10 days; free-circulating catecholamines such as epinephrine have a short half-life of a minute or less. The catecholamines interact with a family of nine closely related cell surface adrenergic receptors and initiate intracellular **second messenger** signal-transduction systems, whereas thyroid hormones move freely across the cell membrane to activate two specific intracellular nuclear receptors (NRs): thyroid hormone receptor- α and - β .

Steroid and Other Lipid-Derived Hormones

Endogenous steroid hormones such as cortisol, estrogen, and testosterone are synthesized from cholesterol, are hydrophobic, and are insoluble in water. These hormones circulate in plasma, reversibly bound to specific transport plasma proteins (e.g., cortisol-binding globulin, sex hormone-binding globulin) with only a small fraction unbound that is freely circulating to exert physiological action. The half-life of circulating steroid hormones is 30 to 90 minutes. Free steroid hormones at their sites of action, because of their hydrophobicity, enter the cell by passive diffusion and bind with intracellular NRs in the cytoplasm or the nucleus.

SYNTHESIS, RELEASE, AND GENERAL ACTION OF HORMONES

The physiological functions of hormones can be broadly categorized as those (1) affecting growth, development, and maturation; (2) controlling systemic homeostasis, energy balance, and integrated metabolism; and (3) regulating reproduction.

Synthesis and Release of Hormones

Many hormones are synthesized in specialized endocrine cells within specific endocrine glands. These include the polypeptide hormone insulin, which is synthesized in the β -cells of the pancreas; estradiol, which is synthesized in the granulosa cells of the ovary; and epinephrine (or adrenalin), which is synthesized by the medullary chromaffin cells of the adrenal gland. Some hormones require biosynthesis via complex enzymatic pathways, such as the cardiovascular hormone aldosterone, which is synthesized from precursor cholesterol in the outer zona glomerulosa cell layer of the adrenal cortex. Other hormones require simpler modification of a precursor compound such as vitamin D. All hormones attain a structural specificity that allows them to bind strongly to and activate specific receptors on target cells. In general, hormones are released from endocrine cells when they are required, either from intracellular stores or by induction

TABLE 25.1 Frequently Measured Endocrine Hormones

Endocrine Organ and Hormone	Hormone Type	Major Sites of Action	Principal Actions
Brain—Hypothalamus			
Thyrotropin-releasing hormone (TRH)	Peptide (3aa, Glu-His-Pro) ^a	Anterior pituitary	Release of thyroid-stimulating hormone (TSH) and prolactin (PRL)
Gonadotropin-releasing hormone (Gn-RH)	Peptide (10aa)	Anterior pituitary	Release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH)
Corticotropin-releasing hormone (CRH)	Peptide (41aa)	Anterior pituitary	Release of adrenocorticotrophic hormone (ACTH) and β -lipotropic hormone (LPH)
Growth hormone-releasing hormone (GH-RH)	Peptides (40, 44aa)	Anterior pituitary	Release of growth hormone (GH)
Neuropeptide Y	36aa peptide released mainly from paraventricular neurons	Hypothalamus, thalamus, hippocampus, and gastrointestinal tract	Increased food intake, energy storage, reduced anxiety, and stress
Prolactin-releasing peptide	Peptide (20aa)	Anterior pituitary	Release of PRL
Kisspeptin	Peptide (54aa precursor cleaved to 13 and 14aa active peptides)	Gn-RH hypothalamic neurons	Stimulation of Gn-RH release via the G protein-coupled receptor GPR54
Anterior Pituitary Lobe			
Thyrotropin or TSH	Glycoprotein, heterodimer ^b (α , 92aa; β , 112aa)	Thyroid gland	Stimulation of thyroid hormone formation and secretion
Follicle-stimulating hormone (FSH)	Glycoprotein, heterodimer ^b (α , 92aa; β , 117aa)	Ovary	Growth of follicles with LH, secretion of estrogens, and ovulation
		Testis	Development of seminiferous tubules; spermatogenesis
Luteinizing hormone (LH)	Glycoprotein, heterodimer ^b (α , 92aa; β , 121aa)	Ovary	Ovulation; formation of corpora lutea; secretion of progesterone
		Testis	Secretion of androgens
Prolactin (PRL)	Peptide (199aa)	Mammary gland	Proliferation of mammary gland; initiation of milk secretion; antagonist of insulin action
Growth hormone or somatotropin	Peptide (191aa)	Liver	Production of insulin-like growth factor (IGF-1) (promoting growth)
		Liver and peripheral tissues	Anti-insulin and anabolic effects
Corticotropin hormone or ACTH	Peptide (39aa)	Adrenal cortex	Stimulation of adrenocortical steroid biosynthesis and secretion
α -Melanocyte-stimulating hormone (α -MSH)	Peptide (13aa)	Skin	Dispersion of pigment granules, darkening of skin
Posterior Pituitary Lobe			
Vasopressin or antidiuretic hormone	Peptide (9aa)	Arterioles	Increase of blood pressure; water reabsorption
		Renal tubules	
Oxytocin	Peptide (9aa)	Smooth muscles (uterus, mammary gland)	Contraction; action in parturition and in sperm transport; ejection of milk
Pineal Gland			
Melatonin	Indoleamine	Hypothalamus	Suppression of gonadotropin and GH secretion; induction of sleep
Thyroid Gland			
Thyroxine (T ₄) and triiodothyronine (T ₃)	Iodoamino acids	General body tissue	Stimulation of oxygen consumption and metabolic rate of tissue
Calcitonin or thyrocalcitonin	Peptide (32aa)	Skeleton	Uncertain in humans
Parathyroid Gland			
Parathyroid hormone (PTH) or parathyrin	Peptide (84aa)	Kidney	Increased calcium reabsorption, inhibited phosphate reabsorption; increased production of 1,25-dihydroxycholecalciferol
		Skeleton	Increased bone resorption

TABLE 25.1 Frequently Measured Endocrine Hormones—cont'd

Endocrine Organ and Hormone	Hormone Type	Major Sites of Action	Principal Actions
Adrenal Cortex			
Aldosterone	Steroid	Kidney	Salt and water balance
Cortisol	Steroid	Many	Metabolism of carbohydrates, proteins, and fats; anti-inflammatory effects; others
Dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulfate (DHEAS)	Steroids	Hormone precursors	Converted to estrogens and testosterone
Adrenal Medulla			
Norepinephrine and epinephrine	Aromatic amines	Sympathetic receptors	Stimulation of sympathetic nervous system
Epinephrine	Aromatic amines	Liver and muscle, adipose tissue	Glycogenolysis Lipolysis
Ovary			
Activin A and B	Peptides ^c 2 β_A subunits 2 β_B subunits	Pituitary, ovarian follicle	Stimulates release of FSH; enhances FSH action; inhibits androgen production by theca cells
Estrogens	Phenolic steroids	Female accessory sex organs Bone	Development of secondary sex characteristics Control of skeletal maturation
Follistatin	Peptides (288aa, 315aa)	Pituitary, ovarian follicles	Inhibits FSH synthesis and secretion by binding activin
Inhibin A and B	Peptide (α subunit and β_A or β_B subunit)	Hypothalamus, ovarian follicle	Inhibits FSH secretion; stimulates theca cell androgen production
Progesterone	Steroid	Female accessory reproductive structure	Preparation of the uterus for ovum implantation, maintenance of pregnancy
Relaxin	Peptide ^d	Uterus	Inhibition of myometrial contraction
Testis			
Inhibin B	See above	Anterior pituitary, hypothalamus	Control of LH and FSH secretion
Testosterone	Steroid	Male accessory sex organs	Development of secondary sex characteristics, maturation, and normal function
Pancreas			
Amylin	Peptide (37aa)	Pancreas	Inhibits glucagon and insulin secretion
Glucagon	Peptide (29aa)	Liver	Glycogenolysis
Insulin	Peptide ^e	Liver, fat, muscle	Regulation of carbohydrate metabolism; lipogenesis
Gastrointestinal Tract			
Gastrin ^f	Peptide (17aa)	Stomach	Secretion of gastric acid, gastric mucosal growth
Ghrelin ^f	Peptide (28aa)	Anterior pituitary	Secretion of GH
Secretin	Peptide (27aa)	Pancreas	Secretion of pancreatic bicarbonate and digestive enzymes
GIP	Peptide (42aa)	Gastrointestinal tract	Inhibition of gastric secretion and motility; increase in insulin secretion
Kidney			
1,25-(OH) ₂ cholecalciferol	Sterol	Intestine Bone	Facilitation of absorption of calcium and phosphorus; increase in bone resorption in conjunction with PTH
Erythropoietin	Peptide (165aa)	Kidney Bone marrow	Increase in reabsorption of filtered calcium Stimulation of red cell formation

Continued

TABLE 25.1 Frequently Measured Endocrine Hormones—cont'd

Endocrine Organ and Hormone	Hormone Type	Major Sites of Action	Principal Actions
Renin-angiotensin-aldosterone system	Peptides (renin, 297aa; Ang I, 10aa; Ang II, 8aa, produced from Ang I by angiotensin-converting enzyme)	Renin (from kidney) catalyzes hydrolysis of angiotensinogen (from liver, 485aa) to Ang I in the intravascular space	Ang II increases blood pressure and stimulates secretion of aldosterone (see adrenal)
Liver			
IGF-1, formerly called somatomedin	Peptide (70aa)	Most cells	Stimulation of cellular and linear growth
IGF-2	Peptide (67aa)	Most cells	Insulin-like activity
Heart			
Atrial natriuretic peptide (atriopeptin)	Peptide with an intrachain disulfide bond (28aa)	Vascular, renal, and adrenal tissues	Regulation of blood volume and blood pressure
B-type natriuretic peptide	Peptide with an intrachain disulfide bond (32aa)	Vascular, renal, and adrenal tissues	Regulation of blood volume and blood pressure
Adipose Tissue			
Adiponectin	Peptide oligomers of 30 kDa subunits	Muscle Liver	Increases fatty acid oxidation Suppresses glucose formation
Leptin	Peptide (167aa)	Hypothalamus	Inhibition of appetite, stimulation of metabolism
Resistin	Peptide (94aa)	Liver	Insulin resistance
Tissue necrosis factor- α	157aa secreted protein	Adipose in an autocrine or paracrine fashion	Pluripotent cytokine with a wide-range of actions
Bone			
Osteocalcin	49aa	Bone, pancreas adipose tissue	Bone mineralization and calcium homeostasis, systemic metabolism
Osteopontin	314aa	Bone, pancreas, neutrophils	Bone remodeling, immune functions, chemotaxis
Osteonectin	285aa	Bone, paracrine action	Bone mineralization
Skeletal Muscle			
Myostatin	109aa monomer, active as a dimer	Skeletal muscle; paracrine actions	Inhibition of muscle differentiation and growth

A more complete list endocrine hormones can be found in [Chapter 36: Hormones](#). In *Tietz textbook of clinical chemistry and molecular diagnostics* (6th ed.).

^aaa, Amino acid residues.

^bGlycoprotein hormones composed of two dissimilar peptides. The α -chains are similar in structure or identical; the β -chains differ among hormones and confer specificity.

^cEach activin and inhibin is found in multiple forms.

^dTwo chains linked by two disulfide bonds: α , 24aa; β , 29aa.

^eTwo chains linked by two disulfide bonds: α , 21aa; β , 30aa.

^fAlso produced in the brain.

of rapid biosynthesis. The biosynthetic pathways of hormones are critical to maintain **homeostasis**. Defects in those pathway enzymes can lead to debilitating endocrine disease, such as the genetic condition of congenital adrenal hyperplasia, which is a disease caused by mutations in the steroid biosynthetic enzymes of the adrenal cortex, which are required for production of cortisol, aldosterone, and androgen precursors from cholesterol. The loss of end-product hormone production or the inappropriate buildup of steroid precursors can lead to complex cardiovascular and reproductive development dysfunction and gender ambiguity. Examples of the three broad functional categories of

hormone action are presented as follows and illustrate specific aspects on the synthesis, release, turnover, and action of endocrine hormones.

Growth, Development, and Maturation

Normal embryonic development and postnatal growth of the whole human organism is dependent on the complex integrative function of many hormones, including growth hormone, insulin-like growth factor-1 (IGF-1), thyroxine, the gonadal steroids (estrogen and androgen), and cortisol. Several pituitary (also called the hypophysis) hormones, such as growth

hormone, ACTH, and thyroid-stimulating hormone (TSH), are responsible specifically for the growth and development of other endocrine glands, such as the adrenal, gonads, and thyroid. For example, growth hormone is synthesized and secreted by pituitary somatotroph cells and stimulates the production and release of hepatic IGF-1. Both factors then have broad somatic growth actions, particularly in bone and cartilage. Therefore these pituitary hormones are responsible for the control of synthesis and the secretion of many secondary hormones. These hormones provide important negative feedback control on the secretion of the pituitary hormones. Other regulators of secretion of the pituitary hormones include **circadian rhythms** and the hypothalamic pulse generator that controls the pulsatile secretion of **gonadotropins**.

Energy Homeostasis and Integrated Metabolism

Energy homeostasis and the activity of many metabolic pathways in cells are tightly regulated by a diverse number of systemic and locally released hormones. There is a continual change in demand for energy use and storage during states such as feeding, exercise, starvation, infection, injury and/or trauma, or emotional stress. These states initiate the release and action of many hormones to regulate energy use and nutrient metabolism, modulate energy storage, and regulate physical and behavioral responses to stress. These hormonal activated pathways in cells are complex and may involve hormones from different organs. In general, systemic nutrient uptake, appetite, energy storage, and release are under neurological control via actions of specific hypothalamic and neuroendocrine hormones (e.g., leptin and neuropeptide Y).

The following are examples illustrating the feedback control of hormone secretion and action, which is critical for homeostasis:

- Regulation of blood glucose concentrations: In response to a glucose load, insulin is promptly released from the pancreatic β -cells, which regulate the uptake of glucose into peripheral metabolic tissues (fat, muscle, liver, and brain) for the metabolism necessary to produce energy from glucose. As circulating glucose concentrations return to preload concentrations, insulin secretion slows. Several counterregulatory hormones come into play to further regulate this process to ensure that blood glucose concentrations do not become too low. These include glucagon, cortisol, epinephrine, and growth hormone.
- Water and electrolyte homeostasis is regulated by the steroid hormone aldosterone released from the adrenal gland, renin from the kidney, and vasopressin (antidiuretic hormone) from the posterior **pituitary gland**.

Endocrine Control of Reproduction

The gonadotropin hormones luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are released from pituitary gonadotroph cells in response to hypothalamic gonadotropin-releasing hormone to regulate the development, growth, and functions of the ovary and testis. In turn, the ovarian and testicular hormones estradiol and testosterone, respectively, initiate and regulate the following: pubertal

growth; development and maintenance of secondary sex characteristics; the growth, development, and maintenance of the skeleton and muscles; and in part, the distribution of body fat.

CELL SIGNALING MECHANISMS OF HORMONE RECEPTORS

The specific action of an endocrine hormone on its target cell or tissue is a function of the interaction between the hormone and its cognate receptor. Several types of hormone-receptor interactions occur with cells, and an individual cell may express and contain hundreds of different receptors that may respond to multiple specific hormones at any given time. The hormone-receptor complex provides the strong specificity of the hormone's action, eliciting a target tissue response. Many endocrine hormones circulate in picomolar or nanomolar concentrations (10^{-9} to 10^{-12} mol/L) but elicit specific and strong responses in specific target cells. Hormone receptors may be present on the cell surface imbedded in the plasma membrane or reside intracellularly within the cytoplasm or nucleus. Receptors at the cell surface and intracellular NRs initiate a variety of different postreceptor cellular responses by activating complex intracellular signal transduction pathways. This is shown schematically in **Fig. 25.1** for three common classes of hormone receptors. Binding of the hormone or ligand to the receptor initiates activation of the receptor and initiation of downstream signaling that cause cellular changes in both the cytoplasm and the nucleus.

Cell Surface Hormone Receptors

Polypeptide or hydrophilic hormones bind to cell surface receptors, and the conformational change or the protein-protein interactions initiated resulting from this binding activates an effector system within the cells, which is responsible for the downstream actions of the hormone (see **Fig. 25.1**). For many peptide and polypeptide hormones, the intracellular effector that is activated by the hormone-receptor interaction is a specific intracellular **G-protein** (guanyl-nucleotide-binding protein), and the cell surface receptors are called **G-protein-coupled receptors (GPCRs)** (see **Fig. 25.1**). GPCRs are the largest family of cell surface receptors, with approximately 830 genes coding for human GPCRs. GPCRs are large proteins with seven membrane-spanning domains, an amino-terminal, a hormone-binding domain that is extracellular, and an intracellular carboxy-terminal tail of loop domains. The second major class of cell surface hormone receptors is the enzyme-coupled receptors (see **Fig. 25.1**). These receptors have been divided into six subfamilies of receptors, of which the most well-characterized family is the receptor tyrosine-kinase (RTK) group of receptors, which mediate the actions of many common hormones and growth factors, such as insulin, IGF-1, epidermal growth factors, and fibroblast growth factors. These receptors are characterized by initiating intracellular kinase cascades and regulating cell growth and metabolism, and are common targets for mutation in tumor cells.

Fig. 25.1 Endocrine cell signaling is mediated by both cell surface and intracellular hormone receptors. Cell surface receptors comprise two main classes of proteins called G-protein–coupled receptors (*GPCR*) and enzyme-coupled receptors (*ENZCR*), whereas intracellular hormone receptors form the nuclear receptor (*NR*) superfamily of proteins. Cell surface receptors bind a circulating hormone using a specific extracellular protein domain and transduce a signal to the interior of the cell. In contrast, receptors for lipophilic hormones (e.g., a steroid hormone) reside within the cell, in many cases in the cytoplasm in an inactive complex of proteins. The activated NR is then targeted to the nucleus. *cAMP*, Cyclic adenosine monophosphate; *JAK/STAT*, Jak kinase/STAT pathway; *MAPK*, MAP kinase pathway; *N*, nucleus; *P*, phosphate; *PKA*, protein kinase A; *PM*, plasma membrane.

SIGNAL TRANSDUCTION FROM CELL SURFACE G-PROTEIN–COUPLED RECEPTORS

GPCRs are grouped under four main classes, each of which contains receptors for specific types of hormones. The class A GPCRs contain the rhodopsin-like receptors that include receptors for olfactory compounds and melatonin; class B represents the secretin-like GPCRs (receptors for secretins, glucagon, and vasoactive intestinal polypeptide); class C, the largest by number, contains the metabotropic glutamate and/or pheromone receptors; and class D contains the fungal mating pheromone receptors. GPCRs are seven transmembrane proteins that on hormone binding undergo a conformational change allowing direct interaction of the intracellular C-terminal tail of the activated GPCR with specific G-proteins that are organized in a trimeric complex of an α , β , and γ G-protein subunit. Activated G-protein subunits then initiate signaling cascades via activation of specific enzymes or generation of small molecules that serve as potent second messengers to mediate the hormone response within the cell. The best known effector enzyme is adenylyl cyclase, which generates the important second messenger **cyclic adenosine monophosphate (cAMP)** (see Fig. 25.1). The activated G-protein α binds a molecule of GTP and is inactivated by an intrinsic GTPase activity that converts the bound GTP to GDP, thereby turning off the downstream signaling pathway.

SIGNAL TRANSDUCTION FROM CELL SURFACE ENZYME–COUPLED RECEPTORS

The insulin receptor is a member of the second major class of cell surface hormone receptors, called the enzyme-coupled

receptors. These have been classified into six subfamilies of enzyme-coupled receptors, with the best characterized being the large family of RTKs, a family of 90 characterized receptors. These receptors mediate the actions of many common growth factor hormones such as the epidermal, fibroblast, platelet-derived, and vascular endothelial growth factors. RTKs are single transmembrane spanning proteins that dimerize upon hormone binding, an event that initiates intracellular signaling responses (see Fig. 25.1). The receptor dimer is then auto-phosphorylated by intrinsic C-terminal tyrosine kinase catalytic domains. The phosphorylated Tyr residues act as specific binding sites for effector signaling proteins, such as phosphoinositol-3-kinase (PI-3-kinase) and **phospholipase C- γ** , which then transmit the signal within the cell. These effector proteins contain SH2 domains that specifically recognize phosphotyrosine residues on the activated receptor. MAP-kinase pathway activation results in subsequent downstream target gene activation, as well as cell proliferation and differentiation. These pathways do not use second messengers but involve activated enzyme cascades. RTKs and downstream signaling components are often mutated in cancer cells that then acquire a high proliferative phenotype. Gene mutations often produce constitutively active receptors or signaling proteins such as RAS and PI-3-kinase.

Intracellular Nuclear Receptors and Signal Transduction

Lipid-soluble hormones (e.g., estradiol) are primarily transported bound to plasma proteins such as albumin, with only a small fraction of the hormone circulating free or unbound. Free hormone enters the cell via passive diffusion and in most cases binds to intracellular NRs in the cytoplasm, or in some

cases the nucleus (see Fig. 25.1). NRs are characterized by a hormone or ligand-binding domain, a central DNA-binding domain, and an amino-terminal variable domain that contributes to recruitment of nuclear proteins such as transcriptional coactivators. In general, lipid-soluble hormones bind and activate the ligand-binding domain of intracellular NRs that then signal specific changes to the nucleus (see Fig. 25.1). The human genome contains a group of 48 NR genes that encode the NR superfamily of receptors and are activated by a range of lipophilic steroid, dietary lipids, vitamins, fatty acid, and special small molecule ligands (e.g., thyroid hormone). A large number of these receptors are still classified as orphan receptors with no known hormone ligand, and little is understood of their functional role in human biology and in clinical disease. Hormone binding initiates a conformational change that enables the hormone-receptor complex to localize to the nucleus and bind specific regulatory DNA hormone response elements (HREs) near specific target genes. Hormone translocation of the cytoplasmic NRs to the nucleus, once activated, is mediated by a conformational change in the receptor that exposes a nuclear localization sequence normally located within the DNA-binding domain. The binding specificity of the activated NR for specific HREs near the target gene is determined by the first **zinc finger motif** in the receptor's DNA-binding domain. Binding of the hormone-receptor complex to HREs promotes recruitment of a co-activator and sometimes co-repressor proteins that ultimately mediate activation or repression of gene transcription. Messenger RNA levels of target genes can be enhanced up to 1000-fold, leading to large changes in the synthesis of specific proteins that then drive cellular and physiological change. In addition to these nuclear gene expression changes, many NRs can be activated to produce rapid so-called nongenomic effects in the cytoplasm or at the cell membrane.

CLINICAL DISORDERS OF HORMONE ACTION

Although several chapters of this textbook detail a variety of endocrine disorders, a brief introduction to endocrine disorders is given here. In general, endocrine diseases may result from a deficiency or an excess of a single hormone or several hormones, or from resistance to the action of hormones in target cells. Hormone deficiency can be congenital (genetically inherited) or acquired, and hormone excess can result from endogenous overproduction (from within the body) or from exogenous overmedication. Hormone resistance can occur at several levels but can most simply be characterized as receptor-mediated, post-receptor-mediated, or at the level of the target tissue. The clinical manifestations will depend on the hormone system affected and the type of abnormality. Diabetes is an example of an endocrine metabolic disorder and is the most common endocrine disorder in Western countries. It is classified as either type 1 or type 2. Type 1 diabetes results from failure of the pancreas to secrete insulin although the pancreas is otherwise normal. Type 2 diabetes results from end-organ resistance to the action of insulin, which, in this case, is secreted from the pancreas in abundant amounts and

circulates at high concentrations. Secondary diabetes occurs when a nonendocrine disease, such as pancreatitis, destroys the pancreas, including the insulin-secreting cells. The biochemical hallmark of diabetes is hyperglycemia, which can be present when there is insulin deficiency or insulin excess, and insulin excess can accompany both hyperglycemia and hypoglycemia.

TECHNIQUES FOR MEASUREMENT OF HORMONES AND RELATED ANALYTES

Hormones are measured with a variety of analytical techniques, including bioassay, receptor assay, immunoassay, and instrumental techniques such as mass spectrometry interfaced with liquid or gas chromatography. Bioassays are based on observations of physiological responses specific for the hormone being measured. *In vivo* bioassays usually involve the injection of test materials (such as blood or urine from a patient) into suitably prepared animals; target gland or organ responses such as growth or steroidogenesis are then measured. *In vitro* bioassays involve the incubation of tissue samples, membranes, dispersed cells, or permanent cell lines in a defined culture medium, with subsequent measurement of an appropriate hormone response. Bioassays tend to be imprecise and are now rarely used in clinical medicine.

Receptor-based binding assays depend on the *in vitro* interaction of a hormone with its biological receptor. In this type of assay, unlabeled hormone displaces trace amounts of radioactively labeled hormone from specific receptor sites. In general, receptor-binding assays are simpler to perform and have greater sensitivity than bioassays, and also have an advantage over immunoassays in that they reflect the biological function of a hormone—namely, the capacity to combine with specific receptors. By contrast, immunoassays may measure active hormone and inactive prohormone, hormone polymer, and metabolites when all share the common antigenic determinant or set of determinants of the assay antibody. In general, receptor-binding assays are not as sensitive as immunoassays, and proteolytic enzymes in the biological specimen may sometimes degrade the receptor or destroy the labeled tracer.

Enzyme-linked immunosorbent assays or standard immunoassays that use specific antibodies are widely used to quantify hormones. Currently labeled antibody (immunometric) assays with nonisotopic labels are the method of choice for measuring concentrations of most hormones, especially peptides and proteins. Immunometric assays use saturating concentrations of two or more antibodies (often monoclonal) that are prepared against different epitopes of the protein molecule. One of the two antibodies is usually attached to a solid-phase separation system and extracts the hormone from the serum specimen. The second antibody is linked to a signal molecule, which is then measured (see Chapter 15). Mass spectrometry coupled with gas and liquid chromatographs are powerful qualitative and quantitative analytical tools that are widely used to measure hormone concentrations. Technical advancements in mass spectrometry have resulted in the development

of matrix-assisted laser desorption and/or ionization and electrospray ionization techniques that allow the sequencing of peptides and mass determination of picomole quantities of analytes. Tandem mass spectrometry offers greater analytical sensitivity, accuracy, and speed, and may allow simultaneous determination of multiple hormones related to a clinical condition (see [Chapter 13](#)).

Specimen Requirements

To prevent preanalytical variation, appropriate protocols must be followed when sending samples to the laboratory for hormone measurement. Some hormones are directly affected by food (e.g., insulin) or by circadian variability (e.g., cortisol; see [Chapter 6](#)). In many clinical circumstances, the metabolic environment plays a crucial role in hormone production, and it is essential to obtain a simultaneous sample for measurement of both the hormone and the molecule(s)

regulated by that hormone. An isolated measurement of plasma insulin without concurrent knowledge of the plasma glucose, or measurement of PTH independent of serum calcium, is of little, if any, value. When a patient is evaluated for possible hormone deficiency or hormone excess, it is often necessary to perform a stimulation or suppression test, such as the Synacthen or ACTH test that is used to assess adrenal insufficiency. Most hormone assays can be performed on plasma or serum, and many can be performed on urine samples, usually a 24-hour collection. Increasingly, saliva has become a convenient body fluid for hormone analysis, particularly for hormones secreted in a diurnal rhythm (e.g., cortisol). Unlike blood sampling, which requires the patient to present to a blood drawing facility, patients can be provided with salivary collection material so they can provide specimens to the laboratory collected at multiple times during the day.

POINTS TO REMEMBER 1

- Hormones provide communication and regulation of activities between cells and tissues of the body.
- Hormones are a diverse group of lipid-based, amino acid–derived and polypeptide molecules.
- Hormones circulate in body fluids at variable levels and are predictive of health and disease.

POINTS TO REMEMBER 2

- Hormones bind and activate specific protein receptors at target cells.
- Hormone receptors are located both at the plasma membrane and in the cytoplasm of the cells.
- Hormones trigger complex intracellular signaling cascades to bring about cellular changes.

REVIEW QUESTIONS

1. Steroid hormones, by binding specific nuclear receptors, have a direct effect on:
 - a. enzyme phosphorylation.
 - b. gene expression.
 - c. cAMP formation.
 - d. DNA replication.
2. When a protein hormone binds a cell membrane receptor, the classical result is:
 - a. phosphorylation of intracellular enzymes.
 - b. inhibition of mRNA within the cell nucleus.
 - c. replication of DNA and division of the cell.
 - d. glycosylation of intracellular proteins.
3. An example of an amino acid–related hormone would be:
 - a. testosterone.
 - b. thyroid hormone.
 - c. growth hormone.
 - d. prostaglandin.
4. Which of the following hormones is classified as a polypeptide?
 - a. Cortisol
 - b. Estrogen
 - c. Adrenocorticotrophic hormone
 - d. Thyroid hormone
5. The type of hormone assay that best reflects hormone functionality as opposed to quantification of the hormone itself is the:
 - a. receptor-based assay.
 - b. mass spectrometry–based assays.
 - c. bioassay technique.
 - d. liquid chromatography.
6. A hormone released from the pancreas in response to a glucose load that is involved in cellular energy production is considered to be involved in:
 - a. modification of the response to stress.
 - b. synthesis of milk proteins.
 - c. promotion of bone development and growth
 - d. homeostatic control of metabolism.
7. Which of the following is a characteristic of steroid hormones?
 - a. Account for the majority of hormones
 - b. Circulate freely
 - c. Water soluble
 - d. Long half-life in the circulation

Catecholamines and Serotonin

Graeme Eisenhofer, Thomas Rosano, Ronald J. Whitley

OBJECTIVES

1. Define the following terms:
 - 5-HIAA
 - Carcinoid
 - Carcinoid syndrome
 - Catecholamine
 - Gastroenteropancreatic neuroendocrine tumor
 - Homovanillic acid
 - Metanephrine
 - Neuroblastoma
 - Normetanephrine
 - Paraganglioma
 - Pheochromocytoma
 - Serotonin
2. Discuss the following biogenic amines, including function and clinical relevance, synthesis, metabolism, and storage and release:
 - Norepinephrine
 - Epinephrine
 - Dopamine
 - Serotonin
 - Melatonin
3. List the clinically relevant metabolites of the biogenic amines as detailed in Objective 2 above.
4. State the clinical significance and function of the catecholamines and serotonin in each of the following systems:
 - Central nervous system
 - Sympathetic nervous system
 - Adrenal medullary system
 - Peripheral dopaminergic system
 - Enteric nervous system
5. Compare pheochromocytoma and neuroblastoma, including causes, symptoms, organ(s) and/or cell type involved, and laboratory evaluation of each; describe the clonidine suppression test and the results obtained when pheochromocytoma is present.
6. Explain the laboratory values obtained for serotonin and 5-HIAA in the assessment of a gastroenteropancreatic tumor and the carcinoid syndrome.
7. Describe the collection techniques used to obtain specimens for catecholamine, metanephrine, and serotonin analysis.
8. Describe how diet interferes with serotonin analysis; state how tricyclic antidepressants interfere in the measurement of catecholamines.
9. List the laboratory methods used to analyze metanephrines, catecholamines, serotonin, and 5-HIAA.
10. Analyze and solve case studies related to catecholamine and serotonin disorders using descriptions of symptoms and results of laboratory analyses.

KEY WORDS AND DEFINITIONS

Carcinoid syndrome A syndrome due to carcinoid tumors and characterized by attacks of severe cyanotic flushing of the skin—lasting from minutes to days—and by diarrheal watery stools, bronchoconstrictive attacks, sudden drops in blood pressure, edema, and ascites. Symptoms are caused by secretion from the tumor of serotonin, prostaglandins, and other biologically active substances.

Carcinoid tumor A yellow circumscribed tumor arising from enterochromaffin cells, usually in the small intestine, appendix, stomach, or colon, and less commonly in the bronchus; sometimes used alone to refer to the gastrointestinal tumor (also called argentaffinoma).

Catecholamine One of a group of biogenic amines having a sympathomimetic action; the aromatic portion of the

molecule is the catechol, and the aliphatic portion is an amine; examples include dopamine, norepinephrine, and epinephrine.

Catecholamine metabolites Products of catecholamine metabolism, such as dihydroxyphenylacetic acid, methoxytyramine, homovanillic acid, dihydroxyphenylglycol, methoxyhydroxyphenylglycol, normetanephrine, metanephrine, and vanillylmandelic acid.

Chromaffin cell Neuroendocrine cell derived from embryonic neural crest found in the medulla of the adrenal gland and in other ganglia of the sympathetic nervous system; so-named because of the presence of cytoplasmic granules that give a brownish reaction with chromium salts.

3,4-Dihydroxyphenylglycol (DHPG) The metabolite produced within the peripheral sympathetic or central nervous system noradrenergic nerves by deamination of norepinephrine (can also be formed from epinephrine); O-methylated to methoxyhydroxyphenylglycol in extraneuronal tissues.

L-Dopa An amino acid—3,4-dihydroxyphenylalanine—produced by oxidation of tyrosine by tyrosine hydroxylase; the precursor of dopamine and an intermediate product in the biosynthesis of norepinephrine, epinephrine. Can also be formed in melanocytes by the actions of tyrosinase as part of the production of melanin, the pigment in skin.

Dopamine A catecholamine formed in the body by the decarboxylation of dopa; an intermediate product in the synthesis of norepinephrine; acts as a neurotransmitter in the central nervous system and is produced peripherally in large amounts with autocrine/paracrine actions.

Epinephrine (adrenaline) A catecholamine hormone secreted by the adrenal medulla.

Gastroenteropancreatic neuroendocrine tumor (GEP-NET) Encompasses neuroendocrine tumors of the digestive system and pancreas but also covers neuroendocrine pulmonary tumors and includes carcinoids.

Homovanillic acid (HVA) A product of dopamine metabolism; elevated urinary concentrations are used to diagnose neuroblastoma.

5-Hydroxyindoleacetic acid (5-HIAA) A metabolite of serotonin (5-hydroxytryptamine) excreted in large amounts by patients with carcinoid tumors.

Metanephrine A catecholamine metabolite resulting from O-methylation of epinephrine; formed mainly within adrenal chromaffin cells; excreted mainly in the urine as a sulfate-conjugated metabolite; measurements of the free and conjugated metabolite with normetanephrine provide useful tests for the diagnosis of pheochromocytoma.

3-Methoxy-4-hydroxyphenylglycol (MHPG) A metabolite of epinephrine and norepinephrine formed primarily from the O-methylation of dihydroxyphenylglycol and in smaller amounts from the deamination of normetanephrine and metanephrine; found in brain,

blood, cerebrospinal fluid, and urine, where its concentrations can be used to measure catecholamine turnover.

Neuroblastoma A type of neural crest-derived tumor usually arising in the autonomic nervous system (sympathicoblastoma) or in the adrenal medulla that affects mostly infants and children up to 10 years of age.

Neuroendocrine tumors (NET) Neoplasms that arise from cells of the endocrine and peripheral nervous systems, most commonly in the digestive tract, but also found in the lung, pancreas, pituitary, thyroid, and other tissues. The tumors include gastroenteropancreatic neuroendocrine tumors, as well as paragangliomas, neuroblastomas, neuroectodermal tumors, medulloblastomas, retinoblastomas, and pineoblastomas. They usually contain secretory granules and often produce biogenic amines and polypeptides.

Norepinephrine (noradrenaline) A major neurotransmitter produced by some brain neurons and peripheral sympathetic nerves, which acts on α - and β_1 -adrenergic receptors; produced in the adrenal chromaffin cells as a precursor for epinephrine.

Normetanephrine An O-methylated metabolite of norepinephrine produced in extraneuronal cells and the adrenal medulla; excreted in the urine largely as a sulfate-conjugated metabolite; measurements of free and conjugated metabolites provide useful tests for diagnosis of pheochromocytoma.

Pheochromocytoma A usually benign, well-encapsulated, lobular, vascular tumor of chromaffin tissue of the adrenal medulla or sympathetic paraganglia.

Serotonin (5-hydroxytryptamine) A monoamine vasoconstrictor synthesized in the intestinal enterochromaffin cells or in central or peripheral neurons; found in high concentrations in many body tissues, including intestinal mucosa, pineal body, and central nervous system.

Vanillylmandelic acid (VMA) The main end-product of norepinephrine and epinephrine metabolism excreted in the urine; formed primarily in the liver from the oxidation of methoxyhydroxyphenylglycol.

Catecholamines and serotonin are biogenic amines that facilitate neuronal or hormonal signaling for a wide range of physiological processes. The naturally occurring catecholamines, **dopamine** and **norepinephrine (noradrenaline)**, function as neuromodulators in the brain. Norepinephrine also functions as a neuromodulator in peripheral sympathetic nerves that innervate tissues throughout the body. **Epinephrine (adrenaline)** functions as a hormone released by the adrenal medulla. Catecholamines are critical in maintaining the body's homeostasis and in responding to acute and chronic stress through the orchestration of cardiovascular,

metabolic, glandular, and visceral organ activities. **Serotonin (5-hydroxytryptamine)** serves as a neuromodulator in the brain and as a modulator of vascular and gastrointestinal functions in the periphery. Abnormal production of catecholamines or serotonin occurs in a number of neuroendocrine tumors, where clinical signs and symptoms reflect the pharmacological properties of the secreted amines. Clinical measurement of the biogenic amines or of their metabolites aids in tumor detection and monitoring, and analytical advances have produced sensitive and specific laboratory methods for clinical practice.

CHEMISTRY, BIOSYNTHESIS, RELEASE, AND METABOLISM

Chemistry

The **catecholamines**—dopamine, norepinephrine, and epinephrine—are phenylethylamines with hydroxyl groups on positions three and four of the benzene ring and an ethylamine sidechain

Fig. 26.1 Chemical structures of the catecholamines and serotonin.

on position one (Fig. 26.1). Hydroxyl and methyl substitutions on the ethylamine sidechain distinguish the individual catecholamines in terms of both structure and function. The catecholamines demonstrate varying degrees of alkaline instability in biological fluids, and their dihydroxybenzene or catechol structure is sensitive to oxidative formation of quinones in the presence of air and light. Serotonin with its indoleamine structure is distinct from the catecholamines but is an important naturally occurring biogenic amine. Melatonin is the principal indoleamine produced from serotonin by the pineal gland.

Biosynthesis

The rate-limiting step in catecholamine biosynthesis involves conversion of tyrosine to 3,4-dihydroxyphenylalanine (**L-dopa**) by the enzyme, tyrosine hydroxylase (Fig. 26.2). A related enzyme, tryptophan hydroxylase, catalyzes conversion of tryptophan to 5-hydroxytryptophan (5-HTP) in the first step of serotonin synthesis. Tissue sources of catecholamines are principally dependent on the presence of tyrosine hydroxylase, which is largely confined to dopaminergic and noradrenergic neurons of the central nervous system and to the sympathetic and adrenal medullary systems in peripheral tissues. Similarly, sources of serotonin are largely dependent on the presence of tryptophan hydroxylase in central nervous system serotonergic neurons, the

Fig. 26.2 Biosynthesis of catecholamines and serotonin, and metabolism of serotonin to melatonin.

pineal gland, and some peripheral endocrine tissue, particularly enterochromaffin cells of the digestive tract. Platelets also contain large amounts of serotonin derived from serotonin synthesized in enterochromaffin cells of the gastrointestinal tract.

Conversion of L-dopa to dopamine and 5-HTP to serotonin is catalyzed by aromatic-L-amino acid decarboxylase (see Fig. 26.2), an enzyme with a wide tissue distribution and broad substrate specificity for aromatic amino acids. The dopamine and serotonin formed in the cytoplasm by aromatic-L-amino acid decarboxylase are transported into vesicular secretory granules, where the amines are concentrated and stored ready for exocytotic release as the principal neuromodulators of central nervous system dopaminergic and serotonergic neurons. The dopamine formed in noradrenergic neurons and chromaffin cells is further converted to norepinephrine by dopamine β -hydroxylase, an enzyme specifically located in secretory granules. The additional presence of phenylethanolamine N-methyltransferase in adrenal medullary chromaffin cells leads to further conversion of norepinephrine to epinephrine.

Melatonin is synthesized from serotonin in the pineal gland by two highly specific enzymes; the first step is catalyzed by serotonin-N-acetyltransferase and the second by hydroxyindole-O-methyltransferase.

Storage and Release

Monoamines, stored in secretory granules, exist in a highly dynamic equilibrium with the surrounding cytoplasm, with passive outward leakage of monoamines into the cytoplasm counterbalanced by inward active transport under the control of vesicular monoamine transporters (Fig. 26.3). Monoamines share the acid environment of the secretory granule matrix with ATP, peptides, and proteins, the best known of which are the chromogranins. The chromogranins are common components of monoamine-containing secretory granules. Their widespread presence among endocrine tissues has led to their measurement in plasma as useful, albeit relatively nonspecific markers of neuroendocrine tumors.

Monoamines are released from secretory vesicles into the extracellular space through the process of exocytosis. Neuronal release may also occur by calcium-independent nonexocytotic processes involving an increased loss of monoamines from storage vesicles into the cytoplasm and the reversal of normal inward carrier-mediated transport to outward transport of monoamines into the extracellular environment. Examples of this process include the release of catecholamines induced by tyramine and amphetamine.

Uptake and Metabolism

Because the enzymes responsible for metabolism of catecholamines have intracellular locations, the primary mechanism limiting the duration of action of catecholamines in the extracellular space is uptake by active transport (see Fig. 26.3). Uptake is facilitated by neuronal or extraneuronal transporters. Neuronal monoamine transporters provide the principal mechanism for rapid termination of the signal in neuronal transmission, whereas transporters at extraneuronal locations are more important for limiting the spread of the signal and for clearing catecholamines from the bloodstream.

Of the norepinephrine released by sympathetic nerves, about 90% is removed back into nerves by neuronal uptake, 5% is removed by extraneuronal uptake, and 5% escapes these processes to enter the bloodstream. In contrast, of the epinephrine released directly into the bloodstream from the adrenals, about 90% is removed by extraneuronal monoamine uptake.

In addition to terminating the actions of released monoamines, plasma membrane monoamine transporters function in sequence with vesicular monoamine transporters to recycle catecholamines for rerelease (see Fig. 26.3). Thus, most of the norepinephrine released and recaptured by sympathetic nerves is sequestered back into secretory granules by vesicular monoamine transporters, thereby reducing the requirements for synthesis of new transmitter. Plasma membrane monoamine transporters also function as part of metabolizing systems, requiring the additional actions of enzymes for irreversible inactivation of the released amines.

Catecholamines undergo metabolism by multiple pathways (Fig. 26.4). Most metabolism occurs within the same cells in which catecholamines are synthesized and is dependent on the leakage of amines from secretory granules into the cytoplasm. In sympathetic nerves, the presence of monoamine oxidase (MAO) leads to conversion of norepinephrine to 3,4-dihydroxyphenylglycol (DHPG). This is then largely

Fig. 26.3 Schematic diagram illustrating the dynamics of synthesis, exocytotic release (*R*), neuronal reuptake (*NU*), extraneuronal uptake (*EU*), vesicular leakage (*VL*), vesicular sequestration (*VS*), and metabolism of norepinephrine (*NE*) in sympathetic nerve endings in relation to extraneuronal tissue and the bloodstream. Relative magnitudes of the various processes are reflected by the relative sizes of arrows. *COMT*, Catechol-O-methyltransferase; *DA*, dopamine; *DHPG*, 3,4-dihydroxyphenylglycol; *L-dopa*, 3,4-dihydroxyphenylalanine; *MAO*, monoamine oxidase; *MHPG*, 3-methoxy-4-hydroxyphenylglycol; *NMN*, normetanephrine; *TH*, tyrosine hydroxylase; *TYR*, tyrosine.

Fig. 26.4 Schematic diagram showing the main pathways for metabolism of the norepinephrine and epinephrine derived from sympatho-neuronal or adrenal medullary sources. Deamination in sympathetic nerves (white) is the major pathway of catecholamine metabolism and involves intraneuronal deamination of norepinephrine leaking from storage granules, or of norepinephrine recaptured after release by sympathetic nerves. Metabolism in adrenal chromaffin cells (black) involves *O*-methylation of catecholamines leaking from storage granules into the cytoplasm of adrenal medullary cells. The extraneuronal pathway (gray) is a relatively minor pathway of metabolism of catecholamines released from sympathetic nerves or the adrenal medulla, but it is important for further processing of metabolites produced in sympathetic nerves and adrenal chromaffin cells. The free metanephrines produced in extraneuronal tissues or adrenal chromaffin cells are further metabolized by deamination or sulfate conjugation. *ADH*, Alcohol dehydrogenase; *COMT*, catechol-*O*-methyltransferase; *DHPG*, 3,4-dihydroxyphenylglycol; *E*, epinephrine; *MAO*, monoamine oxidase; *MHPG*, 3-methoxy-4-hydroxyphenylglycol; *MHPG-SO₄*, 3-methoxy-4-hydroxyphenylglycol sulfate; *MN*, metanephrine; *MN-SO₄*, metanephrine-sulfate; *NE*, norepinephrine; *NMN*, normetanephrine; *NMN-SO₄*, normetanephrine-sulfate; *SULT1A3*, phenolsulfotransferase type 1A3; *VMA*, vanillylmandelic acid.

metabolized by catechol-*O*-methyltransferase (*COMT*) in extraneuronal tissues to **3-methoxy-4-hydroxyphenylglycol (MHPG)**. **Vanillylmandelic acid (VMA)**, the primary end-product of norepinephrine and epinephrine metabolism, is produced almost exclusively in the liver. This process is dependent on the hepatic localization of alcohol dehydrogenase, an enzyme required for the conversion of MHPG to VMA.

In adrenal chromaffin cells, the additional presence of *COMT* leads to the metabolism of norepinephrine to **normetanephrine** and of epinephrine to **metanephrine** (see Fig. 26.4).

Because the intraneuronal deamination pathway far predominates over the extraneuronal *O*-methylation pathway, normetanephrine and metanephrine represent relatively minor products of catecholamine metabolism. As a consequence, the adrenal medulla represents the single largest tissue source of normetanephrine and metanephrine, accounting for 24% to 40% of the former and more than 90% of the latter. The metanephrine and normetanephrine produced in the adrenal medulla or in extraneuronal tissues—the former from catecholamines leaking from secretory granules and the latter from catecholamines released from sympathoadrenal sources—may be deaminated to MHPG and then converted to VMA in the liver or may be sulfate-conjugated by a sulfotransferase enzyme expressed mainly in the gastrointestinal tissues.

Serotonin is not a substrate for *COMT*; it follows simpler pathways of metabolism than those for catecholamines. Serotonin is deaminated to **5-hydroxyindoleacetic acid (5-HIAA)**, the major urinary excretion product of serotonin metabolism.

PHYSIOLOGY OF CATECHOLAMINE AND SEROTONIN SYSTEMS

Catecholamines and serotonin regulate physiological events at the cellular level through interaction with α - and β -adrenergic receptors. Dopamine transmits signals primarily by interaction with a large family of dopamine receptors. The major physiological effects of catecholamines and serotonin are explained in part by the diverse receptor interactions that occur in function-specific locations throughout the vasculature and organ systems of the body.

Central Nervous System

Norepinephrine, dopamine, and serotonin are produced primarily in regions of the brainstem by neurons with projections to other areas of the brain or spinal cord. The norepinephrine-producing neurons of the brainstem participate in regulating the activity of the sympathetic nervous system and the overall state of attention and vigilance.

Dopamine produced in dopaminergic neurons has functions, and shows distributions that are notably different from those of norepinephrine. Dopamine in the brain influences reward-seeking behavior and is important for the initiation and maintenance of movement. Disturbances in dopamine production and release in the brain are therefore involved in drug-dependency states and are central to the movement disorder that characterizes Parkinson disease. Dopamine neurotransmission is also involved in processing sensory signals and in regulating hormonal release. Dopaminergic neurons in the retina and olfactory bulb have ultrashort projections that transmit signals within these neuronal centers for vision and smell. Dopamine neurons in the hypothalamus have regulatory influences on the release of several hormones of the pituitary gland.

Serotonin, like norepinephrine, is produced by small clusters of neurons in the brainstem regions. It serves a diverse range of behavioral and physiological functions including memory, learning, feeding behavior, sleep patterns, thermoregulation, pain modulation, cardiovascular function, and hypothalamic regulation of pituitary hormones.

Fig. 26.5 Schematic diagram of sympathetic division of the autonomic nervous system. Preganglionic cholinergic fibers (*solid lines*) from the spinal cord project to the paravertebral sympathetic chain, visceral peripheral ganglia, and the adrenal medulla, whereas postganglionic noradrenergic fibers (*dashed lines*) project from sympathetic ganglia to sympathetically innervated target organs. About 5% to 10% of the norepinephrine released from sympathetic nerves innervating target organs escapes neuronal and extraneuronal uptake to enter the bloodstream. This contrasts with epinephrine, which functions as a circulating hormone and is released directly from the adrenal medulla into the bloodstream. Most of the catecholamines entering the bloodstream are removed by extraneuronal uptake processes and are metabolized (e.g., in the liver), so that only small proportions are excreted in the urine.

Sympathetic Nervous System

Sympathetic nerve transmission operates below the level of consciousness in controlling the physiological function of many organs and tissues of the body (Fig. 26.5). The sympathetic nervous system plays a particularly important role in regulating cardiovascular function in response to postural,

exertional, thermal, and mental stress. With sympathetic activation, heart rate is increased, peripheral arterioles are constricted, skeletal arterioles are dilated, and blood pressure is elevated. Sympathetic signals work in balance with the parasympathetic portion of the autonomic nervous system to maintain a stable internal environment.

Efferent or outgoing signals from the central nervous system are transmitted by preganglionic cholinergic sympathetic neurons that exit the spinal cord and converge on sympathetic ganglia along the spinal column or in visceral ganglia (see Fig. 26.5). The terminal branches of the postganglionic fibers that project from these ganglia into target organs have varicosities that form a rich ground plexus for synaptic contact with a large number of effector cells in target tissues. Most sympathetic postganglionic nerves liberate norepinephrine as their neurotransmitter. In limited locations, sympathetic nerve endings release acetylcholine. Sympathetic fibers that release acetylcholine innervate sweat glands and the adrenal medulla, the latter stimulating the release of epinephrine from chromaffin cells.

Plasma and urinary norepinephrine are derived primarily from postganglionic sympathetic neurons with little contribution from the central nervous system or from hormonal release by the adrenal medulla. Because of intervening neuronal and extraneuronal removal processes, the amount of norepinephrine that escapes into the bloodstream represents less than 10% of the total norepinephrine released by sympathetic nerves. Alterations in release and plasma concentrations of norepinephrine occur in response to stimuli such as exercise, overeating, low salt intake, upright position, mental stress all of which increase sympathetic outflow. Increased plasma concentrations of norepinephrine also occur with aging and are found in disorders such as cardiac failure, hypertension, and depression.

Adrenal Medullary System

The human adrenal glands overlie the superior poles of the kidneys. Each gland consists of an outer cortex and a thin inner central medulla containing chromaffin cells. A characteristic feature of adrenal medullary chromaffin cells is the presence of numerous catecholamine storage granules. These granules turn brown when exposed to potassium bichromate solutions, ammoniacal silver nitrate, or osmium tetroxide because of the oxidation and polymerization of epinephrine and norepinephrine. This process is known as the *chromaffin reaction*, hence the terms *chromaffin cells* and *chromaffin granules*.

Although often considered a part of the sympathetic nervous system, the adrenal medulla produces and secretes epinephrine with different functions from the norepinephrine secreted by sympathetic nerves. The adrenal medulla and the sympathetic nerves are regulated separately, often in divergent directions in response to different forms of stress. Epinephrine is secreted from adrenal chromaffin cells directly into the bloodstream to act on cells distant from sites of release. Epinephrine and norepinephrine have overlapping but different potencies of effect on α - and β -adrenoceptors. The proximity of sites of norepinephrine and epinephrine release to adrenoceptors determines differences in adrenoceptor-mediated responses to the two catecholamines. Because of the above factors, epinephrine exerts its effects on different populations of adrenoceptors than those affected by norepinephrine. Epinephrine released from the adrenal glands is more important as a metabolic hormone than as a hemodynamic regulatory hormone. In particular, epinephrine stimulates

Fig. 26.6 Schematic representation of the main sources of dopamine and the principal metabolites of dopamine in plasma and urine. The brain makes a relatively minor contribution, whereas dopamine synthesized in the gastrointestinal tract or derived from the diet contributes substantially to dopamine metabolites in the bloodstream and urine. This contrasts with the free dopamine excreted in urine, which is derived almost entirely from renal extraction of circulating L-dihydroxyphenylalanine and local decarboxylation to dopamine by L-aromatic amino acid decarboxylase. AADC, Aromatic acid decarboxylase; DA, dopamine; DA-SO₄, dopamine-sulfate; DOPAC, dihydroxyphenylacetic acid; GI, gastrointestinal; HVA, homovanillic acid; L-dopa, L-dihydroxyphenylalanine; MTY, 3-methoxytyramine; MTY-SO₄, 3-methoxytyramine-sulfate.

lipolysis, ketogenesis, thermogenesis, and glycolysis, and raises plasma glucose by stimulating glycogenolysis and gluconeogenesis. Epinephrine also has potent effects on pulmonary function, causing dilation of airways.

Peripheral Dopaminergic System

Dopamine is usually thought of as a neuromodulator in the brain or as an intermediate in the production of norepinephrine and epinephrine in peripheral tissues. However, the contribution of the brain to plasma concentrations and urinary excretion of dopamine metabolites is relatively minor, and dopamine produced in the sympathetic nerves and the adrenal medulla is mainly converted to norepinephrine. Most circulating and urinary dopamine and dopamine metabolites are therefore derived from other sources (Fig. 26.6).

In the kidneys, dopamine functions as an autocrine or paracrine effector substance contributing to the regulation of sodium excretion. Unlike neuronal catecholamine systems, the production of dopamine in the kidneys is largely independent of local synthesis of L-dopa by tyrosine hydroxylase. Production of dopamine in the kidneys depends mainly on uptake of L-dopa from the circulation and conversion to dopamine by aromatic amino acid decarboxylase (see Fig. 26.6). Thus, most of the free dopamine excreted in urine derives from renal uptake and decarboxylation of circulating L-dopa.

Although the kidneys represent the major source of urinary free dopamine, this source does not account for the much larger quantities of excreted dopamine metabolites, such as *homovanillic acid* (HVA) and dopamine sulfate. Substantial proportions of these metabolites are produced in the gastrointestinal tract, where dopamine appears to function as an enteric neuromodulator or as a paracrine or autocrine substance. However, unlike in the kidneys, where dopamine is produced mainly from circulating L-dopa, in the gastrointestinal tract, production of dopamine requires the presence of tyrosine hydroxylase or other sources of L-dopa.

Consumption of food increases plasma concentrations of L-dopa, dopamine, and dopamine metabolites, particularly dopamine sulfate, indicating that dietary constituents may represent an important source of peripheral dopamine (see Fig. 26.6). It is now clear that dopamine sulfate is produced mainly in the gastrointestinal tract from both dietary and locally synthesized dopamine. This is consistent with findings that the gastrointestinal tract contains high concentrations of the specific sulfotransferase enzyme responsible for sulfate conjugation of catecholamines and **catecholamine metabolites**.

Enteric Nervous System

The enteric nervous system (ENS) is an independent and integrated system of neurons and supporting cells located in the gastrointestinal tract, gallbladder, and pancreas. The ENS is composed of the myenteric plexus and the submucous plexus. Both are embedded in the wall of the gut and extend from the esophagus to the anus, and contain more than 100 million sensory neurons, interneurons, and motor neurons. This network senses the environment within the lumen, regulates local blood flow, and controls epithelial cell secretion.

The ENS is connected to the central nervous system by extrinsic parasympathetic and sympathetic motor neurons, and by spinal and vagal sensory neurons. Through these bidirectional connections, the ENS is monitored and modified. Despite the presence of these extrinsic nerve connections, the ENS functions autonomously in some intestinal regions. Neural transmission within the ENS is controlled by a large variety of neuromodulatory amines and peptides, such as serotonin, norepinephrine, acetylcholine, ATP, and nitric oxide. Serotonin acts as a local paracrine molecule, participating in mucosal sensory transduction. More than 95% of the body's serotonin is produced within the gastrointestinal tract, and most is synthesized and stored in enterochromaffin cells in the gut mucosa. Intrinsic sensory neurons activated by serotonin stimulate peristaltic reflex and secretion, whereas extrinsic sensory neurons initiate bowel sensations such as nausea, vomiting, abdominal pain, and bloating. The paracrine actions of serotonin are terminated by uptake into epithelial cells by the same serotonin transporter used in serotonergic neurons.

Clinical Applications

Measurements of catecholamines, serotonin, and their metabolites are commonly used in studies of physiological function and disease processes, but clinical laboratory measurements of the amines and their metabolites are directed primarily at the diagnosis of neuroendocrine tumors. Catecholamine-producing neuroendocrine tumors include pheochromocytomas, paragangliomas, and neuroblastomas, whereas serotonin-producing tumors are typically carcinoids.

Pheochromocytoma and Paraganglioma

Catecholamine-producing tumors that derive from chromaffin cells of the adrenal glands are referred to as **pheochromocytomas**, whereas extraadrenal tumors are termed *paragangliomas* or *extraadrenal pheochromocytomas*. Pheochromocytomas are rare, with an annual detection rate of 2 to 5 per million. Autopsy studies, indicating the prevalence of 0.05% to 0.1%, suggest that most of the tumors remain undetected and contribute to premature death.

The presence of a pheochromocytoma is usually suspected because of signs and symptoms that reflect the biological effects of catecholamines released by the tumor. Hypertension, the most common sign, can be sustained or paroxysmal. Symptoms include headache, palpitations, diaphoresis (excessive sweating), pallor, nausea, attacks of anxiety, and generalized weakness. Among patients tested because of such signs and symptoms, the pretest prevalence of tumors is low—usually less than 1%.

Patients with a higher risk for pheochromocytoma include those with a hereditary predisposition to the tumor, a previous history of the tumor, or the incidental finding of an adrenal mass during routine abdominal imaging. See the box “Points to Remember: Pheochromocytoma and Paraganglioma” for a summary of the key points of pheochromocytomas.

POINTS TO REMEMBER: PHEOCHROMOCYTOMA AND PARAGANGLIOMA

Biology

- Pheochromocytomas are tumors of mainly adrenal chromaffin cells that produce, store, metabolize, and secrete catecholamines, usually with a predominance of norepinephrine over epinephrine.
- Paragangliomas, developing from extra-adrenal sympathetic chromaffin tissue, usually produce near exclusively norepinephrine and very rarely predominantly dopamine.

Presentation

- Tumor is usually suspected because of signs and symptoms of catecholamine excess (e.g., hypertension, palpitations, headaches, excessive sweatiness) or the incidental finding of an adrenal mass during routine imaging procedures for unrelated medical conditions.
- Most pheochromocytomas are benign; 15% of adrenal tumors and 35% of extra-adrenal tumors are malignant.
- At least 30% of pheochromocytomas have a hereditary basis, resulting from mutations of at least 15 genes identified to date.

Continued

POINTS TO REMEMBER: PHEOCHROMOCYTOMA AND PARAGANGLIOMA—cont'd

- Less than 1% of patients tested because of signs and symptoms have the tumor (low pretest prevalence), but the prevalence is higher among patients with identified mutations of disease-causing genes or those with an incidental adrenal mass; thus testing in these patients is recommended independently of the presence of signs and symptoms.

Biochemical Diagnosis

- Biochemical diagnosis is based on evidence of excess production of catecholamines, which is best determined from measurements of metanephrines in urine or plasma.
- Because secretion of catecholamines by tumors is episodic, but metabolism to metanephrines within tumors is continuous, measurements of plasma or urinary fractionated metanephrines provide more reliable diagnostic tests for the tumor than measurements of catecholamines (metanephrines increased in >97% and catecholamines in 69% to 92% of patients with pheochromocytomas).

The biochemical diagnosis of pheochromocytoma focuses on measurements of metanephrines rather than their precursor catecholamines. Normally, most norepinephrine is metabolized by deamination within sympathetic nerves, so that *O*-methylation represents a minor pathway of catecholamine metabolism. In patients with pheochromocytoma, intratumoral *O*-methylation becomes a dominant pathway of catecholamine metabolism. Consequently, the presence of the tumor leads to relatively large increases in the production of *O*-methylated metabolites, compared with minor increases in deaminated metabolites. The metanephrines are produced continuously as a result of ongoing leakage of catecholamines from chromaffin granule stores into the cell cytoplasm; in contrast, catecholamines are often released episodically or in relatively low quantities compared with metanephrines.

The particularly high diagnostic sensitivity of plasma metanephrines has now been confirmed by numerous independent studies, leading to guidelines that recommend measurements of either plasma or urinary fractionated metanephrines during the initial work-up of a patient with a suspected pheochromocytoma. Negative results of these tests virtually exclude a pheochromocytoma. Exceptions include small (<1 cm) tumors encountered during routine screening and tumors that do not synthesize norepinephrine and epinephrine. Among the latter, tumors that produce only dopamine may be detected by measurements of plasma methoxytyramine, the *O*-methylated metabolite of dopamine. Measurements of plasma dopamine are also useful, whereas urinary dopamine and methoxytyramine provide relatively insensitive and nonspecific tests for the detection of a dopamine-producing tumor (see Fig. 26.6).

Plasma or urinary fractionated metanephrines are usually elevated sufficiently to conclusively establish the presence of most cases of pheochromocytoma. However, in about

20% of patients with the tumor, increases are smaller. Such true-positive results are difficult to distinguish from the larger proportion of false-positive results due to inappropriate sampling conditions (e.g., blood sampling without a preceding 30-minute period of supine rest), medications such as tricyclic antidepressants, or clinical conditions that increase sympathetic outflow. Additional biochemical testing is then necessary.

When biochemical testing continues to yield equivocal results, the clonidine suppression test may be useful for further confirming or excluding a pheochromocytoma. Originally, this test was designed to distinguish increased plasma catecholamines due to pheochromocytoma or sympathetic activation. By activating α_2 -adrenoceptors in the brain and on sympathetic nerve endings, clonidine suppresses norepinephrine release by sympathetic nerves. Decreases in elevated plasma norepinephrine after clonidine therefore suggest sympathetic activation, whereas a lack of decrease suggests a pheochromocytoma. The test has subsequently been shown to be useful for distinguishing increases in plasma normetanephrine due to a pheochromocytoma from those due to sympathetic activation.

Most pheochromocytomas are sporadic, but as many as 30% to 40% have a hereditary basis. Hereditary forms of the tumor result from mutations of at least 15 disease-causing genes identified to date. Pheochromocytomas occur at a relatively low prevalence in about 2% of patients with neurofibromatosis type 1 (NF1). Risk for most of the other known hereditary conditions is higher. Pheochromocytomas in multiple endocrine neoplasia type 2 (MEN 2) result from mutations of the *ret* proto-oncogene, which also predisposes to medullary thyroid cancer. In von Hippel-Lindau syndrome (VHL), family-specific mutations of the VHL tumor suppressor gene determine the varied clinical presentation of tumors, which, in addition to pheochromocytomas and paragangliomas, include retinal angiomas, central nervous system hemangioblastomas, and tumors in the kidneys, pancreas, and testis. Familial paragangliomas and pheochromocytomas may occur secondary to mutations of genes for four subunits of succinate dehydrogenase (*SDHA*, *SDHB*, *SDHC*, and *SDHD*). Mutations of genes encoding the SDH complex assembly factor 2 (*SDHAF2*), transmembrane protein 127 (*TMEM127*), MYC-associated factor X (*MAX*) fumarate hydratase and malate dehydrogenase 2 represent other tumor-susceptibility genes.

Mutations of the different tumor susceptibility genes have been found to give rise to distinct catecholamine metabolite profiles (Fig. 26.7). Tumors in patients with MEN 2 and NF1 are almost always confined to the adrenals and are characterized by increases in plasma-free metanephrine, indicating epinephrine production. In contrast, tumors in patients with *VHL*, *SDHD*, and *SDHB* mutations, including those at adrenal locations, are characterized by increases in plasma or urinary normetanephrine without increases in metanephrine. Increases in methoxytyramine, the metabolite of dopamine, are additionally present in up to 70% of patients with mutations of *SDHD* and *SDHB* genes. In some patients, methoxytyramine represents the only metabolite increased.

Fig. 26.7 Catecholamine biochemical phenotypes among patients with mutations of *RET*, *NF1*, *TMEM127*, *VHL* and *SDHB*, *SDHD*, *SDHC* and *SDHA* (*SDHX*) genes as reflected by patterns of increases in plasma normetanephrine (*NMN*), metanephrine (*MN*) and methoxytyramine (*MTY*) and in relation to tumor location, phenotypic maturity, and malignant risk. (From Eisenhofer, G., & Peitzsch, M. [2014]. Laboratory evaluation of pheochromocytoma and paraganglioma. *Clinical Chemistry*, 60, 1486–1499. Reproduced with permission from the American Association for Clinical Chemistry.)

The distinct mutation-dependent biochemical profiles can be useful for stratifying patients for genetic testing. For mutations that confer a high risk of disease, such screening is generally recommended at yearly intervals and should include biochemical testing for evidence of excess catecholamine production, individualized according to the expected biochemical profile of the tumor.

Although most often benign, about 10% of pheochromocytomas and 35% of paragangliomas eventually metastasize. The risk of malignancy is particularly high in patients with *SDHB* mutations. Tumors in such patients typically produce low quantities of catecholamines and are much larger at diagnosis than tumors in other patients. This fact, along with their typically extra-adrenal location, explains their higher predisposition to malignancy. Measurements of plasma methoxytyramine appear to serve as a promising biomarker for identifying metastatic pheochromocytoma. Diagnosis of malignant pheochromocytoma on the basis of histopathological features is not possible and instead requires evidence of metastatic lesions in liver, lungs, bones, lymph nodes, or other sites where chromaffin cells normally do occur. All patients with a previous history of tumor are at risk of recurrent or metastatic disease and should undergo periodic tumor screening.

Neuroblastoma

Neuroblastomas are neoplasms that derive from primordial neural crest cells of the sympathetic nervous system. Neuroblastomas are almost exclusively a pediatric cancer,

accounting for approximately 7% of all childhood neoplasms; they are the most common malignancies in the first year of life. The incidence of neuroblastoma is approximately 10 cases per million children. The vast majority of neuroblastomas develop sporadically. Activating mutations in the tyrosine kinase domain of the anaplastic lymphoma kinase oncogene account for most cases of hereditary neuroblastoma and may occur as somatic mutations in 5% to 15% of sporadic cases. Mutations of paired-like homeobox 2b (*PHOX2B*), also known as *neuroblastoma Phox* (*NBPhox*), account for other cases of hereditary neuroblastoma.

Most neuroblastomas are intra-abdominal, arising in the adrenal gland or in the upper abdomen. Less frequent locations include chest, neck, and pelvis. About 60% are extra-adrenal. Metastases in disseminated neuroblastomas may involve bone marrow, bone, lymph nodes, liver, and, less frequently, skin, testis, and intracranial structures.

The biological behavior of a neuroblastoma varies from regression or maturation to an aggressive course with an unfavorable outcome. Neuroblastomas are most notable for a subset of cases with complete regression or maturation to ganglioneuroma, a benign neoplasm. However, most clinically diagnosed tumors are aggressive and have an unfavorable outcome. This highly variable clinical outcome underlies the need for diagnostic markers to stratify patients for therapeutic intervention. The patient's age at diagnosis serves as a primary criterion for stratification; infants younger than 18 months have a more favorable outcome than older children. Unfortunately, the overall incidence of metastatic neuroblastoma at the time of diagnosis is approximately 60%, and the need for earlier detection of children with the progressive disseminating tumor remains a diagnostic challenge. See the box "Points to Remember: Neuroblastoma" for a summary of the key points of neuroblastomas.

POINTS TO REMEMBER: NEUROBLASTOMA

Biology

- Tumors that occur almost exclusively in children, which develop from primitive neural crest cells of the sympathoadrenal system, with about 60% derived from extra-adrenal sympathetic tissue and 40% from the adrenals.
- Biological behavior of tumors is highly variable, with some tumors spontaneously regressing but most (60%) having an aggressive course with disseminated malignant disease and an unfavorable outcome.

Presentation

- Neuroblastomas produce variable amounts of dopamine and norepinephrine but show a poor capacity for storage and release of catecholamines. Consequently, the tumors rarely produce signs and symptoms of catecholamine excess.
- Suspicion of disease is usually based on palpation of a mass, space-occupying complications of the tumor, or effects of bone marrow involvement.
- Hereditary causes of neuroblastomas are rare; most neuroblastomas occur sporadically.

Continued

POINTS TO REMEMBER: NEUROBLASTOMA—cont'd

Biochemical Diagnosis

- Biochemical diagnosis is based on overproduction of dopamine and norepinephrine, but because the tumors have poorly developed machinery for catecholamine storage and release, diagnosis depends mainly on measurements of catecholamine metabolites.
- Measurements of urinary vanillylmandelic acid and homovanillic acid represent the most widely used tests, but in a large prospective screening study they were shown to detect only 73% of tumors.

Hypertension and signs and symptoms of catecholamine excess are uncommon in neuroblastoma due to intracellular metabolism and release of mainly inactive metabolites. Patients commonly present with a tumor mass and clinical signs from compression effects on neighboring structures or hematological abnormalities from bone marrow involvement.

Laboratory evidence of a functional catecholamine-producing tumor is important in the clinical evaluation when a neuroblastoma is suspected. Neuroblastoma tumor cells have the capacity to synthesize dopamine and norepinephrine, but lack phenylethanolamine *N*-methyltransferase and consequently do not produce epinephrine. Because of the variability in catecholamine production and metabolism, no single reliable marker of catecholamine overproduction has been identified. Combinations of catecholamines and metabolites are therefore often measured in the diagnostic evaluation of neuroblastoma.

HVA and VMA, produced from dopamine and norepinephrine, respectively, are most widely used for the diagnosis of neuroblastoma. Results are expressed as the ratio of catecholamine metabolites to creatinine excretion in random urine specimens with a reported clinical sensitivity of around 90%. However, diagnostic sensitivity of these measurements in screening programs has been particularly limited (73%) and appears to miss patients with aggressive disease diagnosed at a later age. Consequently, screening programs have been generally unsuccessful in reducing the rate of metastatic neuroblastoma.

Additional markers, such as plasma dopamine and L-dopa, may have clinical value and allow the alternate use of plasma. The measurement of *O*-methylated metabolites, such as normetanephrine and methoxytyramine, may offer additional methods for the diagnosis of neuroblastoma.

Some evidence suggests that the pattern of catecholamine metabolism is associated with important biological and genetic prognostic factors in neuroblastoma. Immature metabolic patterns in neuroblastoma tumor tissue are based on higher excretion of dopamine or HVA relative to norepinephrine or VMA. The immature metabolic pattern is suggested to be associated with aggressive tumor behavior and other unfavorable prognostic factors, but the clinical application of such metabolic patterns has not been established.

Finally, clinical specificity in detecting neuroblastoma with catecholamine and metabolite measurements may be

influenced by the choice of laboratory methods, dietary interference, and other catecholamine overproduction conditions. Significant advances in the analytical specificity of laboratory methods have reduced many of the exogenous sources of interference. Histopathology remains the ultimate diagnostic criterion for diagnosis and distinguishing neuroblastoma from pheochromocytoma or other catecholamine-producing neurogenic tumors, such as ganglioneuroma and ganglioneuroblastoma.

Gastroenteropancreatic Neuroendocrine and Carcinoid Tumors

Gastroenteropancreatic neuroendocrine tumors (GEP-NET), including **carcinoid tumors**, are derived from a variety of neuroendocrine cell types, in particular, enterochromaffin cells. These tumors are widely distributed in the body and are highly heterogeneous in their clinical presentation. The usual carcinoid tumor is solid and yellow-tan in appearance. Tumor cells exhibit a monotonous morphology, with pink granular cytoplasm and round nuclei with infrequent mitoses. Most of these neuroendocrine tumors are recognized by their reactions to silver stains and to neuroendocrine cell markers, such as chromogranin and neuron-specific enolase.

The tumors are traditionally classified according to their presumed origin from the embryonic foregut (bronchus, lung, stomach, duodenum, and pancreas), midgut (ileum, jejunum, appendix, and proximal colon), or hindgut (rectum and distal colon). The most common sites for these tumors are bronchus or lung—33%, ileum or jejunum—20%, rectum—10%, and appendix—8%. The annual detection rate of clinically significant GEP-NET has been estimated at 2.5 to 5 cases per 100,000 persons but has been steadily increasing, presumably as a result of improved recognition. These tumors may develop in all age groups but appear most frequently in adults; a mean age of 63 has been reported for tumors of the small intestine and respiratory tract. Clinically, most patients are asymptomatic until metastases are present. Bowel obstruction and abdominal pain are the most frequent presenting symptoms.

GEP-NET tumors show aggressive malignant behavior depending on the origin, the depth of penetration, and the size of the primary tumor. Most rectal carcinoids are found incidentally at endoscopy. They are often smaller than 1 cm and have a low rate of metastasis, even though they may show extensive local spread. Carcinoids of the appendix are seen in about 1 in every 300 appendectomies. Almost all measure less than 1 cm, and distant metastasis is rare. By contrast, 90% of intestinal neuroendocrine tumors that penetrate halfway through the muscle wall will have spread to lymph nodes and distant sites at the time of diagnosis. More than 70% of these tumors, 1 to 2 cm in diameter, metastasize to the liver. Fortunately, most grow slowly, and patients may live for many years. See the box “Points to Remember: Gastroenteropancreatic and Carcinoid Tumors” for a summary of the key points of carcinoid and GEP-NET.

POINTS TO REMEMBER: GASTROENTERO-PANCREATIC AND CARCINOID TUMORS

Biology

- Neuroendocrine tumors derived from enterochromaffin cells of the gastrointestinal and respiratory tracts.
- Usually develop as small tumors (<2 cm) with slow growth but with the propensity to metastasize.
- Synthesize, store, and release a variety of peptide hormones and biogenic amines, including serotonin.

Presentation

- Bowel obstruction and abdominal pain.
- Symptoms related to secretion of vasoactive amines and peptides resulting in carcinoid syndrome (flushing, diarrhea, bronchoconstriction, and right-sided heart failure); relatively uncommon and usually occurring only after the development of metastases.

Biochemical Diagnosis

- Biochemical diagnosis of carcinoids depends mainly on measurements of serotonin, serotonin metabolites (5-hydroxyindoleacetic acid), and the serotonin precursor (5-hydroxytryptophan) in urine, plasma, whole blood, and platelets.
- False-positive results are a common problem resulting from dietary influences.

As with normal gut endocrine cells, GEP-NET synthesize, store, and release a variety of hormones and biogenic amines. One of the best characterized of these substances in **carcinoid syndrome** is serotonin. These tumors also produce and secrete other biologically active substances, including histamine, kallikrein, bradykinins, tachykinins, prostaglandins, dopamine, norepinephrine, and peptide hormones. Production of these substances varies in relation to the tissue origin of the tumor. Midgut neuroendocrine tumors release large quantities of serotonin, whereas tumors derived from the foregut secrete primarily 5-HTP (a serotonin precursor) and histamine, rather than serotonin. Primary hindgut NET usually show no secretory activity. Pancreatic NET are capable of producing gastrin, insulin, glucagon, and vasoactive intestinal peptide (VIP).

Secretion of vasoactive substances into the systemic circulation plays an important role in the development of carcinoid syndrome. The fully developed syndrome associated with humoral manifestations of these tumors is striking but uncommon, usually occurring only after metastasis to the liver and the release of these substances directly into the systemic circulation. The classic clinical presentation of the carcinoid syndrome includes pronounced flushing (especially on the face and neck), diarrhea, and bronchoconstriction, and eventual right-sided valvular heart failure. Overproduction of serotonin is found in 90% to 100% of patients with the carcinoid syndrome and is thought to be responsible for diarrhea through its known effects on gut motility and fluid secretion.

Clinical laboratory evaluation of the carcinoid syndrome relies on measurements of serotonin and its metabolites in

body fluids and tissue. In patients with the typical carcinoid syndrome, 5-HTP is converted to serotonin and is stored in tumor secretory granules and in platelets. A small amount of serotonin remains in plasma, but most is converted to 5-HIAA, which is excreted in urine. These patients have increased blood and platelet serotonin concentrations and increased urinary 5-HIAA excretion. However, some foregut NET lack aromatic L-amino acid decarboxylase and secrete 5-HTP rather than serotonin into the bloodstream. Patients with these tumors have normal serotonin concentrations in blood and in platelets, but urinary amounts are increased because 5-HTP is converted to serotonin in the kidney; urinary 5-HIAA may be slightly elevated.

Patients with serotonin-producing carcinoid tumors usually have striking increases in urinary 5-HIAA excretion (at least tenfold), but occasionally elevations are smaller. False-positive elevations have been known to occur if the patient ingests a wide range of serotonin-rich foods or medications. Conversely, alcohol, aspirin, and other drugs suppress 5-HIAA concentrations. Patients should avoid these agents during 24-hour urine collections. Fasting plasma 5-HIAA has been proposed as a convenient replacement for urine collections.

Most physicians rely on the measurement of 5-HIAA to diagnose carcinoid syndrome. But when a patient who is strongly suspected for carcinoid syndrome shows normal or borderline increases in urinary 5-HIAA, the documentation of elevated serotonin concentrations in whole blood or platelets may help establish the diagnosis. Platelet serotonin has been reported to be more sensitive than urinary 5-HIAA for detecting carcinoids that produce small or moderate amounts of serotonin, such as foregut and hindgut carcinoids, and midgut carcinoids with low tumor volume. Also, platelet serotonin concentrations are not affected by the patient's diet. However, platelets can be saturated at high serotonin secretion rates, and 5-HIAA is often preferred for monitoring high serotonin production. Measurements of chromogranin A provide an important complement to measurements of serotonin and 5-HIAA and are particularly useful for many GEP-NET that do not produce appreciable amounts of serotonin.

Preanalytical and Analytical Considerations

In clinical practice, laboratory determinations of catecholamines, serotonin, and their metabolites in biological fluids are performed primarily for the diagnosis and follow-up of patients with catecholamine- or serotonin-producing tumors. In accordance with guidelines, most laboratories now offer measurements of urinary or plasma metanephrines (normetanephrine and metanephrine) as primary tests for the diagnosis of pheochromocytoma and paraganglioma. Liquid chromatography with tandem mass spectrometry (LC-MS/MS) has increasingly become the method of choice for these measurements (Fig. 26.8). Measurements of catecholamines, usually in urine and less frequently in plasma, are also employed at some medical centers as secondary tests. Measurements of urinary VMA have shown declining importance. For the detection of neuroblastoma, urinary HVA and VMA remain the most

Fig. 26.8 Chromatograms obtained by liquid chromatography with tandem mass spectrometry for simultaneous measurement of urinary catecholamines and their free *O*-methylated derivatives for a calibrator (A) and extracted urine samples of two patients (B). Chromatographic peaks are shown for norepinephrine (1), epinephrine (2), normetanephrine (3), dopamine (4), metanephrine (5), and 3-methoxytyramine (6), with respective concentrations in the calibrator (A) of 59.1, 54.6, 54.6, 65.3, 50.7, and 59.8 nmol/L. For the calibrator, internal standards are shown by a dotted line. Patient sample-derived chromatograms (B) represent the urinary output of catecholamines and their *O*-methylated metabolites from a patient with confirmed pheochromocytoma (*dashed line*) and a patient without pheochromocytoma. Note the much larger signal intensity (*peak height*) for normetanephrine (3) in the patient with rather than without pheochromocytoma.

commonly ordered biochemical tests in clinical practice, but other catecholamine metabolites and dopamine are also measured. Diagnostic evaluation of patients with carcinoid tumor routinely involves measurement of 5-HIAA; the measurement of serotonin in platelets and urine has also been advocated.

Collection, Processing, and Storage of Samples

The conditions for plasma or urine collection are crucial to the reliability and interpretation of test results. Some clinicians prefer 24-hour urine collection to blood sampling because the former avoids the rigid sampling conditions associated with blood catecholamine collection (e.g., samples should be taken after supine rest) and is more convenient for clinical

staff to implement. However, 24-hour urine collections are often difficult and inconvenient for patients. Spot or overnight urine collection with correction to urinary creatinine excretion provides an alternative to 24-hour urine collection and may overcome some of these problems.

For measurements of urinary metanephrines, no preservatives are required, whereas for catecholamines, samples are best preserved with hydrochloric acid. For storage over protracted periods, aliquots are best kept frozen at -80°C to minimize auto-oxidation and deconjugation. Blood samples for both metanephrines and catecholamines are best collected into tubes containing heparin or ethylenediaminetetraacetic acid (EDTA) as an anticoagulant and stored on ice before centrifugation at 4°C , with separation of plasma for further storage at -80°C .

Whole blood measurement of serotonin is popular because time-consuming isolation of platelets is not required. For whole blood serotonin, venous blood is drawn into a tube containing potassium EDTA as an anticoagulant, gently mixed and placed on ice, and transferred to a storage tube. An aliquot of blood is then removed for a platelet count. Blood serotonin samples are stored frozen at -20°C , preferably within 2 hours after collection.

Platelet-rich plasma samples are prepared from whole blood by low-speed centrifugation. To prevent lowering of serotonin concentration, platelet-rich plasma is prepared within 1 hour after the blood is collected and placed on ice. Plasma and pellets are stored frozen at -20°C and are analyzed within 1 to 2 weeks after collection.

Twenty-four-hour urine samples for serotonin and 5-HIAA are collected in 2-L brown polypropylene bottles, containing 250 mg of sodium metabisulfite and EDTA as preservatives. Samples are acidified to pH 4 with acetic acid before freezing and, importantly, the specimen should be refrigerated during collection.

Influences of Diet and Drugs

Dietary constituents or drugs may cause direct analytical interference in assays or may influence the physiological processes that determine plasma and urinary concentrations of monoamines and monoamine metabolites. In the former circumstances, interference is highly variable depending on the particular measurement method used. In the latter circumstances, interference is usually of a more general nature and is independent of the measurement method.

The development of new drugs, the variations in assay techniques, and the continuing improvements in analytical procedures make it difficult to identify which directly interfering medications should be avoided for a given analytical test. However, for modern mass spectrometric detection methods, such interferences are rarely a problem compared with electrochemical and spectrophotometric detection methods.

More readily identifiable sources of interference, which are independent of the particular assay method, tend to be associated with drugs that have primary actions on monoamine systems. Tricyclic antidepressants, which inhibit monoamine reuptake, are a major source of false-positive results for

norepinephrine and normetanephrine. Other medications that cause significant interference but are less commonly encountered during testing for pheochromocytoma include L-dopa, Sinemet, α -methyldopa (Aldomet), and MAO inhibitors.

Dietary interference is sometimes particularly troublesome for measurements of serotonin metabolites. Dietary sources of 5-hydroxyindoles, such as walnuts, bananas, avocados, eggplants, pineapples, plums, and tomatoes, should be restricted 3 to 4 days before and during urine collection. If possible, patients should abstain from all known medications that may cause an apparent increase, such as guaiacolate, mephenesin, phenacetin, and acetaminophen, or a decrease in 5-HIAA, including methenamine, phenothiazine tranquilizers, homogentisic acid, acetic acid, and levodopa. Due to influences of dietary catecholamines, plasma methoxytyramine should be measured after an overnight fast.

Analysis of Urinary and Plasma Fractionated Metanephrines

Normetanephrine, metanephrine, and methoxytyramine, are present in plasma and urine in free and sulfate-conjugated forms. Plasma concentrations of the conjugates are 20- to 30-fold higher than those of the free metabolites, reflecting more rapid circulatory clearance of free than conjugated metabolites. Clearance of free metabolites occurs by active uptake into tissues followed by deamination or conjugation. The conjugated metabolites are cleared relatively slowly by renal excretion. Metanephrines in urine are therefore routinely measured after acid hydrolysis and represent mainly conjugated metabolites, whereas metanephrines in plasma are usually measured in the free form.

Measurements of metanephrines in urine and plasma are now widely performed in many laboratories by LC-MS/MS (see Fig. 26.7). Such methods offer advantages of short chromatographic run times, high sample throughput, and elimination of drug interference that render earlier methods, using liquid chromatography with electrochemical detection (LC-EC), obsolete. A sample preparation step, usually employing ion exchange chromatography, remains a requirement; however, this is accomplished more simply for LC-MS/MS than for LC-EC methods, with some methods allowing on-line sample purification.

Immunoassay measurements of plasma and urine metanephrines suffer from relatively poor accuracy and precision and are not recommended for routine clinical use.

Analysis of Urinary and Plasma Catecholamines

Plasma catecholamines are still commonly measured by LC-EC methods, whereas urinary catecholamines are increasingly measured with LC-MS/MS methods. The most common extraction procedure employed for LC-EC measurements of catecholamines involves alumina extraction, sometimes combined with an additional cation-exchange step. For LC-MS/MS methods, simpler methods of extraction can be used, such as 96-well based ion-exchange chromatographic procedures, but with final elution of the analytes from extraction columns under acid conditions rather than

basic conditions commonly used for metanephrines. Further advantage of the LC-MS/MS method is that both catecholamines and metanephrines can be purified and measured together

Analysis of Urinary Vanillylmandelic Acid and Homovanillic Acid

VMA, in contrast to HVA, is not significantly conjugated; both are excreted in urine in relatively high amounts, making their analysis relatively simple. Because large amounts of HVA are also present in urine in the free form, both metabolites are commonly measured without a hydrolysis step. Compared with metanephrines and catecholamines, measurements of VMA and HVA have limited value in diagnosing pheochromocytoma but are commonly used for the diagnosis of neuroblastoma.

Spectrophotometric methods for determination of VMA and HVA have been superseded by gas or liquid chromatography-based methods, employing today mainly mass spectrometric detection. Mass spectrometric methods are highly specific and, along with combined measurements of VMA and HVA, certain methods allow the additional measurement of 5-HIAA. Gas chromatography-based methods typically employ extraction of urinary analytes into an organic phase followed by derivatization of analytes in the dried down residue. Sample preparation is simpler still for LC-MS/MS methods, some of which involve only the dilution of urine in the mobile phase.

Analysis of Serotonin and 5-Hydroxyindoleacetic Acid

Analyses of serotonin, its deaminated acid metabolite, and 5-HIAA and its precursor, 5-HTP, provide important biomarkers for the diagnosis of carcinoid tumors. Typically, circulating serotonin is almost entirely confined to platelets, so that measurements are usually performed in whole blood, platelet-rich plasma, or isolated platelet pellets. With sensitive analytical instruments, measurements are possible in platelet-free plasma, which has been proposed as an alternative matrix, and which is useful for the detection of serotonin-producing neoplasms at locations where venous outflow does not empty into the portal circulation.

Measurements of urinary serotonin are of less importance because the serotonin in this matrix primarily reflects the clearance of plasma-free serotonin and renal decarboxylation of circulating 5-HTP. Nevertheless, urinary measurement is helpful in identifying tumors deficient in aromatic amino acid decarboxylase that produce substantial amounts of 5-HTP, which consequently shows up in urine as serotonin. Such tumors may be more directly detected by the measurement of circulating 5-HTP.

Measurements of 5-HIAA are most commonly carried out in urine. As an end-product of serotonin production, 5-HIAA better reflects tumor burden than serotonin. Measurements in plasma after an overnight fast have been advocated as more reliable because they avoid the confounding influence of dietary serotonin.

Liquid chromatography with fluorometric or electrochemical detection remains the most frequently used method for measurements of serotonin and 5-HIAA. Usually these techniques have been developed for measuring serotonin and 5-HIAA separately, but some methods allow for simultaneous measurement of catecholamine and 5-HIAA, VMA, and HVA. For detection of high concentrations of serotonin, as in platelet-rich plasma, simple methods of deproteinization of samples with perchloric acid or trichloroacetic acid before direct injection onto the high-performance liquid chromatography (HPLC) column are used.

Most HPLC assays for serotonin and 5-HIAA employ octadecylsilyl (C18) reversed-phase columns, although strong cation exchange columns have been used for serotonin. The chromatography is usually performed with an isocratic mobile phase at an acid pH that contains an organic modifier and perhaps an ion-pair reagent for serotonin measurements. As with catecholamines, serotonin is protonated in the pH range of 3 to 6, and the addition of an anionic ion-pair reagent creates an uncharged conjugate, which enhances the affinity of serotonin for the hydrophobic stationary phase.

For the measurement of very small amounts of serotonin or for specialized projects, HPLC with amperometric or coulometric detection is often favored over fluorometric detection. To enhance analytical sensitivity, some HPLC procedures incorporate precolumn derivatization with fluorescent and chemiluminescent reagents, thereby achieving detection limits in the femtomole range. Electrochemical detection using amperometric or coulometric measurement is preferred for the specific measurement of small quantities of 5-HIAA. Some HPLC systems use fluorometric detection,

with or without derivatization, for a less demanding measurement of 5-HIAA.

As with measurements of metanephrines and catecholamines, the use of LC-MS/MS methods for the quantification of serotonin and 5-HIAA is increasing. With these methods, sample clean-up procedures are simpler, enabling online sample purification.

Postanalytical Considerations and Reference Intervals

The use of appropriately matched reference populations is important for effective screening for monoamine-producing tumors among different populations of patients. Plasma and urinary metanephrines show variable sex and age differences, and may have different ranges in hospitalized patients compared with normotensive healthy volunteers. The amounts of catecholamines and metanephrines in 24-hour urine specimens and plasma are non-normally distributed so that non-parametric methods are most appropriate for establishing reference intervals (see [Chapter 5](#)). For plasma metanephrines it is essential that reference intervals are established using blood samples collected supine, and for methoxytyramine after an overnight fast. Age can be particularly important to consider, especially for pediatric populations, but also in adults for plasma normetanephrine. Because of the variations in methods of analysis and subsequent analytical test results, any laboratory establishing measurements of monoamines or metabolites for diagnostic purposes should validate its own reference intervals in line with current standards in clinical practice (for details, see [Chapter 5](#)).

REVIEW QUESTIONS

1. The urinary metabolite measured as an indicator of norepinephrine synthesis is:
 - a. dopamine.
 - b. homovanillic acid (HVA).
 - c. serotonin.
 - d. vanillylmandelic acid (VMA).
2. False-positive elevations of 5-hydroxyindoleacetic acid (5-HIAA) in urine can occur if:
 - a. an individual is a chronic alcoholic.
 - b. a patient is receiving aspirin therapy.
 - c. an individual has recently eaten fruit, such as bananas, kiwis, and plums.
 - d. a patient is currently using tricyclic antidepressants.
3. The two urine metabolites that are most widely used for the diagnosis of neuroblastoma are:
 - a. HVA and VMA.
 - b. VMA and 5-HIAA.
 - c. HVA and 5-HIAA.
 - d. dopamine and epinephrine.
4. Midgut neuroendocrine tumors release which of the following substances in a large quantity when compared with tumors derived from other developmental gut components?
 - a. 5-hydroxytryptophan
 - b. Serotonin
 - c. Epinephrine
 - d. Dopamine
5. The method most frequently used for measuring 5-HIAA in urine to detect serotonin production is:
 - a. nephelometry.
 - b. liquid chromatography with UV detection.
 - c. liquid chromatography with electrochemical, fluorimetric or mass spectrometric detection.
 - d. ion exchange chromatography.
6. The recommended analytes for diagnosis of pheochromocytoma are:
 - a. urinary VMA and HVA.
 - b. plasma or urinary metanephrines.
 - c. urinary or plasma catecholamines.
 - d. urinary 5-HIAA and HVA.
7. A catecholamine-producing tumor derived from the chromaffin cells of the adrenal medulla is referred to as a:
 - a. neuroblastoma.
 - b. pheochromocytoma.
 - c. paraganglioma.
 - d. gastroenteropancreatic neuroendocrine tumor.

8. More than 95% of the serotonin in the body is produced within the gastrointestinal tract.
 - a. True.
 - b. False.
9. Chromaffin cells are located in the ____ and are responsible for synthesis of ____:
 - a. kidney; renin.
 - b. brain; dopamine.
 - c. adrenal gland; epinephrine.
 - d. gut; serotonin.
10. Epinephrine is also called:
 - a. noradrenaline.
 - b. adrenaline.
 - c. metanephrine.
 - d. serotonin.

Vitamins and Trace Elements

Ravinder Sodi, Andrew Taylor

OBJECTIVES

1. Classify the vitamins discussed in this chapter according to their water or fat solubility.
2. State the chemical names of each vitamin discussed in this chapter.
3. Summarize the physiological roles of each vitamin discussed.
4. Describe the symptoms of toxicity and deficiency of each vitamin.
5. Describe methods used in the analysis of each vitamin and the factors which affect them.
6. State what is meant when an element is considered “essential.”
7. Summarize the physiological functions and clinical significance of each trace element discussed.
8. Describe methods used in the analysis of trace elements and the factors which affect them.
9. Describe disorders associated with deficiency of the trace elements discussed.

KEY WORDS AND DEFINITIONS

Acrodermatitis enteropathica A hereditary disorder due to defective zinc uptake resulting in dermatitis, diarrhea, and alopecia.

Acute-phase response (APR) A response of the body to inflammation that results in an increase or decrease in the plasma concentrations of a class of proteins known as acute phase reactants.

Apoenzyme A protein moiety of an enzyme that requires a coenzyme to be fully functional.

Beriberi A disease caused by a deficiency of thiamine (vitamin B₁) and characterized by polyneuritis (dry form), cardiac pathology with edema (wet form).

Coenzyme An organic molecule (sometimes derived from a vitamin) of low molecular weight that, when combined with an inactive protein called an *apoenzyme*, forms an active compound or a complete enzyme called a *holoenzyme*, which functions catalytically in an enzyme system.

Cofactor A natural reactant, usually a metal ion or a coenzyme, that is required in an enzyme-catalyzed reaction.

Hartnup disease An inborn error of metabolism affecting the absorption of nonpolar amino acids (particularly tryptophan) characterized by a massive aminoaciduria.

Hemorrhagic disease of the newborn A self-limited hemorrhagic disorder of the first days of life, caused by a deficiency of the vitamin K-dependent blood coagulation factors II, VII, IX, and X.

Imerslund-Grasbeck syndrome A rare autosomal recessive, familial form of vitamin B₁₂ deficiency caused by defects in the cubam receptor located in the terminal ileum, which is involved in vitamin B₁₂ absorption.

Kashin-Beck disease A chronic, endemic disease of the bone resulting from mainly selenium and iodine deficiency.

Keshan disease A fatal, congestive cardiomyopathy caused by deficiency of essential trace elements in the diet particularly selenium.

Menkes syndrome An X-linked recessive disorder of copper metabolism caused by mutations in the *ATP7A* gene (locus: Xq12-q13), which encodes a copper transporter leading to copper deficiency. Signs and symptoms include kinky hair, hypotonia, and developmental delay.

Nyctalopia Visual disturbances that occur in dim light that may be caused as a result of vitamin A deficiency among other causes. Also known as night blindness.

Pellagra A clinical deficiency syndrome due to deficiency of niacin (or failure to convert tryptophan to niacin) and characterized by dermatitis, inflammation of mucous membranes, diarrhea, and dementia.

Pernicious anemia A deficiency in the production of red blood cells through a lack of vitamin B₁₂.

Recommended dietary allowance (RDA) The average daily level of intake of nutrients sufficient to meet the requirements of nearly all (97% to 98%) healthy people.

Scurvy A condition due to deficiency of ascorbic acid (vitamin C) in the diet.

Systemic inflammatory response syndrome (SIRS) The systemic inflammatory response to a wide variety of severe clinical insults.

Total parenteral nutrition (TPN) The practice of feeding a person intravenously, circumventing the gut.

Trace elements Inorganic molecules found in human and animal tissues in milligram per kilogram amounts or less.

Vitamer Term used to describe any of a number of compounds that possess a given vitamin activity.

Vitamin An essential organic micronutrient that must be supplied exogenously and in many cases is the precursor to a metabolically derived coenzyme.

Wilson disease A rare, progressive, autosomal recessive disease due to a defect in metabolism of copper resulting in excessive copper accumulation in the liver, brain, eye, and other organs.

Wernicke encephalopathy Condition arising as a result of thiamine deficiency, which presents with ophthalmoplegia, ataxia, and confusion usually in alcoholics.

Xerophthalmia Refers to the spectrum of ocular manifestations due to vitamin A deficiency, ranging from night blindness to conjunctival dryness to the appearance of small gray plaques with foamy surfaces (Bitot spots).

VITAMIN AND TRACE ELEMENT STATUS

An adequate supply of **vitamins** and trace elements is critical in maintaining health. There is increasing public awareness that good nutrition including supplementation with vitamins and trace elements is necessary for improving the quality of life but this has not necessarily been supported by randomized trials in selected groups. The general principle regarding assessment of nutritional status is to determine the extent to which the metabolic demand for nutrients has been or is currently being met by the supply. In clinical practice, this requires balancing supply and demand.

The requirements for most nutrients including vitamins and trace elements, to maintain health have been characterized and made available in reports from the Institute of Medicine (IOM) of the National Academies (US). However, the effects of disease may increase demands. For example, hypermetabolism, as a result of trauma or infection, increases the need for protein and energy and for the vitamin and trace element **cofactors** necessary for their metabolism. Increased losses from the gut, kidney, and skin, or through dialysis, may also increase the overall demand for these nutrients.

An estimate of supply also is obtained from a careful dietary history, especially if performed by a dietitian, together with knowledge of any artificial nutritional supplements or therapy that may have been provided enterally or intravenously. **Table 27.1** summarizes the **Recommended Dietary Allowance (RDA)** used in the United States and the Population Reference Intakes from the European community for vitamins and trace elements in adults. **Table 27.1** also summarizes the amounts present in 2000 kcal of most tube feeds used in nutritional support and common dietary sources. For details regarding children, see the suggested readings. **Table 27.2** summarizes the functions of vitamins in man.

In an attempt to improve accuracy of assessment of nutritional status, clinicians often turn to the laboratory

to obtain a result that may reflect the net balance of supply and demand. Clinical laboratorians need to be aware of when such tests are useful and how to place the results of laboratory tests into the context of the clinical situation of the patient. It is important to be aware of the limitations of laboratory tests, especially in acutely ill patients. Nutritional assessment in health and disease is considered in detail in Suggested Reading reference 7.

Effect of Inflammation on Vitamins and Trace Elements

The concentration in plasma of various vitamins and trace elements can alter significantly when a **systemic inflammatory response syndrome (SIRS)**; previously known as the **acute-phase response [APR]** results from trauma or infection. This usually occurs independently of tissue stores. The associated changes may be due to alterations in the binding proteins in plasma such as albumin or retinol-binding protein (RBP), which decrease as part of SIRS or due to protein malnutrition. Studies in patients with SIRS as categorized on the basis of elevated C-reactive protein (CRP) concentrations have documented decreases in vitamin A, E, B₂, B₆, C, D, and carotenoids. One study in 1303 patients examined the effect of the magnitude of SIR on plasma micronutrient concentrations with the aim of providing guidance on the interpretation of results. The findings are shown in **Table 27.3**. This study concluded that the degree of inflammatory response affected the interpretation of plasma micronutrient concentrations and showed that a reliable clinical assessment could only be made if the CRP was less than 10 mg/L for vitamins A and D or less than 5 mg/L for vitamins B₆ and C. There have been guidelines issued on nutrition support by national bodies such as the National Institute for Health and Care Excellence (NICE) in the United Kingdom that recommend the monitoring of micronutrient concentrations in patients receiving **total parenteral nutrition (TPN)**; therefore when implementing guidelines and deciding on nutritional support, it is important to take the effect of SIRS into account.

TABLE 27.1 Daily Oral and Intravenous Vitamin and Trace Element Intakes for Adults

	RDA (USA)	PRI (Europe)	Some Natural Food Sources	Amount in 2000 kcal Tube Feed	IV Intake
Vitamins					
A, μg	900 (men); 700 (women)	700	Liver, yellow/orange fruits, leafy vegetables, fish, milk	1000–2160	1000
E, mg	15 (men and women)	0.4/g PUFA	Fruits and vegetables, meats, vegetable oils, unprocessed cereals, nuts, and seeds	20–64	9.1
K, μg	120 (men); 90 (women)	100–200	Leafy green vegetables, especially spinach, eggs, liver	—	150
B ₁ , mg	1.2 (men); 1.1 (women)	1.1	Brown rice, vegetables, potatoes, liver, eggs	1.4–3.4	6
B ₂ , mg	1.3 (men); 1.1 (women)	1.6	Vegetables such as green beans and asparagus, bananas, dairy products	2–6	3.6
B ₆ , mg	1.3 (men and women <50 year); 1.7 (men >50 year); 1.5 (women >50 year)	1.5	Meat, bananas, vegetables, nuts	2–13.8	6
B ₁₂ , μg	2.4	1.4	Meat and animal products	3–15	5
Folate, μg	400	200	Leafy vegetables, cereal especially if fortified, bread, pasta, liver	340–880	600
C, mg	90 (men); 75 (women)	45	Fruits especially citrus fruits and vegetables	100–300	200
Biotin, μg	30 ^a	15–100	Eggs, organ meats, yeast, milk	100–660	60
Niacin, mg	16 (men); 14 (women)	18	Meat, fish, eggs, vegetables, mushrooms, nuts	18–45	40
Pantothenic acid, mg	5 ^a	3–12 ^b	Meat, vegetables like broccoli, avocados, grains	7–20	15
Trace Elements					
Copper, mg	0.9	1.1	Organ meats, seafood, nuts, seeds, grains, cocoa products	2–3.4	0.3–1.3
Selenium, μg	55	55	Organ meats, seafood, nuts, vegetables (dependent of soil selenium content)	30–130	40–100
Zinc, mg	11 (men); 8 (women)	9.5	Red meats and some seafood	13–36	2.5–6.0
Iodine, μg	150	150	Milk, iodized salt	N/A	70–170
Manganese, mg	2.3 ^a (men); 1.8 ^a (women)	1–10 ^b	Nuts, legumes, tea, grains	2.4–8	0.06–0.1
Chromium, μg	25 ^a (men); 35 ^a (women)	30–200	Cereals, meats, fish	10–20	10–15
Molybdenum, μg	45 ^a	74–240	Legumes, grains, and nuts	19	10–25

^aAdequate intake.^bAcceptable range.

VITAMINS

Vitamin A

Vitamin A is the nutritional term for the group of compounds with a 20-carbon structure containing a methyl-substituted cyclohexenyl ring (β -ionone ring) and an isoprenoid side chain (Fig. 27.1), with a hydroxyl group (retinol), an aldehyde group (retinal), a carboxylic acid group (retinoic acid), or an ester group (retinyl ester) at the terminal C15. Included in the vitamin A family are some dietary carotenoids (C40

polyisoprenoid compounds) that are classified as provitamin A because they are cleaved biologically to yield retinol. The principal dietary carotenoids are β -carotene, α -carotene, and β -cryptoxanthin.

Absorption, Transport, Metabolism, and Excretion

Preformed vitamin A, most often in the form of retinyl ester, or carotenoids are subject to emulsification and mixed micelle formation by the action of bile salts before they are transported into the intestinal cell. Here the

TABLE 27.2 Vitamins Required by Humans

Common or Generic Name	Vitamin or Common Chemical Name	Function	Symptoms and Causes of Deficiency or Associated Diseases	Currently Used Methods	Reference Intervals
Fat-Soluble Vitamins					
Vitamin A	Retinol, retinal, retinoic acid, carotenoids	Antioxidant, role in vision, gene expression, embryonic development, immune and reproductive functions	Nyctalopia (night blindness), Bitot spot, xerophthalmia, keratomalacia; common in infants and children, especially in less developed countries; due to fat malabsorption, cystic fibrosis and may occur due to retinol-binding protein deficiency as a result of protein malnutrition, liver disease, and zinc deficiency	HPLC, LC-MS/MS	1–6 year: 20–40 µg/dL (0.70–1.40 µmol/L) 7–12 year: 26–49 µg/dL (0.91–1.71 µmol/L) 13–19 year: 26–72 µg/dL (0.91–2.51 µmol/L) >19 year: 30–80 µg/dL (1.05–2.80 µmol/L)
Vitamin E	Tocopherols, tocotrienols	Antioxidant (prevents the peroxidation of unsaturated fatty acids), role in gene transcription, immunity, inhibits platelet aggregation, recently been implicated in bone physiology	Lipid peroxidation, red blood cell fragility causing hemolytic anemia especially in premature infants; may occur due to fat malabsorption, cystic fibrosis	HPLC, LC-MS/MS	Premature neonates: 0.1–0.5 mg/dL (2.3–11.6 µmol/L) 1–12 year: 0.3–0.9 mg/dL (7–21 µmol/L) 13–19 year: 0.6–1.0 mg/dL (14–23 µmol/L) >19 year: 0.5–1.8 mg/dL (12–42 µmol/L) As a ratio of cholesterol: 3.5–9.5 µmol/mmol cholesterol
Vitamin K	Phylloquinones (K ₁), menaquinones (K ₂), menadiones (K ₃)	Coagulation, bone metabolism	Increased clotting time, hemorrhagic disease of the newborn; also due to fat malabsorption, cystic fibrosis, liver disease	Prothrombin time, PIVKA, HPLC, LC-MS/MS	0.2–2.2 nmol/mmol triglyceride
Water-Soluble Vitamins					
Vitamin B ₁	Thiamine, aneurin	Forms the coenzyme thiamine pyrophosphate (TPP) required for decarboxylation reactions involved in carbohydrate metabolism, and nerve function	Beriberi, Wernicke-Korsakoff syndrome in alcoholics, rare thiamine-responsive IOM	Erythrocyte transketolase, HPLC, LC-MS/MS	Erythrocyte transketolase activity: 0.75–1.30 U/g Hb (48.4–83.9 kU/mol Hb) Percent TPP effect (activation): Normal: 0%–15% Marginal: 16%–25% Deficient: >25% TPP concentration: 173–293 nmol/L or 280–590 ng/g Hb (erythrocytes); 90–140 nmol/L or 275–675 ng/g Hb (whole blood)

Continued

TABLE 27.2 Vitamins Required by Humans—cont'd

Common or Generic Name	Vitamer or Common Chemical Name	Function	Symptoms and Causes of Deficiency or Associated Diseases	Currently Used Methods	Reference Intervals
Vitamin B ₂	Riboflavin	Essential component of coenzymes involved in reduction-oxidation (redox) reactions in the body	Angular stomatitis, dermatitis, photophobia, riboflavin-dependent IOM	Erythrocyte glutathione reductase, HPLC, LC-MS/MS	Erythrocyte glutathione reductase activation by FAD: Adequacy: 1.20 Marginal: 1.21–1.40 Deficiency: >1.41 Serum or plasma concentrations of riboflavin (median [range]): plasma FAD: 101 [57–170] nmol/L plasma FMN: 6.3 [3.3–14.1] nmol/L plasma riboflavin: 11 [4–34] nmol/L erythrocyte FAD: 1.9 [0.7–3.8] pmol/g Hb erythrocyte FMN: 0.11 [0.04–0.44] pmol/g Hb erythrocyte riboflavin: 0.02 [0.01–0.13] pmol/g Hb
Vitamin B ₃	Niacin, nicotinic acid, nicotinamide	Coenzyme or cosubstrate in many biological redox reactions, and thus for energy metabolism	Pellagra (dermatitis, dementia, diarrhea) Seen in communities with corn-based staple diets, in carcinoid syndrome (precursor tryptophan diverted to serotonin formation), Hartnup disease (unable to absorb tryptophan), and medications such as isoniazid	HPLC & LC-MS/MS for urine metabolite, nicotinamide coenzymes	2.4–6.4 mg/day (17.5–46.7 μmol/day) or 1.6–4.3 mg/g creatinine (11.7–31.4 μmol/g creatinine)
Vitamin B ₅	Pantothenic acid, panthenol, pantotheine	General metabolism, acetyl and acyl transfer	Burning feet syndrome	Microbiological, CPB, HPLC, LC-MS, GC-MS	Whole blood or serum: 344–583 μg/L (1.57–2.66 μmol/L) Urinary excretion: 1–15 mg/day (5–68 μmol/day)
Vitamin B ₆	Pyridoxine, pyridoxal, pyridoxamine	The active form pyridoxal phosphate is required for synthesis, catabolism of various amino acids	Epileptiform convulsions, dermatitis, anemia, medications such as penicillamine and isoniazid decrease it, pyridoxine-responsive IOM notably homocystinuria, and hyperhomocysteinemia (together with vitamin B ₁₂ and folate deficiencies)	Aspartate transaminase, HPLC, LC-MS/MS	Plasma PLP: 9.5–24 ng/mL (39–98 nmol/L). Erythrocyte PLP: 250–680 pmol/g Hb
Vitamin B ₇	Biotin, vitamin H	Coenzyme for carboxylation reactions involved in gluconeogenesis, lipogenesis and catabolism of branched-chain amino acids; roles in cell signaling, epigenetic regulation of genes and chromatin structure	Dermatitis, developmental delay Seen with excessive raw egg consumption, those on parenteral nutrition, and IOM notably biotinidase deficiency	Microbiological, CPB, carboxylases, avidin binding, urinary metabolites	0.5–2.20 nmol/L

Vitamin B ₉	Pteroylglutamic acid, folic acid, folate	Required for the interconversions of amino acids such as homocysteine to methionine and the biosynthesis of purines and pyrimidines, required for DNA synthesis	Megaloblastic anemia, neural tube defects Caused by gut sterilization, malabsorption, decreased intake, increased requirements (e.g. pregnancy), medications (e.g. methotrexate), anticonvulsants Deficiency linked to hyperhomocysteinemia, cancer and stroke	Red blood cell and serum folate, CPB, microbiological, homocysteine	>3 µg/L (7.0 nmol/L) for serum folate and <150 µg/L (340 nmol/L) for RBC folate
Vitamin B ₁₂	Cyanocobalamin, hydroxycobalamin, methylcobalamin	Required for erythropoiesis, methylation processes necessary for DNA and cell metabolism, and is cofactor for various enzymes notably those involved in the metabolism of methylmalonic acid and homocysteine	Pernicious and megaloblastic anemia, peripheral neuropathy Caused by decreased intake (vegetarians), short bowel syndrome (loss of distal ileum), malabsorption syndromes, medications (N ₂ O, phenytoin, methotrexate, and proton pump inhibitors), and Imerslund-Grasbeck syndrome Deficiency results in methylmalonic aciduria and homocysteinemia	CPB, immunometric, microbiological, methylmalonate, homocysteine, holotranscobalamin	WHO consultation defined a serum vitamin B ₁₂ concentration <203 ng/L (150 pmol/L) as deficient
Vitamin C	Ascorbic acid	Connective tissue formation, antioxidant	Scurvy, infantile scurvy (Barlow disease) Linked with osteoporosis, anemia, diabetes mellitus, cancer	Spectrophotometric-enzymatic methods, HPLC	0.4 and 1.5 mg/dL (23–85 µmol/L) or 20–53 µg/10 ⁸ leukocytes (1.14–3.01 fmol/leukocyte)

Reference intervals are likely to vary between laboratories and are influenced by variables including the systemic inflammatory response.

CPB, Competitive protein binding; HPLC, high-performance liquid chromatography; IOM, inborn errors of metabolism; LC-MS/MS, liquid chromatography-tandem mass spectrometry; PIVKA, protein induced by vitamin K absence or antagonism; RIA, radioimmunoassay.

retinyl esters are moved across the mucosal membrane and hydrolyzed to retinol within the cell to be then re-esterified by cellular RBP II and packaged into chylomicra, which then enter the mesenteric lymphatic system and pass into the systemic circulation. A small amount of the ingested retinoid is converted into retinoic acid in the intestinal cell.

Carotenoids, also in micellar form, are absorbed into the duodenal mucosal cells by passive diffusion. Once inside the mucosal cell, β -carotene is principally converted to retinal by the enzyme β -carotene-15,15'-dioxygenase. Retinal is converted by retinal reductase to retinol and esterified. The newly synthesized retinyl esters, from both preformed vitamin A and carotenoids, along with exogenous lipids and nonhydrolyzed carotenoids, then pass with chylomicrons via the lymphatic system to the liver, where uptake by parenchymal cells again involves hydrolysis. In

the liver, retinol is bound with RBP and transthyretin (TTR or thyroxine-binding prealbumin) in a 1:1:1 complex of sufficient size to prevent loss by glomerular filtration and is returned to the circulation, or stored as esters within the stellate cells.

Functions

The participation of retinal in vision is considered the most important physiologic function of vitamin A. All-*trans*-retinol is the predominant circulating form of vitamin A. Cells of the retina isomerize this to the 11-*cis* alcohol that is reversibly dehydrogenated to 11-*cis* retinal, which combines with proteins (e.g., opsin) to generate photosensitive pigments, such as rhodopsin. Illumination of such pigments causes photoisomerization and the release of all-*trans*-retinal and the protein, a process that couples the large conformational change with ion flux and optic nerve transmission. The all-*trans*-retinal is isomerized to the 11-*cis* isomer, which combines with the liberated protein to reconstitute the photo pigment in a visual cycle, as shown in Fig. 27.2.

Other functions of vitamin A include its role in reproduction, growth, embryonic development, and immune function; many of these functions are mediated through the binding of retinoic acid to specific nuclear receptors that regulate genomic expression.

Deficiency

Vitamin A deficiency primarily affects infants and children, and its prevalence is subject to World Health Organization (WHO) surveillance. Risk factors include poverty, low birth weight, poor sanitation, malnutrition, infection, and parasitism. As hepatic accumulation of vitamin A occurs during the last trimester of pregnancy, preterm infants are relatively vitamin A deficient at birth.

Neonatal vitamin A supplementation has been a matter of some controversy, with trials giving mixed results dependent on the population studied. At the present time neonatal vitamin A supplementation is not recommended as a public health intervention. Fat malabsorption, particularly caused

TABLE 27.3 Median Plasma Vitamin Concentrations According to C-Reactive Protein Concentrations

CRP Concentration (mg/L)	Vitamin A (μ mol/L)	Vitamin D (nmol/L)	Vitamin B ₆ (μ mol/L)	Vitamin C (μ mol/L)
<5	2.0	34	48	23
>5–10	2.0	33	27	18
>10–20	1.8	31	32	17
>20–40	1.6	27	24	8
>40–80	1.4	23	18	6
>80	1.0	20	15	5

Data in bold depict significant ($P < .05$) decrease compared to CRP category <5 mg/L.

Conversion factors for traditional units: Vitamin A—divide by 0.0349 to μ g/dL; Vitamin D—divide by 2.496 to ng/mL; Vitamin B₆—divide by 4.046 to ng/mL; Vitamin C—divide by 56.78 to mg/dL.

CRP, C-reactive protein.

Modified from Duncan, A., Talwar, D., McMillan, D. C., Stefanowicz, F., & O'Reilly, D. S. (2012). Quantitative data on the magnitude of the systemic inflammatory response and its effect on micronutrient status based on plasma measurements. *The American Journal of Clinical Nutrition*, 95, 64–71.

Fig. 27.1 Vitaminic forms of A₁, A₂, and β -carotene.

by celiac disease or chronic pancreatitis, and protein-energy malnutrition predispose to vitamin A deficiency. Liver disease diminishes RBP synthesis, and ethanol abuse leads to both hepatic injury and competition with retinol for alcohol dehydrogenase, which is necessary for the oxidation of retinol to retinal and retinoic acid. Vitamin A deficiency may lead to anemia, although the precise mechanism is not known.

Clinical features of vitamin A deficiency include degenerative changes in eyes and skin, and poor dark adaptation or *night blindness* (**nyctalopia**) followed by degenerative changes in the retina. **Xerophthalmia** refers to the spectrum of ocular manifestations due to vitamin A deficiency, ranging from night blindness to conjunctival dryness to the appearance of small gray plaques with foamy surfaces (*Bitot spots*). These lesions are reversible with vitamin A administration. More serious effects of deficiency are known as *keratomalacia*, and cause ulceration and necrosis of the cornea that lead to perforation, prolapse, endophthalmitis, and blindness. Usually associated skin changes include dryness, roughness, papular eruptions, and follicular hyperkeratosis.

Toxicity

Toxic effects of hypervitaminosis A occur mainly as a result of ingestion of excess vitamin or as a side effect of inappropriate therapy. The elderly are more susceptible to vitamin A toxicity at lower doses, as exposure to retinyl esters is longer because of delayed postprandial clearance of lipoproteins.

Symptoms of acute toxicity present as abdominal pain, nausea, vomiting, severe headaches, dizziness, sluggishness, and irritability, followed within a few days by desquamation of the skin and recovery. Chronic toxicity from moderately high doses taken for protracted periods is characterized by bone and joint pain, hair loss, dryness and fissures of the lips, anorexia, benign intracranial hypertension, weight loss, and hepatomegaly.

Epidemiologic and experimental evidence has supported the view that high vitamin A intake in humans, acting via 13-*cis*-retinoic acid, is teratogenic. A further intriguing association, supported in part by epidemiologic studies, is that observed

between excessive vitamin A intake and reduction in bone mineral density (BMD). Hypervitaminosis A is also a known cause of hypercalcemia, especially in chronic kidney disease.

Carotenemia results from chronic excessive intake of carotene-rich foods, principally carrots, and is usually reported in infants and children. This condition, in which yellowing of the skin is observed, is benign because the excess carotene is deposited rather than converted to vitamin A. Carotenemia has also been linked to amenorrhea, but the mechanism behind this association remains unknown. Elevated concentrations have also been found in hypothyroid patients, in whom conversion to vitamin A is decreased, and in patients with hyperlipemia associated with diabetes mellitus.

Laboratory Assessment of Status

Although measurement of the plasma concentration of vitamin A is the most convenient and widely used assessment of vitamin A status, it is not an ideal indicator because it does not decline until liver stores become critically depleted, which is thought to occur at a concentration of approximately 20 µg/g liver.

Vitamin A status is assessed by the measurement of retinol concentration. Retinol circulates in plasma as a 1:1:1 complex with RBP and TTR. The circulating concentration of RBP is determined by dietary protein and zinc, which are necessary for RBP synthesis. Thus protein malnutrition, liver disease, and zinc deficiency resulting in RBP deficiency will lead to hypovitaminosis A. In contrast, renal failure resulting in decreased excretion of RBP has been reported to result in hypervitaminosis A. Another confounding factor in the assessment of vitamin A status is the effect of inflammation as discussed above. Both RBP and TTR are negative acute-phase proteins; thus inflammatory changes will result in transient falls in both proteins and plasma retinol. To distinguish inflammatory from nutritional causes of reduced plasma retinol concentrations, it may be necessary to measure CRP.

Currently high-pressure liquid chromatography (HPLC; see Chapter 12) after solvent extraction with fluorometric or spectrophotometric detection is mainly used to measure vitamin A. HPLC has brought enhanced specificity, lowered limits of detection, improved accuracy using primary standards, reference materials, and quality assurance schemes, and made acceptable reproducibility achievable (between batch coefficients of variation [CV] of <15% for both vitamin A and β-carotene). In the normal-phase HPLC, compounds to be separated are adsorbed to microparticulate silica gel and are eluted in the order of least polar to most polar. Reversed-phase HPLC is preferable for acid-sensitive compounds such as 5,6-epoxyretinoic acid. Photometric, electrochemical, and mass spectrophotometric detectors have all been used. Refer to Chapter 12 for general principles of chromatography. Vitamin A is light-sensitive, and samples should be protected from light.

Vitamin D

Vitamin D plays an essential role as a hormone in the control of calcium and phosphorous metabolism and bone physiology. It is discussed in Chapter 39.

Fig. 27.2 Participation of A vitamers in the visual cycle. NAD, Nicotinamide-adenine dinucleotide.

Fig. 27.3 Vitaminic forms of vitamin E.

Vitamin E

Vitamin E is the nutritional term for the group of tocopherols and tocotrienols that have biological activity similar to RRR- α -tocopherol (formerly D- α -tocopherol). The Greek letter prefixes α , β , γ , and δ indicates the presence or absence of methyl groups at positions 5 and 7 (Fig. 27.3).

Absorption, Transport, Metabolism, and Excretion

In the presence of bile, vitamin E is absorbed from the small intestine. Most forms of vitamin E are absorbed non-selectively and are secreted in chylomicron particles along with triacylglycerol and cholesterol. Some of this chylomicron-bound vitamin E is transported and delivered to the peripheral tissue (mainly adipose tissue) with the aid of lipoprotein lipase. The liver takes up the chylomicron remnants where α -tocopherol is incorporated into very low-density lipoproteins (VLDLs) by α -tocopherol transfer protein (α -TTP), enabling further distribution of α -tocopherol throughout the body. Vitamin E is excreted via the bile and in the urine as tocopheronic acid and its β -glucuronide conjugate.

Functions

The inhibition of free radical mediated lipid peroxidation is the main role for vitamin E. Tocopherols and tocotrienols inhibit lipid peroxidation largely because they scavenge lipid peroxy radicals faster than the radical can react to adjacent fatty acid side chains or membrane proteins. The resultant tocopheryl or tocotrienyl radicals may then react with additional peroxy radicals to produce tocopherones (nonradicals), or they may be regenerated by transfer of an electron to ascorbate to form the ascorbyl radical. Thus, vitamins E and C act synergistically to reduce lipid peroxidation (Fig. 27.4). α -Tocopherol also induces inhibition of cell proliferation, platelet aggregation, and monocyte adhesion, which are thought to be the result of direct interaction of α -tocopherol with cell components. There is some evidence that vitamin E may have anti-inflammatory properties. A recent study has shown that serum vitamin E is a determinant of bone mass by stimulating osteoclast fusion.

Deficiency

Premature and low birth weight infants are particularly susceptible to the development of vitamin E deficiency because placental transfer is poor and infants have such limited adipose tissue where much of the vitamin is normally stored. Signs of deficiency include (1) irritability, (2) edema, and (3) *hemolytic anemia*. Anemia reflects the shortened life span of erythrocytes with fragile membranes; it does not respond to iron therapy, which may aggravate the condition. Although symptoms of vitamin E deficiency are rare in children and adults, deficiency can occur in some conditions, such as fat malabsorption states including cystic fibrosis and chronic cholestasis in children that in turn cause neuropathy and hemolytic anemia. The genetic disorder *abetalipoproteinemia* (vitamin E is transported on lipoproteins) can also confer vitamin E deficiency (see Chapter 23).

Toxicity

Vitamin E toxicity is usually only ever achieved by excessive dietary supplementation. The US Food and Nutrition Board has recommended a tolerable upper limit of 1000 mg/day of vitamin E for adults 19 years and older.

Laboratory Assessment of Status

HPLC is currently the method of choice for quantification of tocopherols in serum, as it offers the advantages of accuracy (through the use of primary standards) and reproducibility (between-batch CV of <5%) and the ability to quantitate multiple analytes, including vitamin A and some carotenoids, in a single analytical run. Both α - and γ -tocopherols are the principal **vitamers** seen, although others may be detected with minor modifications to the analytical conditions. HPLC-mass spectrometry methods have also been developed and are increasingly being used, given the widespread adoption of this technique by clinical laboratories. Vitamin E is light-sensitive, and it is recommended samples should be protected from light.

Vitamin K

Vitamin K is the common generic name for a group of compounds with a methylated naphthoquinone structure (2-methyl-1,4-naphthoquinones), which are substituted with side chains at carbon 3. *Phylloquinone* (K_1 type) synthesized in plants and *menaquinones* (K_2 type) of bacterial origin are the two principal natural classes of vitamin K (Fig. 27.5). Several synthetic analogs and derivatives have been used in human nutrition; most relate to or derive from *menadione* (K_3).

Absorption, Transport, Metabolism, and Excretion

As for other fat-soluble vitamins, the absorption of natural vitamin K from the small intestine into the lymphatic system is facilitated by bile. Vitamins K_1 and K_2 are bound to chylomicrons for transport from mucosal cells to the liver. Menadione (K_3) is more rapidly and completely absorbed from the gut before entering the portal blood. In the liver, intracellular distribution is seen mostly in the microsomal

Fig. 27.4 Lipoperoxidation and synergistic action of vitamin E and vitamin C.

Fig. 27.5 Vitaminic forms of vitamin K.

fraction, where phenylation of menadione to form K_2 occurs. Release of vitamin K to the bloodstream allows association with circulating β -lipoproteins for transport to other tissue. Only traces of urinary metabolites of vitamins K_1 and K_2 appear in urine.

Functions

The main role of vitamin K is as a cofactor to vitamin K-dependent carboxylase, an enzyme necessary for the

posttranslational conversion of specific glutamyl residues in target proteins to γ -carboxyglutamyl (Gla) residues. This γ -carboxylation increases the affinity of these proteins for calcium. The antihemorrhagic function of vitamin K depends on the formation of the Gla proteins prothrombin (factor II), proconvertin (factor VII), plasma thromboplastin component (factor IX), and Stuart factor (factor X), which together with two other hemostatic vitamin K-dependent proteins, proteins C and S, and Ca^{2+} initiate a process to form thrombin that then catalyzes the conversion of fibrinogen to a fibrin clot.

Proteins that contain γ -carboxyglutamyl are also abundant in bone tissue, with osteocalcin accounting for up to 80% of the total γ -carboxyglutamyl content of mature bone. Epidemiologic studies have shown an association between low vitamin K intakes and hip fracture risk. Evidence indicates that vitamins K and D may act synergistically in maintaining bone density.

Deficiency

Although vitamin K deficiency in the adult is uncommon, the risk is increased with fat malabsorption states such as (1) bile duct obstruction, (2) cystic fibrosis, and (3) chronic pancreatitis and liver disease. Risk is also increased by the use of drugs

that interfere with vitamin K metabolism, such as the coumarin anticoagulants (e.g., warfarin) and antibiotics containing the *N*-methylthiotetrazole side chain (e.g., cephalosporin). Other at-risk groups are hospitalized patients with poor nutrient intakes or those receiving TPN, when fat-soluble vitamin supplements may not fully meet requirements. Conversely, ingestion of supraphysiologic doses of vitamins A and E has been reported to induce vitamin K deficiency, probably through competitive mechanisms. Defective blood coagulation and demonstration of abnormal noncarboxylated prothrombin are at present the only well-established signs of vitamin K deficiency.

Hemorrhagic disease of the newborn can develop because of (1) poor placental transfer of vitamin K, (2) hepatic immaturity leading to inadequate synthesis of coagulation proteins, and (3) the low vitamin K content of early breast milk. Severe diarrhea and antibiotics used to suppress diarrhea exacerbate the situation, so prothrombin concentrations can drop significantly, resulting in bleeding. This condition is routinely prevented by the prophylactic administration of phyloquinone intramuscularly immediately after birth.

Toxicity

The use of high doses of naturally occurring vitamin K (K_1 and K_2) appears to have no known toxic effect; however, menadione (K_3) treatment can lead to the formation of erythrocyte cytoplasmic inclusions known as Heinz bodies and hemolytic anemia.

Laboratory Assessment of Status

Because of its relatively low plasma concentration, vitamin K has long presented an analytical challenge. For this reason, vitamin K status has traditionally been assessed by functional methods, primarily by its effect on clotting time. The *prothrombin time* (PT) is assessed by adding a portion of tissue thromboplastin to recalcified plasma and measuring the clotting time against a normal control sample. In vitamin K deficiency, the PT may rise above 30 seconds (normal, 10 to 14 seconds), and at least 2 seconds beyond the control time. Attempts at cross-laboratory standardization led to the introduction of the international normalized ratio (INR), by which PT can be expressed as a fraction of the control time.

A more sensitive assessment of vitamin K status with respect to prothrombin can be made by the immunoassay of des- γ -carboxy prothrombin, or undercarboxylated prothrombin, PIVKA-II (protein induced by vitamin K absence or antagonism). PIVKA-II has proved to be a useful marker of subclinical vitamin K deficiency. Another measurement of deficient γ -carboxylation, plasma undercarboxylated osteocalcin, has been shown to correlate individually with PIVKA-II and plasma phyloquinone concentrations and has a better correlation with plasma phyloquinone than PIVKA-II.

Direct measurement of plasma phyloquinone is probably the best indicator of vitamin K status and has been shown to correlate with intake. HPLC methods are the mainstay of vitamin K measurement. HPLC-mass spectrometry methods have also been developed.

Fig. 27.6 Thiamine and the pyrophosphate coenzyme.

Vitamin K is light-sensitive, and it is recommended samples should be protected from light.

Vitamin B₁

The structure of *thiamine* (3-[4-amino-2-methyl-pyrimidyl-5-methyl]-4-methyl-5-[β -hydroxyethyl]thiazole) is that of a pyrimidine ring, bearing an amino group, linked by a methylene bridge to a thiazole ring (Fig. 27.6). The thiazole has a primary alcohol side chain at C5, which can be phosphorylated *in vivo* to produce thiamine phosphate esters, the most common of which is thiamine pyrophosphate (TPP; also known as thiamine diphosphate [cocarboxylase]). Monophosphate and triphosphate esters also occur.

Absorption, Transport, Metabolism, and Excretion

Thiamine absorption occurs primarily in the proximal small intestine by a saturable (thiamine transporter) process at low concentration (1 μ mol/L or lower) and by simple passive diffusion beyond that, although percentage absorption diminishes with increased dose. Absorbed thiamine undergoes intracellular phosphorylation, mainly to the pyrophosphate, but at the serosal side, 90% of transferred thiamine is present in the free form. Thiamine uptake is enhanced by thiamine deficiency and is reduced by thyroid hormone, diabetes, and ethanol ingestion. The free vitamin is present in plasma, but the **coenzyme**, TPP, is the primary cellular component. Approximately 30 mg is stored in the body, with 80% as pyrophosphate, 10% as triphosphate, and the rest as thiamine and its monophosphate. About half of body stores are found in skeletal muscle, with much of the remainder in heart, liver, kidneys, and nervous tissues (including the brain, which contains most of the triphosphate).

Functions

Thiamine is required by the body as the pyrophosphate (TPP) in two general types of reactions: (1) the oxidative decarboxylation of 2-oxo acids catalyzed by dehydrogenase complexes, and (2) the formation of α -ketols (ketoses) as catalyzed by transketolase and as the triphosphate (TTP) within the nervous system. TPP functions as the Mg^{2+} -coordinated coenzyme for so-called active aldehyde transfers in multienzyme dehydrogenase complexes that affect decarboxylative conversion of α -keto (2-oxo) acids to acyl-coenzyme A (acyl-CoA) derivatives, such as pyruvate dehydrogenase and α -ketoglutarate dehydrogenase. These are often localized in the mitochondria, where efficient use in the Krebs tricarboxylic acid (citric acid) cycle follows.

Transketolase is a TPP-dependent enzyme found in the cytosol of many tissues, especially liver and blood cells, in which principal carbohydrate pathways exist. In the pentose phosphate pathway, which additionally supplies reduced nicotinamide-adenine dinucleotide phosphate (NADPH) necessary for biosynthetic reactions, this enzyme catalyzes the reversible transfer of a glycoaldehyde moiety from the first two carbons of a donor ketose phosphate to the aldehyde carbon of an aldose phosphate. TTP is also thought to be involved in the regulation of ion channels—specifically chloride channels of large unitary conductance, the so-called maxi-Cl channels.

Deficiency

Causes of thiamine deficiency include inadequate intake caused by diets largely dependent on milled, nonenriched grains such as rice and wheat, or the ingestion of raw fish containing thiaminases, which hydrolytically destroy the vitamin in the gastrointestinal tract. Tea may also contain antithiamine factors. Chronic alcoholism often leads to thiamine deficiency caused by reduced intake, impaired absorption, impaired use, and reduced storage, and may lead clinically to the *Wernicke-Korsakoff syndrome*. **Wernicke encephalopathy** classically presents with ophthalmoplegia, ataxia, and confusion. Other at-risk groups include those receiving parenteral nutrition without adequate thiamine supplementation, elderly patients taking diuretics, and patients undergoing long-term renal dialysis.

Beriberi (origin: Sinhalese from a word meaning weakness) is the disease resulting from thiamine deficiency. Clinical signs of thiamine deficiency primarily involve the nervous and cardiovascular systems. In the adult, symptoms most frequently observed include mental confusion, anorexia, muscular weakness, ataxia, peripheral paralysis, ophthalmoplegia, edema (*wet beriberi*), muscle wasting (*dry beriberi*), tachycardia, and an enlarged heart. In infants, symptoms appear suddenly and severely, often involving cardiac failure and cyanosis. Commonly, the distinction between wet (cardiovascular) and dry (neuritic) manifestations of beriberi relate to duration and severity of the deficiency, the degree of physical exertion, and caloric intake. The wet or edematous beriberi results from severe physical exertion and high carbohydrate intake, whereas the dry or polyneuritic beriberi stems from relative inactivity with caloric restriction during the chronic deficiency. Nervous system involvement includes peripheral neuropathy, Wernicke encephalopathy, and the amnesic psychosis of Korsakoff syndrome. More rarely, but especially in seriously ill patients in hospitals, an acute form of cardiac failure has been described (*Shoshin beriberi*), which may be fatal but can be successfully and rapidly reversed with high-dose intravenous thiamine.

Toxicity

No reports have described adverse effects from consumption of excess thiamine from food and supplements.

Laboratory Assessment of Status

The free or phosphorylated forms of thiamine can be measured directly in a suitable body fluid or tissue, or its properties as an enzymatic cofactor can be exploited in a functional assay.

Fig. 27.7 Riboflavin and flavin mononucleotide (FMN) as components of flavin adenine dinucleotide (FAD).

The most commonly used enzyme for the functional assay is transketolase. Transketolase catalyzes two reactions in the pentose phosphate pathway. As an enzyme within the erythrocyte, transketolase is independent of nonspecific changes in the extracellular plasma. As vitamin B₁ deficiency becomes more severe, (1) thiamine becomes limiting in the body cells, (2) the amount of the coenzyme is depleted, and (3) transketolase activity subsequently diminishes. The *TPP effect* measures the extent of depletion of the transketolase enzyme for coenzyme by assaying enzyme activity before and after TPP supplementation.

Circulating thiamine concentration may be directly measured in plasma, erythrocytes, or whole blood. The plasma (or serum) concentration is thought to reflect recent intake and is mainly unphosphorylated thiamine at low concentration (around 10 to 20 nmol/L). Because the erythrocyte contains approximately 80% of the total thiamine content of whole blood (mainly as the pyrophosphate) and erythrocyte thiamine stores deplete at a similar rate to other major organs, HPLC measurement of TPP in erythrocytes is a good indicator of body stores. Whole blood samples may be analyzed in a similar manner to washed erythrocytes and may provide the advantage of simpler sample handling, but they are subject to variable plasma dilution. However, a good correlation has been obtained between erythrocyte and whole blood TPP concentrations, particularly when whole blood TPP included a correction for hemoglobin (Hb).

Vitamin B₂

Riboflavin, commonly known as vitamin B₂, is the precursor of all biologically important flavins, notably flavin mononucleotide, FMN (riboflavin-5'-phosphate) and flavin adenine dinucleotide, FAD (Fig. 27.7). FMN is formed from riboflavin by flavokinase-catalyzed phosphorylation, and FAD is formed from FMN and ATP by the action of FAD synthetase, also called *pyrophosphorylase*. FAD is further converted by covalent bonding to form various tissue flavoproteins.

Absorption, Transport, Metabolism, and Excretion

Most dietary riboflavin is taken in as a complex of proteins with the coenzymes FMN and FAD. These coenzymes are released from noncovalent attachment to proteins as a consequence of gastric acidification. Nonspecific action of pyrophosphatase and phosphatase on the coenzyme occurs in the upper gut. The vitamin is primarily absorbed in the proximal small intestine by a saturable active transport system. Bile salts appear to facilitate uptake, and a modest amount of the vitamin circulates via the enterohepatic system. The transport of flavins in human blood involves loose binding to albumin and tight binding to numerous immunoglobulins. Pregnancy increases the concentration of carrier protein for riboflavin, which results in a higher rate of riboflavin uptake at the maternal surface of the placenta. Uptake of riboflavin into the cells of organs such as liver is facilitated, possibly requiring a specific carrier at physiologic concentrations, but it can occur by diffusion at higher concentrations.

Functions

Riboflavin and its coenzyme derivatives are involved in a large variety of chemical reactions. These derivatives are capable of one- and two-electron transfer processes and play a pivotal role in coupling the two-electron oxidation of most organic substrates to the one-electron transfer of the respiratory chain, thus being involved in energy production. They also function as electrophiles and nucleophiles, with covalent intermediates of flavin and substrate frequently involved in catalysis. Flavoproteins catalyze dehydrogenation reactions, hydroxylations, oxidative decarboxylations, deoxygenations, and reductions of oxygen to hydrogen peroxide. Other major functions of riboflavin include drug metabolism in conjunction with the cytochrome P450 enzymes and lipid metabolism. Flavins also have pro-oxidative and antioxidative functions. They are thought to contribute to oxidative stress through their ability to produce superoxide and to catalyze the production of hydrogen peroxide. As an antioxidant, FAD is a coenzyme to glutathione reductase in the regeneration of reduced glutathione from oxidized glutathione, which is necessary for the removal of lipid peroxides. Riboflavin deficiency is associated with increased lipid peroxidation. FAD is a cofactor to methylenetetrahydrofolate reductase (MTHFR) in the remethylation of homocysteine.

Deficiency

Although riboflavin has a wide distribution in foodstuffs, many people live for long periods on low intakes; consequently, minor signs of deficiency are common in many parts of the world. In addition to poor intake, other causes of deficiency include hypothyroidism and adrenal insufficiency, which inhibit the conversion of riboflavin to its coenzyme derivatives; drugs such as chlorpromazine, imipramine, and amitriptyline, which have a similar tricyclic structure to riboflavin; the anticancer drug doxorubicin; and the antimalarial quinacrine. Excess ethanol ingestion interferes with both digestion and absorption of riboflavin.

Because flavin coenzymes are widely distributed in intermediary metabolism, the consequences of deficiency may be widespread. Riboflavin coenzymes are involved in the metabolism of vitamin B₁₂ and folic acid (irreversible reduction of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate) and therefore are a determinant of plasma homocysteine concentration; pyridoxine (PN; conversion to pyridoxal 5-phosphate [PLP]); and niacin (conversion of 5-hydroxytryptamine to tryptophan that is required for niacin synthesis). Therefore deficiency will affect enzyme systems other than those requiring flavin coenzymes *per se*.

The deficiency syndrome is characterized by (1) sore throat; (2) hyperemia; (3) edema of the pharyngeal and oral mucous membranes; (4) cheilosis; (5) angular stomatitis; (6) glossitis (magenta tongue); (7) seborrheic dermatitis; and (8) normochromic, normocytic anemia associated with pure red blood cell (RBC) aplasia of the bone marrow.

Toxicity

Probably as a result of its limited solubility and limited gastric absorption, no adverse effects have been associated with ingestion of riboflavin appreciably above RDA amounts.

Laboratory Assessment of Status

Riboflavin status can be assessed by (1) determination of urine riboflavin excretion, (2) by a functional assay measuring the erythrocyte glutathione reductase activation coefficient (EGRAC), which is the ratio between enzyme activity determined with and without the addition of the cofactor, FAD, or (3) direct measurement of riboflavin or its metabolites in plasma or erythrocytes.

Riboflavin status is commonly assessed by the determination of FAD-dependent glutathione reductase activity in freshly lysed erythrocytes. This enzyme-based assay has been chosen for most surveys of riboflavin status. Most methods measure the rate of change of absorbance at 340 nm caused by the oxidation of NADPH and have been automated to give rapid throughputs and CVs of less than 2% within the run, although some have used fluorescence detection with increased sensitivity. Direct measurement of riboflavin, FMN, and FAD in plasma or erythrocytes is undertaken by HPLC, usually with fluorescence detection after protein precipitation, or by capillary zone electrophoresis with laser-induced fluorescence detection (CZE-LIF). In critically ill patients, plasma FAD, which is bound to albumin, may fall as a result of the systemic inflammatory response and due to redistribution of FAD, as there is increased tissue requirement whereas red cell FAD is unaffected. Therefore the measurement of red cell FAD is more sensitive and recommended, especially in critically ill patients. As vitamin B₂ is light-sensitive, samples should be protected from light.

Vitamin B₆

The vitamin B₆ group comprises three natural forms, *pyridoxine* (pyridoxol; PN), *pyridoxamine* (PM), and *pyridoxal* (PL), which are 4-substituted 2-methyl-3-hydroxyl-5-hydroxymethyl pyridines (Fig. 27.8). During metabolic conversion, each vitamin

Fig. 27.8 Free and phosphorylated forms of vitamin B₆. R = CH₂OH for pyridoxine, CH₂NH₂ for pyridoxamine, and CHO for pyridoxal.

becomes phosphorylated at the 5-hydroxymethyl substituent. PLP is the coenzyme form that participates in a large number of B₆-dependent enzyme reactions.

Absorption, Transport, Metabolism, and Excretion

The phosphorylated sources are hydrolyzed by the intraluminal action of intestinal alkaline phosphatase to enable cellular uptake. The nonphosphorylated forms are readily absorbed by the mucosal cells through a process of passive diffusion. In other cells requiring vitamin B₆, the unphosphorylated vitamers may be “metabolically trapped” as phosphorylated forms by cytoplasmic PL kinase, which is responsible for catalyzing the ATP-dependent phosphorylation of all three vitamin forms. Transport to the liver via the portal vein is done by the unphosphorylated form.

Release of free vitamin, mainly PL, occurs when physiologic nonsaturating concentrations of vitamin are absorbed. Here the phosphates are hydrolyzed by nonspecific alkaline phosphatase located on the plasma membrane of cells. Some PLP is released into the circulation by the liver and circulates complexed to proteins—mostly albumin. PLP is the principal tissue form of vitamin B₆, whereas PL constitutes much of the circulating vitamin. The main catabolite excreted in urine is 4-pyridoxic acid (4-PA), which is formed by the action of the FAD-dependent general liver aldehyde oxidase.

Functions

As coenzyme PLP, vitamin B₆ functions in more than 100 reactions that embrace the metabolism of macronutrients, such as proteins, carbohydrates, and lipids. These enzymes include aminotransferases; decarboxylases that lead to the formation of various functional amines, including epinephrine and norepinephrine; phosphorylases; and cystathionine β-synthase in the trans-sulfuration pathway of homocysteine. The biosynthesis of heme depends on the early formation of 5-aminolevulinate from PLP-dependent condensation of glycine and succinyl-CoA, followed by decarboxylation. In lipid metabolism, PLP-dependent condensation of L-serine with palmitoyl-CoA forms 3-dehydrosphinganine, a precursor of sphingomyelins. Therapeutically, vitamin B₆ has been used for the treatment of some intractable seizures in neonates and infants and for the treatment of other vitamin B₆-responsive inborn errors of metabolism and the carpal tunnel syndrome.

Deficiency

Vitamin B₆ deficiency in isolation is rare; it is more usual in association with deficits in other vitamins of the B-complex. Deficiency has been observed with the antituberculosis drug

isoniazid (isonicotinic acid hydrazide). Penicillamine (β-dimethyl cysteine), used in the treatment of patients with Wilson disease, inactivates PLP by forming a thiazolidine derivative. Other drugs that can cause vitamin B₆ deficiency include the antiparkinsonian drugs benserazide and carbidopa, which react by forming hydrazones, and theophylline.

Several vitamin B₆-responsive inborn errors of metabolism are known, including homocystinuria, xanthurenic aciduria, primary cystathioninuria, and pyridoxine-responsive epilepsy. Low vitamin B₆ status (together with low vitamin B₁₂ and folate status) in humans has been linked to hyperhomocystinemia and is an independent risk factor for cardiovascular disease, although clinical trials have been inconclusive.

Toxicity

Although no adverse effects have been observed with high intakes of vitamin B₆ from food sources, high oral supplemental doses have been found to have neurotoxic and photosensitive effects. Based on the end point of development of sensory neuropathy, a tolerable upper intake amount of 100 mg/day for adults is recommended.

Laboratory Assessment of Status

As with the other B vitamins that act as coenzymes, biochemical assessment of vitamin B₆ can be made by direct chemical analysis of the vitamer or its metabolites, or by functional means. Measurements that have been used are PLP in plasma or red cells, its metabolite 4-PA in urine or plasma, the activity and activation coefficient of the red cell aminotransferases (aspartate and alanine), and the tryptophan load metabolite excretion test. Because no single marker adequately reflects status, a combination of these markers offers the best approach.

Plasma PLP and plasma or urine 4-PA are most commonly measured by HPLC, PLP with fluorescence detection following precolumn fluorophore formation as a semicarbazone or a pyridoxic acid phosphate, and 4-PA with its natural fluorescence. Using ion-pair reversed-phase chromatography, plasma vitamin B₆ vitamers (PLP, PL, PN, PMP, PM, and 4-PA) can be measured.

Functional assessment of vitamin B₆ status may be made by measuring the activity of red cell aspartate (or alanine) aminotransferase and its activation coefficient on incubation with PLP, although because the **apoenzyme** is highly unsaturated with PLP, the results obtained have greater variability than those derived by corresponding methods for vitamins B₁ and B₂ and thus are considered less useful.

Vitamin B₆ is light-sensitive, samples should be protected from light.

Vitamin B₁₂

Vitamin B₁₂ is one of the most structurally complex small molecules produced by nature, and the only known carbon-metal bond (involving cobalt) found in a biologically active molecule. The generic term *vitamin B₁₂* refers to a group of physiologically active substances chemically classified as cobalamins or corrinoids. They are composed of tetrapyrrole

Fig. 27.9 The structure of 5'-deoxyadenosyl cobalamin.

rings surrounding central cobalt atoms and nucleotide side chains attached to the cobalt atoms. The cobalamin tetrapyrrole ring, exclusive of cobalt and other side chains, is called a *corrin*. All compounds containing this corrin nucleus are corrinoids. The cobalt-corrin complex is termed *cobamide* (Fig. 27.9). Cobalamins differ in the nature of additional side groups bound to cobalt. Examples include methyl (methylcobalamin), 5'-deoxyadenosine (deoxyadenosyl [short form, adenosyl], cobalamin, or coenzyme B₁₂), hydroxyl (hydroxocobalamin), H₂O (aquocobalamin, or vitamin B_{12b}), and cyanide (cyanocobalamin).

Absorption, Transport, Metabolism, and Excretion

Vitamin B₁₂ is known to be tightly bound to proteins and has to be released from food by acid and the enzyme pepsin present in the stomach. The synthetic form is free and therefore readily available for metabolism. Thus acid-blocking drugs such as proton pump inhibitors (e.g., omeprazole) can cause vitamin B₁₂ deficiency. The free vitamin B₁₂ molecule is bound to haptocorrin (HC, R protein) and travels with it into the duodenum, where the HC is digested by pancreatic enzymes. Liberated vitamin B₁₂ then binds to intrinsic factor (IF), a glycoprotein with a molecular weight of approximately 50 kDa that is produced by the gastric parietal cells in the fundus and body of the stomach. One molecule of IF binds one molecule of vitamin B₁₂. Gastric secretion of IF is stimulated by food, histamine, and gastrin produced by the antrum portion of the stomach; it is inhibited by vagal blockade. When the vitamin B₁₂-IF complex reaches the distal ileum, it is bound by specific receptors known as the cubam complex, which consists of two subunits, namely cubilin and amnionless on the surface of mucosal epithelial cells, and it is internalized. The vitamin B₁₂-IF complex is dissociated within the mucosal epithelial cells by lysosomes and released into blood.

In circulation, vitamin B₁₂ then binds to two circulating binding proteins, HC (referred to as holohaptocorrin when bound to vitamin B₁₂ and previously known as transcobalamin [TC] I) and TC (holotranscobalamin when bound to vitamin B₁₂ and previously known as TC II); however, it is only the TC-bound fraction for which there is a receptor-mediated cellular uptake as described above and is therefore the bioactive fraction. The function of HC that is released by granulocytes is currently unknown, and low haptocorrin concentrations, found in approximately 15% of persons with low serum cobalamin, could be one of the most common causes of low cobalamin concentrations. HC accounts for 80% to 94% of endogenous plasma vitamin B₁₂, whereas TC accounts for the remainder, but the latter is the more important vitamin B₁₂ transport protein in plasma. TC transports vitamin B₁₂ to receptors on cell membranes throughout the body. The TC-vitamin B₁₂ complex enters the cell by pinocytosis. Lysosomal proteolysis degrades TC and releases the vitamin B₁₂. Unbound vitamin B₁₂ can enter the tissue cells, but the process is very inefficient.

As discussed above, only vitamin B₁₂ bound to TC is capable of cellular uptake and as a result malabsorption of TC-bound vitamin B₁₂ leads to deficiency in a large proportion of cases. Almost all vitamin B₁₂ (bound to TC) is taken up by hepatocytes as the blood in the portal vein passes through the liver where it is stored, and released into blood to meet physiologic demands. If the quantity of vitamin B₁₂ exceeds the capacity of hepatocyte receptors, most of the excess is excreted by the kidneys. Normally, approximately 1 mg of vitamin B₁₂ is stored in the liver—a quantity equivalent to the daily metabolic requirement for 2000 days. Thus when the dietary supply of vitamin B₁₂ is interrupted or mechanisms of absorption are impaired, vitamin B₁₂ deficiency does not become evident for several years.

Vitamin B₁₂ is continually secreted in the bile, but most is reabsorbed and is available for metabolic functions. If circulating vitamin B₁₂ concentrations exceed the binding capacity of the blood, the excess will be excreted in the urine, but in most circumstances, the highest losses of vitamin B₁₂ occur through the feces.

Functions

Vitamin B₁₂ is a cofactor or coenzyme for various enzyme systems. In humans it is required in both adenosylcobalamin and methylcobalamin. Adenosylcobalamin is a coenzyme to L-methylmalonyl-CoA mutase in the conversion of L-methylmalonyl CoA to succinyl-CoA. The conversion of L-methylmalonyl-CoA to succinyl-CoA links propionyl-CoA, which is formed from branched-chain amino acids such as valine, isoleucine, and methionine with the tricarboxylic acid (TCA) cycle. Congenital defects of mutase synthesis or the inability to synthesize adenosylcobalamin results in life-threatening methylmalonic aciduria and metabolic ketoacidosis. Methylcobalamin is a coenzyme to methionine synthase in the conversion of homocysteine to methionine. In this reaction (Fig. 27.10), methylcobalamin serves as an intermediate in the transfer of a methyl group from 5-methyltetrahydrofolate to homocysteine

Fig. 27.10 Metabolism of homocysteine and methionine. *NADPH*, Nicotinamideadenine dinucleotide phosphate.

for the formation of methionine. Methionine is required for protein synthesis and as the methyl donor, S-adenosylmethionine. Congenital defects in methionine synthase or the synthesis of methylcobalamin result in severe hyperhomocysteinemia. As discussed under the section on vitamin B₆, defects in the enzyme cystathionine β-synthase or its cofactor vitamin B₆ also results in hyperhomocysteinemia.

Deficiency

Deficiency of vitamin B₁₂ in humans is associated with macrocytosis, megaloblastic anemia, and neuropathy. The most common cause of vitamin B₁₂ deficiency is **pernicious anemia**, an autoimmune disease in which chronic atrophic gastritis in the fundus and body region of the stomach results from autoantibodies to gastric parietal cells directed against gastric parietal cell H⁺/K⁺-ATPase, which is responsible for secreting acid (H⁺) in exchange for potassium (K⁺). Loss of parietal cells also leads to decreased production of IF. In addition to IF deficiency, blocking autoantibodies that bind the Vitamin B₁₂-binding sites of IF prevent the formation of Vitamin B₁₂-IF complex required for recognition by the cubam complex in the distal ileum. At-risk groups include (1) those older than 65 years of age; (2) those with malabsorption; (3) vegetarians or vegans; (4) those with autoimmune disorders (pernicious anemia usually occurs as part of the autoimmune polyglandular syndrome type 3B that includes autoimmune thyroiditis); and (5) those taking prescribed medication known to interfere with vitamin absorption or metabolism, including nitrous oxide (also known as laughing gas that inactivates vitamin B₁₂ by oxidizing its cobalt atom),

phenytoin, dihydrofolate reductase inhibitors, metformin, and proton pump inhibitors; as well as (6) infants with suspected metabolic disorders.

Intestinal malabsorption of vitamin B₁₂ may be caused by gastrectomy or ileal resection, with an inverse relationship noted between the length of ileum resected and absorption of vitamin B₁₂. Other causes of malabsorption include tropical sprue, inflammatory disease of the small intestine such as celiac disease, intestinal stasis with overgrowth of colonic bacteria, which consume vitamin B₁₂ ingested by the host, and human immunodeficiency virus (HIV) infection. Another cause of vitamin B₁₂ malabsorption is failure to extract cobalamin from food. This is particularly a problem in patients with compromised gastric status or early in the course of development of pernicious anemia.

Vegetarians have a lower intake of vitamin B₁₂ than omnivores, and although clinical signs of deficiency are uncommon, biochemical markers of status indicate functional vitamin B₁₂ deficiency.

A large number of disorders are associated with cobalamin deficiency in infancy or childhood. Of these, the most commonly encountered is the **Imerslund-Grasbeck syndrome**, a condition that is characterized by inability to absorb vitamin B₁₂, with or without IF, and proteinuria. It appears to be due to an inability of intestinal mucosa to absorb the vitamin B₁₂-IF complex as a result of mutations in cubilin or amnionless. The second most common of these is congenital deficiency of gastric secretion of IF. Very rarely, congenital deficiency of vitamin B₁₂ in a breast-fed infant is due to deficiency of vitamin B₁₂ in maternal breast milk resulting from unrecognized

pernicious anemia in the mother. This is rare because most women with undiagnosed and untreated pernicious anemia are infertile. Methylmalonic acidemias (acidurias) and homocystinemias may be due to vitamin B₁₂ deficiency and, depending on the underlying mutation, may or may not be responsive to supplementation with the vitamin.

The hematologic effects of vitamin B₁₂ deficiency are indistinguishable from those of folate deficiency. Classical morphologic changes in the blood, in approximate order of appearance, are as follows: hypersegmentation of neutrophils, macrocytosis, anemia, leukopenia, and thrombocytopenia, with megaloblastic changes in bone marrow accompanying peripheral blood changes.

In addition to hematologic changes, vitamin B₁₂ deficiency can lead to a demyelinating disorder of the central nervous system in man. Serious and often irreversible neurologic disorders can occur, such as burning pain or loss of sensation in the extremities, weakness, spasticity and paralysis, confusion, disorientation, and dementia. This condition has been given the name *subacute combined degeneration of the spinal cord*. Neurologic symptoms may occur without any discernible hematologic changes in the blood; indeed an intriguing inverse relationship between the hematologic and the neurologic has been observed. Vitamin B₁₂ deficiency may be associated with other mainly gastrointestinal complications, such as glossitis of the tongue, appetite and weight loss, flatulence and constipation, mental changes, and infertility.

Depending on the laboratory and the procedure used, reference intervals vary widely. A recent WHO consultation defined a serum vitamin B₁₂ concentration less than 203 ng/L (150 pmol/L) as deficient. Vitamin B₁₂ concentrations within the reference interval may not necessarily reflect adequate vitamin B₁₂ status, because serum concentrations may be maintained at the expense of tissue stores. Conversely, low serum vitamin B₁₂ concentrations may not be indicative of vitamin B₁₂ deficiency.

Toxicity

No adverse effects have been associated with excess vitamin B₁₂ intake from food or supplements in healthy people.

Laboratory Assessment of Status

Both direct and indirect (functional) methods are available for assessment of vitamin B₁₂ status. Indirect tests include assays for urinary and serum concentrations of methylmalonic acid (MMA), plasma homocysteine, the deoxyuridine suppression test, and the now rarely used vitamin B₁₂ absorption (Schilling) test. Cytochemical staining of RBC precursors and the test for IF blocking antibodies are other ancillary methods of assessing vitamin B₁₂ status.

Multiple automated and semiautomated systems are available for measuring vitamin B₁₂ using, for example, chemiluminescence as a signal. Most immunometric methods use solid-phase separation by immobilizing the IF antibodies on beads or magnetic particles. Spurious elevations of vitamin B₁₂ have been reported in patients with pernicious anemia when using automated analyzers based on the competitive

binding of serum vitamin B₁₂ with reagents using IF. This has been attributed to the high levels of IF-blocking autoantibodies in these patients interfering in the assay. Up to 70% of patients with pernicious anemia have IF-blocking antibodies. Assay manufacturers are aware of this problem and have taken steps to inactivate the IF-blocking antibodies. However, at the present time the scale of the problem is unknown, and alternative methods should be used if in doubt, including the measurement of IF-blocking antibodies.

Indirect tests assess the functional adequacy of vitamin B₁₂. Serum MMA concentration is increased when lack of adenylobalamin causes a block in the conversion of methylmalonyl-CoA to succinyl-CoA. It is a sensitive test of status, being often the first analyte to be raised in subclinical vitamin B₁₂ deficiency. It has a further advantage in that it is unaffected by folate deficiency. Unfortunately MMA is increased by renal insufficiency and in persons above the age of 65 years. Plasma total homocysteine concentration is also a sensitive indicator of vitamin B₁₂ status because methylcobalamin is required for the remethylation of homocysteine to methionine, but it is not specific, being elevated in deficiencies of folate, vitamin B₁₂, vitamin B₂, and vitamin B₆. There are several preanalytical variables affecting it: high protein meal and venous stasis may increase it; it is decreased in the supine position as it is bound to albumin. EDTA plasma is the most widely recommended sample type and should be centrifuged within 1 hour or kept cold by collecting on ice until centrifugation.

The measurement of holotranscobalamin is potentially useful as a specific marker of biologically available vitamin B₁₂, because it is the only vitamin B₁₂ moiety that is specifically available for uptake by all cells and has been shown to have the best diagnostic accuracy for vitamin B₁₂ deficiency. However, assays for holotranscobalamin are not widely available at present, and their sensitivity and specificity in the diagnosis of vitamin B₁₂ deficiency remains to be established.

Folic Acid

Vitamin B₉, folate, and folic acid are generic terms for a family of compounds that function as coenzymes in the processing of one-carbon units and that are derived from pteric acid, to which one or more molecules of glutamic acid are attached. Pteric acid is composed of a pteridine ring joined to a *p*-aminobenzoic acid residue (Fig. 27.11). When pteric acid is conjugated with one molecule of L-glutamic acid, pteroylglutamic acid is formed; this can be reduced to dihydrofolic acid (DHF) with hydrogens in positions 7 and 8, or to tetrahydrofolate (THF) with hydrogens in positions 5, 6, 7, and 8. Only the reduced forms are biologically active. Other folate derivatives have multiple glutamic acid residues ranging from 1 to 7. As a summary, folate is converted by specific enzymes to dihydrofolate (DHF), which is converted to THF and is in turn converted to methylene-THF and finally to 5-methyl-THF.

Absorption, Transport, Metabolism, and Excretion

Folate is absorbed from dietary sources mainly as reduced methyl- and formyl-tetra-hydropteroylpolyglutamates. The

Fig. 27.11 Structure and relationships of folic acid and its derivatives.

bioavailability of folate from food sources is variable and is dependent on factors such as incomplete release from plant cellular structure, entrapment in food matrix during digestion, inhibition of deglutamation by other dietary constituents, and possibly the degree of polyglutamation. Polyglutamate forms of folate present in food are first converted to monoglutamates, by pteroylpolyglutamate hydrolase, in the intestinal mucosa. Absorption of monoglutamyl folates at low concentration occurs through a saturable transport process at an acidic pH of around 5, with an additional, apparently nonsaturable absorption mechanism when intestinal folate concentrations exceed 5 to 10 $\mu\text{mol/L}$. After cellular uptake, most of the folate is reduced and methylated and enters the circulation as THF, circulating loosely bound to albumin or to a lesser degree to a high-affinity folate-binding protein (FBP). Uptake by certain cells (kidney, placenta, and choroid plexus) occurs by membrane-associated FBPs that act as folate receptors, and the reduced folate carrier, a member of the SLC19 family, facilitates uptake by most tissue. Once THF is demethylated and converted to the polyglutamyl form by folypolyglutamate synthase, it is retained within the cell. For release into the circulation, the polyglutamates are reconverted to monoglutamates by polyglutamate hydrolase.

Folic acid and vitamin B₁₂ metabolism is linked by the reaction that transfers a methyl group from THF to cobalamin. In cases of cobalamin deficiency, folate is “trapped” as methyl-THF and is “metabolically dead.” It cannot be recycled as THF back into the folate pool to serve as the main one-carbon unit acceptor for many biochemical reactions. Eventually, cellular depletion of methylene-THF ensues, causing a reduction in thymidyl acid synthesis, which, in turn, results in megaloblastic anemia and neuropathies. This

concept is supported by the fact that THF corrects megaloblastic anemia in patients with congenital methylmalonic aciduria and homocystinuria, whereas it is not corrected with methyl-THF.

Protein-free plasma folate is filtered at the glomerulus, and most is reabsorbed by the proximal renal tubules. Most of the biliary excreted folate is reabsorbed in the enterohepatic circulation. Fecal losses are similar to urinary losses.

Functions

Folate coenzymes, together with coenzymes derived from vitamins B₁₂, B₆, and B₂, are essential for one-carbon metabolism. Biochemically, a carbon unit from serine or glycine is transferred to THF to form methylene-THF, which then is (1) used in the synthesis of thymidine (and incorporation into DNA), (2) oxidized to formyl-THF for use in the synthesis of purines (precursors of RNA and DNA), or (3) reduced to methyl-THF, which is necessary for the methylation of homocysteine to methionine. Much of this methionine is converted to S-adenosylmethionine, a universal donor of methyl groups to DNA, RNA, hormones, neurotransmitters, membrane lipids, and proteins. Some of these reactions are illustrated in Fig. 27.12.

Deficiency

Deficiency of folate may result from (1) absence of intestinal microorganisms (gut sterilization), (2) poor intestinal absorption (e.g., after surgical resection, in celiac disease or sprue), (3) insufficient dietary intake (including chronic alcoholism), (4) excessive demands (as in pregnancy, liver disease, and malignancies), (5) administration of antifolate drugs (e.g., methotrexate), and (6) anticonvulsant therapy

Fig. 27.12 The five major metabolic functions of folate in human cells.

(that increases folate requirements, especially during pregnancy). Inadequate folate intake leads first to decreased serum folate concentration, then to a decrease in RBC folate concentration and an increase in plasma homocysteine, and then to megaloblastic changes in the bone marrow and other tissues. Megaloblastic anemia (characterized by large, abnormally nucleated erythrocytes in the bone marrow) is the major clinical manifestation of folate deficiency, although sensory loss and neuropsychiatric changes may also occur. Deficiencies of folate and iron may coexist in malnourished people, in which case the latter may mask the expected macrocytic and megaloblastic changes.

Pregnancy brings increased demand to folate stores because of increased DNA synthesis, and one-carbon transfer reactions and low serum folate concentrations in pregnancy are associated with adverse outcomes, including preterm delivery, infant low birth weight, and fetal growth retardation. In addition, many observational studies have confirmed a reduction in risk of neural tube defects (NTDs) with periconceptual folic acid supplementation. Current suggestions are that women planning pregnancy should take at least 400

µg/day until the 12th week of pregnancy, although a daily intake of 5 mg of folic acid is recommended, especially for those with a previous history of NTD. Recent meta-analyses have strongly suggested a significant association of the variant 5,10-methylenetetrahydrofolate reductase (MTHFR) C677T polymorphism with increased risk of NTDs.

The increase in plasma homocysteine concentration has been postulated to be an independent risk factor for coronary artery disease and cerebrovascular disease. The involvement of folate in its coenzyme forms with homocysteine and methionine metabolism is summarized in Fig. 27.10. Folate is the principal micronutrient determinant of homocysteine status, and supplementation with folate (0.5 to 5.0 mg/day) has been used as a treatment modality to reduce circulating homocysteine concentrations. However, the most recent Cochrane meta-analyses of trials of homocysteine-lowering therapy with folate, vitamins B₆ or B₁₂ given alone or in combination have not shown a reduction in cardiovascular disease.

Folate appears to have a protective effect on colorectal cancer development but is associated with increased risk of gastric cancer, prostate cancer, and may be associated with lung

cancer. One meta-analysis of 10 randomized clinical trials (RCTs) showed a borderline significant increase in frequency of overall cancer in the folic acid-supplemented group compared with controls.

Toxicity

No adverse effects have been reported from the consumption of folate-fortified foods; thus any signs of toxicity are associated with supplemental folate. Most of the limited evidence suggests that excessive folate supplementation can precipitate or exacerbate neuropathy in vitamin B₁₂-deficient subjects, and it is this end point that has been used to set a tolerable upper intake concentration of 1 mg/day from fortified foods or supplements for adults. One recognized complication of folate supplementation is that it “masks” vitamin B₁₂ deficiency, because the associated anemia responds to folate. This may delay treatment of any neurologic abnormalities. It has been recommended that if a low serum folate is present concomitantly with low vitamin B₁₂, the latter should be corrected first.

Laboratory Assessment of Status

Folate status may be reliably assessed by direct measurement of serum and RBC or whole blood concentrations using immunometric assays, and its metabolic function as a coenzyme may be assessed by metabolite concentrations such as plasma homocysteine. Serum folate concentrations are considered indicative of recent intake and not of tissue stores, but serial measurements have been used to confirm adequate intake. Whole blood and RBC folate concentrations are more indicative of tissue stores over the lifetime of RBCs and are therefore a better indicator of longer term folate status than serum folate. Because folate is taken up only by the developing RBC in the bone marrow and not by the mature cell, RBC concentrations reflect folate status over the 120-day life span of the cell. However, in general serum and RBC folate provide equivalent information regarding folate status.

Plasma homocysteine is considered a sensitive indicator of folate status and is strongly correlated with serum folate concentration in the lower range, which is below 10 nmol/L (4.5 µg/L). A homocysteine concentration above 15 µmol/L is indicative of folate deficiency. However, as the concentration of homocysteine is dependent on age, gender, renal function, genetic factors, and the status of other vitamins (B₆ and B₁₂), it is not a specific marker of folate status.

Due to the instability of folate in serum, it is therefore recommended that if delay in transportation is anticipated, serum should be separated from RBCs by centrifugation and stored frozen until analysis. As there is a significant amount of folate in RBCs, hemolysis invalidates serum folate results.

Vitamin C

The term *vitamin C* refers to all molecules that exhibit antiscorbutic properties (derived from Latin word for scurvy, scorbutus) in humans and includes both ascorbic acid and its oxidized form, dehydroascorbic acid (DHA), as shown in Fig. 27.13.

Fig. 27.13 L-Ascorbic and dehydroascorbic acids.

Absorption, Transport, Metabolism, and Excretion

Gastrointestinal absorption of ascorbic acid occurs throughout the ileum via a combination of sodium-dependent active transport at low concentrations and simple diffusion at high concentrations. Vitamin C is found in most tissues including the brain, but glandular tissues, such as pituitary, adrenal cortex, corpus luteum, and thymus, have the highest amounts, and the eye lens has 20 to 30 times the plasma concentration. In plasma, vitamin C exists predominantly as the ascorbate ion. Excretion of unchanged ascorbate occurs increasingly with increased dosage, with almost all of an injected dose of more than 500 mg excreted over 24 hours.

Functions

Ascorbic acid, working in synchrony with vitamin E, is one of the most effective antioxidants in biological fluids and is capable of scavenging physiologically important reactive oxygen species and reactive nitrogen species. Vitamin C has been shown to also exhibit pro-oxidant properties, and although pro-oxidants tend to have deleterious effects, pharmacologic doses of ascorbate may have beneficial pro-oxidant activity in the treatment of certain diseases especially cancer. It is increasingly being recognized that the balance between antioxidant and pro-oxidant activity is important for health, and too much antioxidant might actually be harmful.

Ascorbic acid acts as a cofactor for a number of mixed function oxidases in hydroxylation processes in which it promotes enzyme activity by maintaining metal ions in their reduced form (particularly iron and copper). Vitamin C has a functional role in the formation of collagen by acting as a cofactor for procollagen hydroxylase, the enzyme responsible for hydroxylation of prolyl and lysyl residues within nascent peptides in connective tissue proteins. Among these are collagen and related proteins, which make up the intercellular material of cartilage, dentin, and bone.

Ascorbate is also involved in (1) carnitine biosynthesis, serving as a cofactor to 6-*N*-trimethyl-L-lysine hydrolase; (2) γ -butyrobetaine hydrolase, which converts γ -butyrobetaine to carnitine; (3) degradation of tyrosine via 4-OH phenylpyruvate dioxygenase; (4) synthesis of adrenal hormones via dopamine β -hydroxylase; (5) biosynthesis of corticosteroids and aldosterone; (6) hydroxylation of cholesterol in the formation of bile acids; and (7) folate metabolism and leukocyte functions.

Vitamin C also has an important role in the intestinal absorption of nonheme iron by maintaining it in its reduced

ferrous (Fe^{2+}) form. More recently identified functions include nucleic acid and histone dealkylation and proteoglycan deglycanation.

Deficiency

Scurvy results due to deficiency of vitamin C and still occurs in developed countries, albeit rarely either as part of general malnutrition or in isolation. Those most at risk of the disease include (1) elderly men, particularly those who live alone; (2) those with alcohol dependence and smokers; (3) those taking unbalanced diets especially populations who have limited access to fresh fruits and vegetables either due to weather conditions or disasters both natural and manmade; (4) some mentally ill patients; (5) renal failure patients undergoing peritoneal dialysis or hemodialysis; (6) those with increased requirements, such as the sick and pregnant women; and (7) some patients with cancer.

Lack of vitamin C or scurvy causes an inability to form adequate intercellular cement substance in connective tissue, bones, and dentin resulting in swollen, tender, and often bleeding or bruised loci at joints and in other areas where structurally weakened tissue cannot withstand stress. Bone formation is usually impaired causing poor growth and lesions. Infantile scurvy, also known as *Barlow disease*, exhibits a bayonet-rib syndrome. The gums are livid and swollen, cutaneous bleeding often begins on the lower thighs as perifollicular hemorrhages, and large spontaneous bruises (ecchymoses) may arise almost anywhere on the body. This condition may be misconstrued as child abuse. Ocular hemorrhages, drying of salivary and lacrimal glands, parotid swelling, femoral neuropathy, edema of the lower extremities, and psychologic disturbances have also been described. Some scorbutic patients may develop anemia, display radiologic changes characteristic of osteoporosis, or die suddenly from heart failure.

Vitamin C deficiency has also been linked to anemia, diabetes mellitus, various types of cancer, cataract formation, and osteoporosis, but there is no clear evidence for a causal link. A meta-analysis found that regular vitamin C supplementation did not significantly reduce the incidence of common cold in the general population.

Toxicity

Rare adverse effects include increased oxalate excretion and kidney stone formation, increased uric acid excretion, excess iron absorption, lowered vitamin B_{12} concentrations, systemic conditioning, and “rebound” scurvy. The tolerable upper intake amount for vitamin C is 2 g/day for adults older than 19 years.

Laboratory Assessment of Status

At present, no useful functional tests of vitamin C adequacy are available; thus laboratory assessment of status is made by direct measurement of plasma, urine, or tissue concentrations of ascorbic acid, total vitamin C, or (rarely) metabolite. Plasma ascorbate concentration is considered a reliable indicator of vitamin C intake and has been measured photometrically by oxidation with 2,4-dinitrophenylhydrazine to form the

Fig. 27.14 Structure of biotin.

red *bis*-hydrazone, or with 2,4-dichlorophenol-indophenol, which is reduced to a colorless form. A more specific approach is to use the enzyme ascorbate oxidase to convert ascorbate to dehydroascorbate, which then is coupled with *o*-phenylene diamine to form a product that is measured fluorometrically or at 340 nm on an automated analyzer. HPLC methods offer the potential advantage of specificity but generally are time-consuming. Detection may be done by precolumn derivatization to the fluorescent quinoxaline, or by electrochemical or coulometric means. Care must be taken during the analysis to prevent oxidation of the ascorbate before detection by using dithiothreitol or homocysteine added to the sample and mobile phase.

Vitamin C in plasma or serum is known to be readily degraded by oxidation caused by high temperature, light, neutral pH, pro-oxidant material such as certain enzymes, and interaction with iron or copper. Plasma samples should be treated with a metal-chelating and protein-precipitating acid, such as metaphosphoric or sulphosalicylic acids, soon after a phlebotomy followed by prompt freezing. Dithiothreitol may also be used as a preservative.

Biotin

Biotin is *cis*-tetrahydro-2-oxothieno[3,4-*D*]-imidazoline-4-valeric acid (Fig. 27.14). The vitamin in most organisms occurs mainly bound to protein.

Absorption, Transport, Metabolism, and Excretion

Biotin in the diet is largely linked to lysine residues on protein, and digestion of these proteins by gastrointestinal proteases and peptidases produce biocytin (ϵ -*N*-biotinyl lysine) and biotinyl peptides, and the latter may be further hydrolyzed by intestinal biotinidase to release biotin. Avidin, a protein found in raw egg whites, binds biotin tightly and prevents its absorption, and therefore raw egg consumption has been known to result in biotin deficiency.

A biotin carrier, the sodium-dependent multivitamin transporter (SMVT) for which pantothenic acid and lipoate compete, is located in the intestinal brush border membrane and transports biotin against a sodium ion concentration gradient. At higher biotin doses ($>25 \mu\text{mol/L}$), there is passive diffusion across cell membranes. By contrast, transport of biotin across the basolateral membrane is sodium-independent and electrogenic. The enzyme biocytinase (biotin amidohydrolase) in plasma and erythrocytes catalyzes the hydrolysis of biocytin to yield free biotin. Biotin is cleared from the circulating blood more rapidly in deficient than in normal mammals; it is taken up by such tissues as liver, muscle, and kidney and is localized in cytosolic and mitochondrial carboxylases.

Functions

The principal biochemical function of biotin in humans is as a cofactor for carboxylation reactions. Five carboxylases are currently found in human tissue; one of these, an acetyl-CoA carboxylase, is inactive and may act as a storage vehicle for biotin. The others are carboxylases for acetyl-CoA, propionyl-CoA, β -methylcrotonyl-CoA, and pyruvate. Recent advances have implicated biotin in the epigenetic regulation of gene expression.

Deficiency

Biotin deficiency is uncommon but may be seen (1) with prolonged consumption of raw egg white, which contains the protein avidin that binds biotin in the intestines preventing absorption, (2) in those on TPN without biotin supplementation, and (3) in those with inborn errors of biotin metabolism. The first two situations may be complicated by effects on gut flora that produce biotin.

Symptoms of biotin deficiency include anorexia, nausea, vomiting, glossitis, pallor, conjunctivitis, ataxia, hypotonia, depression, dry scaly dermatitis, and developmental delay in infants and children. Significantly lowered urinary excretion or circulating blood concentrations have been found in alcoholic individuals, in patients with achlorhydria, and among the elderly and some athletes. Biotin has also been linked to immune function and lipid metabolism.

Two inborn errors of biotin metabolism include (1) deficiency of biotinidase leading to the inability to utilize protein-bound biotin in the diet or to recycle endogenous biotin from holocarboxylases and also (2) an autosomal recessive condition known as biotin-responsive basal ganglia disease, which presents in childhood with subacute episodes of encephalopathy usually triggered by febrile illnesses and disappears without neurological manifestations, if biotin is given.

Toxicity

No adverse effects of biotin in doses up to 300 times normal dietary intake have been reported, which has been administered to patients with biotinidase deficiency.

Laboratory Assessment of Status

Traditionally biotin has been measured in biological samples by microbiological assays, but HPLC methods are mainly used at present. Lymphocyte propionyl-CoA carboxylase has been shown to be an early and sensitive indicator of biotin deficiency.

Niacin

The term *niacin* (also known as niacinamide or vitamin B₃) refers to nicotinic acid (pyridine-3-carboxylic acid), its amide nicotinamide, and derivatives that show the same biological activity as nicotinamide. Structures of both vitamers and the two coenzyme forms containing the nicotinamide moiety are shown in Fig. 27.15.

Absorption, Transport, Metabolism, and Excretion

Dietary NAD and NADP are hydrolyzed by enzymes, such as NAD glycohydrolase, in the intestinal mucosa to release

Fig. 27.15 Niacin, niacinamide, and coenzyme.

nicotinamide, which, together with any nicotinic acid, is rapidly absorbed in the stomach and the intestine by Na⁺-dependent facilitated diffusion at low concentrations and passive diffusion at higher concentrations. Nicotinamide is the main circulating form in the plasma post absorption or following release from hydrolyzed liver NAD; it can be taken up by most tissues requiring NAD by simple diffusion. Once inside blood, kidney, brain, and liver cells, both nicotinic acid and nicotinamide are converted to coenzyme forms. Little storage of niacin as such occurs.

Functions

Niacin is essential as the coenzymes NAD and NADP in which nicotinamide acts as an electron acceptor or a hydrogen donor in a large number of redox reactions. Many enzymes function as dehydrogenases and catalyze such diverse reactions as the conversion of alcohols (often sugars and polyols) to aldehydes or ketones, hemiacetals to lactones, aldehydes to acids, and certain amino acids to keto acids.

Nicotinic acid, when used as a pharmaceutical agent, has important antiatherogenic properties. It effectively lowers triglycerides, raises HDL cholesterol, and shifts LDL particles to a less atherogenic phenotype (see Chapter 23).

Deficiency

Tryptophan is a precursor of niacin. As much as two-thirds of niacin required by adults can be derived from tryptophan metabolism via nicotinic acid ribonucleotide to NAD and NADP. It has been shown that 60 mg of tryptophan can provide the equivalent of 1 mg of niacin in the adult.

Pellagra is the classic deficiency disease presenting with dementia, diarrhea, and dermatitis. Niacin deficiency and therefore pellagra may occur in (1) people who consume corn-based staple diets in less developed countries, although this is now rare except during war or famine; (2) *carcinoid syndrome*, in which up to 60% of tryptophan is catabolized to

5-hydroxytryptophan and serotonin resulting in niacin deficiency; (3) **Hartnup disease**, an autosomal recessive disorder in which several amino acids, including tryptophan, are poorly absorbed in the intestines, resulting in inadequate niacin for body requirements; and (4) treatment with the antituberculous drug isoniazid, which competes with PL-5-phosphate (vitamin B₆), required as a cofactor in the conversion of tryptophan to niacin.

Toxicity

High doses are commonly associated with vascular dilation or “flushing,” a burning, tingling sensation of the face (that may be reddened), arms, and chest that is thought to be mediated by prostaglandins. The symptoms of flushing have been taken as an end point sign in the formulation of a tolerable upper intake amount for niacin. This has been set at 35 mg/day for adults 19 years and older, with lower amounts for children and adolescents.

Laboratory Assessment of Status

At present, no blood markers are commonly used as indicators of niacin status. Most assessments of niacin nutriture have been based on measurement of the two urinary metabolites, *N*-methylnicotinamide and *N*-methyl-2-pyridone-5-carboxamide. HPLC-based methods are currently the methods of choice, although some capillary electrophoresis methods have been developed. Another approach that may prove valuable is the ratio of erythrocyte niacin coenzymes NAD to NADP. NAD concentrations respond to the niacin status, whereas NADP concentrations remain relatively constant under different conditions of niacin status. The niacin number is $\text{NAD}/\text{NADP} \times 100$; a niacin number less than 130 is indicative of a risk of developing niacin deficiency.

Pantothenic Acid

Pantothenic acid, also known as vitamin B₅ (name derived from Greek *pantothēn* meaning from everywhere), is of ubiquitous occurrence in nature, where it is synthesized by most microorganisms and plants. It is the amide formed by the linkage between pantoic acid (D-2,4-dihydroxy-3,3-dimethylbutyric acid) derived from L-valine, and β-alanine derived from L-aspartate.

Absorption, Transport, Metabolism, and Excretion

Pantothenic acid is taken in as dietary CoA compounds and 4'-phosphopantetheine, and is hydrolyzed by pyrophosphatase and phosphatase in the intestinal lumen to dephospho-CoA, phosphopantetheine, and pantetheine, which are further hydrolyzed to pantothenic acid. The vitamin is primarily absorbed as pantothenic acid through a saturable process at low concentrations and through simple diffusion at higher ones. After absorption, pantothenic acid enters the circulation and is taken up by cells in a manner similar to its intestinal adsorption. Pantothenic acid is excreted in the urine after hydrolysis of CoA compounds by enzymes that cleave phosphate and the cysteamine moieties.

Functions

Pantothenic acid has two major metabolic roles—the first as part of CoA, and the second as the prosthetic group of the acyl-carrier protein (ACP). In the former role, CoA is primarily involved in acetyl and acyl transfer reactions in catabolic processes of carbohydrate, lipid, and protein chemistry.

Deficiency

The widespread availability of pantothenic acid in food is commensurate with its many roles and makes dietary deficiency of pantothenate unlikely in humans. Symptoms have been produced in a few volunteers who received ω-methylpantothenic acid as an antagonist and in people fed semisynthetic diets virtually free of pantothenate. Subjects became irascible and developed postural hypotension and rapid heart rate on exertion, epigastric distress with anorexia and constipation, numbness and tingling of the hands and feet, hyperactive deep tendon reflexes, and weakness of finger extensor muscles.

Toxicity

No reports have described adverse effects, with the exception of occasional mild diarrhea, with oral pantothenic acid given in doses as high as 20 g/day.

Laboratory Assessment of Status

No convenient or reliable functional tests of pantothenic acid status are currently available; thus assessment is made by direct measurement of whole blood or urine pantothenic acid concentrations. Methods that have been used to measure pantothenic acid in human samples include radioimmunoassay, liquid chromatography coupled to mass spectrometry, gas chromatography–mass spectrometry, and a stable isotope dilution assay based on liquid chromatography–mass spectrometry. CoA and ACP have been measured by enzymatic methods.

TRACE ELEMENTS

The term **trace element** was originally used to describe the residual amount of inorganic analyte quantitatively determined in a sample. More sensitive methods allow accurate determination of most inorganic micronutrients present at very low concentrations in body fluids and tissue. Those present in body fluids (μg/L) and in tissue (mg/kg) are, however, still widely referred to as “trace elements.” The corresponding dietary requirements are quoted in mg/day or μg/day, respectively. The biological effects of deficiency disease define the essential trace elements. For example, an element is considered essential when signs and symptoms induced by a deficient diet are uniquely reversed by an adequate supply of the particular trace element under investigation.

Dose-Effect Relationships

At low intakes of essential trace elements, deficiency disease may be seen. With increasing supply, a plateau region of optimal status is reached. Still higher intakes result in adverse effects. The concentration window separating beneficial from

Fig. 27.16 Model of the relationship between tissue concentration and intake of an essential nutrient and dependent biological function.

toxic intakes varies depending on the element in question. This is similar to the dose-effect relationship described for organic micronutrients (Fig. 27.16). Therefore the RDA is set at amounts that are sufficient to prevent deficiency. A tolerable upper intake value that will prevent toxicity has been proposed for the inorganic micronutrients of known importance to human health.

Trace elements discussed in this chapter include copper, selenium, zinc, iodine, manganese, chromium, cobalt, and molybdenum. Iron is discussed in Chapter 28. Dietary sources, RDAs, and intravenous intakes are shown in Table 27.1. The reference intervals are given in Table 27.4.

LABORATORY ASSESSMENT OF TRACE ELEMENT STATUS

Specimen Requirements

Direct determination of trace elements is done in many types of specimens—blood, plasma or serum, and urine. Less often, other sample types (e.g., leukocytes, saliva) may be analyzed. Tissue samples obtained by needle biopsy (e.g., liver, bone) or following an autopsy, and also hair and nail samples offer a noninvasive means of sampling tissue. Measurements of hair and nails for essential elements may be of value on a group basis during studies of severely depleted populations but are of limited value in the investigation of individual hospital patients. Problems of external contamination from environmental pollution, cosmetics, shampoos, and other sources are difficult to control.

Preanalytical Factors

Numerous variables can affect trace element determinations before analysis of the sample and should be considered. Age, sex, ethnic origin, time of sampling in relation to food intake, time of day, medication, and other factors should be noted. In patients with infection, after injury or postsurgery, the systemic inflammatory response affects the concentration of essential elements in circulating blood, independently of nutritional status.

Collection Equipment

Contamination from collection equipment can be a problem. Trace metal-free vacutainers are commercially available. To

TABLE 27.4 Reference Intervals for Trace Elements

Trace Element	Mass Unit	SI Units
Chromium (serum)	0.1–0.15 µg/L	<6 nmol/L
Chromium (urine)	<1–1.0 µg/24 h	2–19 nmol/24 h
Cobalt (serum)	<0.6 µg/L	<10 nmol/L
Cobalt (urine)	<1 µg/g creatinine	<17 nmol/L
Copper (serum)	70–140 µg/dL	10–22 µmol/L
Concentrations increase during pregnancy and oral contraception		
Copper (urine)	<50 µg/24 h	<0.7 µmol/24 h
Wilson disease	>200 µg/24 h	>3 µmol/24 h
Wilson disease postpenicillamine	>1700 µg/24 h	>25 µmol/24 h
Copper (liver)	8–40 µg/g dry weight	
Wilson disease	>250 µg Cu/g dry weight	
Iodine (urine)	76–546 µg/L	0.60–4.30 µmol/L
WHO-recommended urinary concentrations for various population groups are given in (WHO/NMH/NHD/EPG/13.1)		
Manganese (serum)	0.6–2.3 µg/L	11–42 nmol/L
Manganese (blood)	5–15 µg/L	90–270 nmol/L
Molybdenum (serum)	0.4–1.2 µg/L	4–12 nmol/L
Molybdenum (urine)	14.4–119 µg/24 h	0.15–1.24 µmol/24 h
Selenium (serum)	60–125 µg/L	0.75–1.57 µmol/L
Adult (UK)	26–77 µg/L	0.33–0.97 µmol/L
<1.5 years old	40–88 µg/L	0.51–1.12 µmol/L
1.5–3 years old	48–100 µg/L	0.6–1.29 µmol/L
4–18 years old		
Zinc (serum)	63–134 µg/dL	9.6–20.5 µmol/L
Zinc (urine)	0.2–1.3 mg/24 h	3–21 µmol/24 h

WHO, World Health Organization.

avoid contamination from the needle during venous sampling, at least the third specimen from the order of draw should be used. For some elements, collection is via plastic cannulae with the sample then placed into acid-washed containers. Urine collection bottles may be washed thoroughly with ultrapure water. For random urine samples and tissue biopsy samples, a plain plastic container with no added preservative is preferable.

ANALYTICAL METHODS FOR MEASURING TRACE ELEMENTS

Analytical methods should provide sufficient sensitivity to reliably determine the concentrations in the limited specimen

usually available. Techniques that are appropriate include atomic absorption spectrometry (AAS), inductively coupled plasma-optical emission spectrometry (ICP-OES), and inductively coupled plasma-mass spectrometry (ICP-MS). UV-vis spectrophotometry is possible for elements where concentrations are higher. Other techniques have been applied to elemental analysis. Using laser ablation ICP-MS or X-ray fluorescence spectrometry, 2D or even 3D images of trace element distributions within biological materials can be produced. Speciation methods involve techniques to separate compounds of individual elements in a sample. A typical procedure involves HPLC coupled to ICP-MS, to separate methyl mercury from inorganic mercury. Details of these procedures are given in [Chapters 9 and 13](#).

Copper

Absorption, Transport, Metabolism, and Excretion

Copper absorption occurs mainly in the small intestine, although some gastric uptake has been shown. The extent of intestinal copper absorption varies with dietary copper content and is around 50% at low intakes (<1 mg/day) but only 20% at higher intakes (>5 mg/day). Absorption is reduced by other dietary components such as zinc (which induces metallothionein that binds Cu^{2+}), vitamin C (which converts Cu^{2+} to insoluble nonabsorbable Cu^+), molybdate, and iron, and is increased by amino acids and by dietary sodium.

Absorbed copper is transported to the liver in portal blood, bound to albumin, where it is incorporated by hepatocytes into cuproenzymes and other proteins, and is then exported as ceruloplasmin via peripheral blood to tissues. Although two-thirds of the 80 to 100 mg total body content is located in the skeleton and muscle, the liver is the key organ in copper homeostasis. The ceruloplasmin molecule contains 6 to 8 atoms of copper per molecule, with 6 atoms of copper involved in the protein's ferroxidase and free radical scavenging activities.

Ceruloplasmin is a positive acute-phase reactant, and concentrations increase during infection, after tissue injury, and also in pregnancy and during the use of oral contraceptives. The increase is accompanied by a rise in serum copper concentration. A smaller amount of copper in plasma (<10%) is bound to albumin by specific peptide sequences, and this copper is in equilibrium with plasma amino acids. This fraction may be important for cellular uptake.

Copper is predominantly excreted via bile into feces. Patients with cholestatic jaundice or other forms of liver dysfunction are at risk for copper accumulation caused by failure of excretion.

Functions

Copper is a catalytic component of numerous enzymes and a structural component of other important proteins.

Energy Production. Cytochrome *c* oxidase contains copper and iron. Located on the external face of mitochondrial membranes, the enzyme catalyzes four-electron reduction of molecular oxygen, establishing a high-energy proton gradient across the inner mitochondrial membrane that is necessary for ATP production.

Connective Tissue Formation. Protein-lysine 6-oxidase (lysyl oxidase) is a cuproenzyme essential for stabilizing extracellular matrixes by cross-linking of collagen and elastin.

Iron Metabolism. Copper-containing enzymes, ferroxidase I (ceruloplasmin) and ferroxidase II, and hephaestin in the enterocyte oxidize ferrous, to ferric, iron. This allows incorporation of Fe^{3+} into transferrin and eventually into Hb.

Central Nervous System. Dopamine mono-oxygenase is an enzyme that requires copper as a cofactor and uses ascorbate as an electron donor. This enzyme catalyzes the conversion of dopamine to norepinephrine, an important neurotransmitter. Monoamine oxidase, one of the numerous amine oxidases, is a copper-containing enzyme that catalyzes the degradation of serotonin in the brain and is involved in the metabolism of catecholamines.

Melanin Synthesis. Tyrosinase is a copper-containing enzyme that is present in melanocytes and catalyzes the synthesis of the melanin biopigments pheomelanin and eumelanin.

Antioxidant Functions. Both intracellular and extracellular superoxide dismutases (SODs) are Cu- and Zn-containing enzymes, able to convert superoxide radicals to hydrogen peroxide, which can be removed subsequently by catalase and other antioxidant defenses.

Regulation of Gene Expression and Intracellular Copper Handling. Copper-dependent proteins act as transcription factors for specific genes, such as those regulating SOD, and catalase. Synthesis of metallothionein, important in regulating the intracellular distribution of copper, is controlled by copper-responsive transcription factors. Additional specialized proteins act as "copper chaperones" to deliver copper to intracellular sites and to prevent oxidative damage by free copper ions.

Aceruloplasminemia is another genetic defect resulting in failure of hepatic synthesis of ceruloplasmin leading to secondary iron overload, and insulin-dependent diabetes developing in the 4th to 5th decade of life.

Deficiency

Anemia. Copper deficiency is a rare but treatable cause of hematologic abnormalities. Usual hematologic features include anemia, leucopenia, and rarely thrombocytopenia. The mechanism is not clear.

Zinc-Induced Hypocupremia. Zinc intake (e.g., via dental fixatives) induces metallothionein expression in the intestinal mucosa, which sequesters copper blocking its absorption leading to copper deficiency.

Menkes Syndrome. This is a rare (1/100,000 live births), X-linked mutation disorder due to impaired intestinal transport of copper caused by a mutation in the ATP7A gene that leads to severe copper deficiency. It occurs in male infants at 2 to 3 months who present with hypotonia, seizures, failure to thrive, kinky hair (pili torti), facial changes, and neurologic abnormalities. Low concentrations of copper in plasma, liver, and brain occur because of the impaired intestinal absorption. Findings include very low plasma copper and ceruloplasmin concentrations.

Deficiency of the copper enzyme dopamine mono-oxygenase in CSF may allow early diagnosis. Therapy with parenteral copper histidine is rarely successful, and patients usually die following aortic rupture.

Cardiovascular Disease. The role of copper in human cardiovascular disease is controversial. The possible importance illustrates the Janus phenomenon of duality, with evidence suggesting both protective and harmful scenarios. Evidence for a positive link with low dietary copper intake comes from epidemiologic surveys showing that increased plasma copper values are a positive cardiovascular risk factor.

Neuropathy. Copper deficiency-associated myeloneuropathy is an increasingly recognized disorder. Deficiency secondary to celiac disease and excessive zinc intake are among the causes suggested.

Toxicity

Toxicity can arise from ingestion of contaminated diet or drinking water. Symptoms of acute poisoning include bloody vomiting, melena, and hypotension. Fatal renal failure has been recorded following accidental or intentional ingestion of copper sulfate. Indian childhood cirrhosis is recognized in children who may be genetically sensitive to copper in drinking water.

Wilson disease, the genetic disorder due to a mutation in the ATP7B gene, affects copper incorporation into ceruloplasmin and excretion into bile causing increased copper accumulation in tissues. With an incidence of 1/30,000 live births, Wilson disease is one of the more common genetic disorders. The presentation is highly variable. Primarily, it affects either the liver or the brain, but rare cases are diagnosed with renal tubular disease or hemolytic anemia. Severe liver disease typically develops in young children while neurological signs tend to appear in teenagers and early adults, but onset and diagnosis may be made at any age. Initial investigations include plasma copper and ceruloplasmin, which will usually be low. Although the total plasma copper is decreased, the non-ceruloplasmin-bound free fraction is increased. However, methods for analysis of this fraction are not particularly reliable. Other signs and symptoms include copper deposits in the eye (Kayser-Fleischer rings), abnormal liver function tests, and increased urine copper excretion. In cases that are difficult to diagnose, analysis of liver biopsies for copper may help and a test involving an oral dose of stable ^{65}Cu isotope has been developed. Genetic testing is possible, but because several hundred mutations exist, this may not always be informative. Transplantation is required for cases of acute liver disease, while the chronic form of Wilson disease is treated by oral chelating agents (penicillamine) that remove excess copper from tissue and increase urinary excretion. Maintenance therapy may involve oral administration of zinc salts or ammonium molybdate that block intestinal absorption of copper.

Laboratory Assessment of Status

Serum copper and ceruloplasmin concentrations are measured, but factors that increase the hepatic synthesis of

ceruloplasmin, such as the APR, pregnancy or estrogen-containing contraceptive pill, will increase plasma copper independently of dietary copper intake. Urinary excretion of copper is decreased during dietary deprivation, but the change from an already low basal value is small, which makes this of limited use.

Selenium

Absorption, Transport, Metabolism, and Excretion

Intestinal absorption of various dietary forms of selenium is efficient and is not regulated. The inorganic salts, selenite (Se^{IV}) and selenate (Se^{VI}), used in some dietary supplements and in food fortification are almost completely absorbed, but much of the selenate ion is rapidly excreted in urine. Selenium from inorganic salts is more rapidly incorporated into glutathione peroxidase and other selenoproteins than selenium from organic sources containing selenomethionine. However, selenium-enriched yeast containing the organic forms is considered less toxic and is widely used as a dietary supplement.

Whole body selenium is about 15 mg, with higher concentrations in the kidney and liver, followed by the other organs. The concentrations of selenium in whole blood and in plasma are related to dietary intake. About 50% to 60% of total plasma selenium is present as the protein selenoprotein P, a highly basic protein having multiple histidine residues and about 10 atoms of selenium per molecule. Around 30% of plasma selenium is present as glutathione peroxidase (GSHPx-3), the remainder being incorporated into albumin as selenomethionine.

The major route of excretion is via the urine and reflects recent dietary selenium intake. The amounts excreted vary widely, ranging from less than 20 $\mu\text{g/L}$ to more than 1000 $\mu\text{g/L}$.

Functions

More than 30 biologically active selenocysteine-containing proteins have been identified and their biological function investigated. Some of these are discussed below.

Glutathione Peroxidase (GSHPx). This enzyme has at least eight isoforms with GSHPx-3 present in plasma. These enzymes use the reducing power of glutathione to remove an oxygen atom from hydrogen peroxide and lipid hydroperoxides.

Iodothyronine Deiodinase. Type I (Dio1), II (Dio2), and III (Dio3) isoforms of this enzyme are responsible for conversion of the precursor hormone T_4 to the active hormone T_3 . Type 1 is located in the thyroid, liver, kidney, and muscle and is responsible for more than 90% of plasma T_3 production. Pituitary, brain, and brown adipose tissue contain the type II and III deiodinases.

Thioredoxin Reductases. Three isoforms catalyze the NADPH-dependent reduction of thioredoxin and are important in maintaining the intracellular redox state.

Selenophosphate Synthetase. This enzyme is required for the intracellular synthesis of selenoproteins via a monoselenium phosphate intermediate.

Selenoprotein P. This protein is the major selenium-containing protein in blood plasma; it may be a transport protein for the element, and it has an antioxidant function.

Deficiency

Selenium enters the food chain mainly as selenomethionine from plants. The soil content of selenium is highly variable, and the geographic source of plant and animal foodstuffs determines the dietary intake. Soils in parts of China and New Zealand are particularly low in selenium, while wheat and other cereal products from North America are good sources.

Keshan Disease. Conclusive evidence of a role for selenium in human nutrition came with the results from large-scale trials in China that showed the protective effects of selenium supplementation in children and young adults suffering from an endemic cardiomyopathy. This was observed in areas of the country (Keshan region) with low soil selenium concentrations.

Kashin-Beck Disease. A type of severe arthritis described in parts of China and neighboring areas of Russia.

Nutritional Depletion in Hospital Patients. The need for selenium supplementation, with monitoring, during nutritional support is well established, and few cases of symptomatic deficiency are now reported.

Thyroid Function. As noted above, deiodinase enzymes are selenoproteins and are necessary for normal thyroid function. Children with biochemical and clinical signs of hypothyroidism were successfully treated with oral selenium. A report of a study in the United Kingdom concluded that supplementation had no effect on thyroid status.

Immune Function. Deficiency of selenium is accompanied by loss of immunocompetence, and this is related to the reduction of selenoproteins in the liver, spleen, and lymph nodes.

Inflammatory Conditions. Many conditions associated with inflammation and increased oxidative stress could be influenced by selenium status.

Cardiovascular Disease. A protective role for selenium against cardiovascular disease has been extensively investigated, but with no conclusive findings.

Viral Virulence. It is possible that an unusually virulent strain of the Coxsackie virus is part of the cause of cardiomyopathy in selenium-depleted regions of China.

Cancer Chemoprevention. Epidemiologic surveys suggest an association between cancer incidence and soil selenium. However, a large selenium and vitamin E study known as the Selenium and Vitamin E Cancer Prevention Trial (SELECT) concluded that selenium or vitamin E, alone or in combination at the doses and formulations used, did not prevent prostate cancer in healthy men.

Toxicity

Clinical signs of selenosis include garlic odor on the breath, hair loss, nail damage, nervous system and skin disorders, poor dental health, and paralysis in extreme cases. The tolerable upper limit has been set at 400 µg/day for adults and less than 280 µg/day for children. Cases of toxicity and even

death from self-administration or homicidal dosages have been reported. Some parts of the world, generally where there are volcanic soils, are naturally selenium-rich, and locally produced food contains high concentrations of selenium. Consumption of these foods leads to chronic selenosis typified by cases reported from Enshi City in the Hubei region of China.

Laboratory Assessment of Status

Selenium concentrations in whole blood or plasma/serum are the usual markers of selenium status. Samples may be analyzed by electrothermal-AAS or by ICP-MS (note the interference due to the Gd^{2+} ion). Urinary selenium is measured where there is occupational exposure. Measurement of glutathione peroxidase (GSHPx-3) activity in whole blood or serum is an additional biomarker of selenium status. Results are dependent on the substrate and other assay conditions so that comparisons among different studies require careful interpretation. Plasma selenoprotein P may be determined, but methods are not readily available. Plasma selenoprotein P, plasma GSHPx-3, and total plasma selenium concentration are all lowered by the APR to injury or infection. This effect should be considered when results are being interpreted. Hair and nail selenium concentrations can be useful in population studies.

Zinc

Zinc is second to iron as the most abundant trace element in the body.

Absorption, Transport, Metabolism, and Excretion

Intestinal absorption of zinc is controlled in the face of variable dietary zinc input and is usually from 20% to 50% of the dietary content. Uptake from the gut lumen into intestinal cells is achieved and regulated by zinc transporter proteins. Several factors such as dietary phytate, fiber calcium, and iron reduce intestinal absorption by forming insoluble complexes. Profound zinc deficiency in humans was first recognized in a population where geophagia (eating soil) was practiced; because zinc is bound to the soil components, deficiency resulted.

Absorbed zinc is transported to the liver by the portal circulation, where incorporation into metalloenzymes and plasma proteins occurs. Plasma contains less than 1% of the total body content of zinc and lies within a narrow concentration interval. About 80% of plasma zinc is associated with albumin, and most of the rest is tightly bound to α_2 -macroglobulin. The zinc on albumin is in equilibrium with plasma amino acids (mostly histidine and cysteine), and this small (<1%) ultrafiltrable fraction may be important in cellular uptake mechanisms (Fig. 27.17). Red cell zinc concentrations are about 10 times higher than in plasma. Fecal excretion includes both unabsorbed dietary zinc and zinc resecreted into the gut. The amount normally equals the total dietary intake and is about 10 to 15 mg/day. Urine excretion of zinc is normally about 0.5 mg/day, but this can increase markedly during catabolic illness.

Fig. 27.17 Zinc metabolism.

Functions

More than 300 zinc metalloenzymes have been described. Some important examples include carbonic anhydrase, alkaline phosphatase, RNA and DNA polymerases, and alcohol dehydrogenase. The key roles of zinc in protein and nucleic acid synthesis explain the failure of growth and impaired wound healing observed in individuals with zinc deficiency. In some enzymes, such as Cu and Zn SOD, structural stability is ensured by zinc protein binding and the catalytic activity of the enzyme by the active copper site. Proteins can form domains that bind tetrahedral zinc atoms by coordination with histidine and cysteine to form folded structures known as “zinc fingers.” These molecules have important roles in gene expression and hormone function.

Deficiency

Increased amounts are required during pregnancy and lactation. Strict vegetarians may need as much as 50% more zinc per day because of increased phytic acid and fiber in their diet. As might be expected from the multiple biochemical functions of zinc, the clinical presentation of deficiency disease is varied, nonspecific, and related to the degree and duration of depletion. Signs and symptoms include depressed growth with stunting; increased incidence of infection, possibly related to alterations in immune function; diarrhea; altered cognition; defects in carbohydrate use; reproductive teratogenesis; skin lesions; alopecia; eyesight defects; and other adverse clinical outcomes.

Acrodermatitis enteropathica is an autosomal recessive disorder resulting in failure to absorb zinc characterized by severe periorificial and acral dermatitis, alopecia, and

diarrhea. Patients with this disorder have abnormally low blood zinc concentrations ($<30 \mu\text{g/dL}$). Symptoms are reversed by oral zinc supplementation. Regular monitoring of serum concentrations is recommended.

Immune Function. Zinc depletion impairs immunity and has a direct effect on the gastrointestinal tract that increases the severity of enteric infections. A review of controlled trials of zinc supplementation of children in low-income countries found significant clinical benefits with substantial reduction in the incidence of severe diarrhea and respiratory infection.

Subclinical Effects of Deficiency. Marginal zinc deficiency, not severe enough to cause clinical signs and symptoms, may be associated with “subclinical” effects. These include susceptibility to sickle cell disease, impaired immune response, and mental well-being.

Toxicity

Zinc toxicity is unusual and is generally associated with ingestion of zinc-contaminated food or water. Symptoms include abdominal pain, diarrhea, nausea, and vomiting. Chronic ingestion can lead to a zinc-induced deficiency of copper.

Laboratory Assessment of Status

Although plasma zinc determination is insensitive to dietary zinc intake and is subject to a variety of influences, it remains the most widely used laboratory test to confirm severe deficiency and to monitor adequacy of zinc provision, especially when interpreted together with changes in serum albumin and the APR. A clinical and biochemical response to zinc supplementation supports a diagnosis of deficiency. It is

important to recognize that a low plasma zinc concentration may not mean deficiency. Plasma albumin is a negative acute-phase reactant that redistributes, together with zinc, into interstitial space from the plasma pool during infection, after trauma, and in chronic disease. It is essential to consider plasma zinc results along with plasma albumin and a marker of the APR. Increased urine zinc is an important source of loss in the severely injured catabolic patient. Urine output increases with amino acid infusion given during TPN.

Iodine

Absorption, Transport, Metabolism, and Excretion

Absorption of dietary iodide is not entirely understood. The Na^+/I^- symporter (NIS) on the apical surface of enterocytes of the small intestine is responsible for uptake into vesicles within the cell, but movement into the circulation is not clear. Under normal circumstances, 90% to 95% of the intake is absorbed. Subsequent transport, movement into thyroid cells (which also involves an NIS), synthesis of thyroid hormones, and release is discussed in [Chapter 42](#). Iodine is primarily excreted in the urine.

Functions

The essential function for iodine relates to thyroid physiology (see [Chapter 42](#)). While iodine is concentrated in thyroid tissue and hormones, around 70% of the body's iodine is distributed in many other tissues. Its role in mammary tissue relates to fetal and neonatal development, but its role in other tissues is partially unknown.

Deficiency

Deficiency of iodine is a major health problem throughout the world, occurring in regions where the soil and groundwater are deficient in the element. Deficiency may also develop following prolonged use of special diets that may have low iodine content. The most serious adverse effect of iodine deficiency is impaired development of nervous tissue in the fetus. Thyroid hormones are required for neuronal migration and myelination of the fetal brain. Severe maternal iodine deficiency during pregnancy increases the risk of stillbirths and congenital abnormalities. A decrease in intelligence quotient (IQ) points has been shown in children who are iodine deficient.

Toxicity

Iodine is a strong oxidizing agent and acts as an acid corrosive. Iodine vapor irritates the eyes, skin, and mucous membranes. Common causes of acute toxicity include accidental or deliberate ingestion, resulting in corrosive damage to the gastrointestinal tract, cardiovascular collapse, and renal failure; liberal use of iodine to open wounds; large injections of iodine-containing radio-contrast media; and amiodarone treatment for cardiac arrhythmias. Iodine toxicity causes a rapid decrease in release of thyroxine and 3,5,3'-triiodothyronine from thyroglobulin, decreased uptake of iodide by the thyroid gland, and hence decreased synthesis of thyroid hormones. This culminates in acute hypothyroidism.

Laboratory Assessment of Status

Urine is the matrix of choice for suspected iodine toxicity and for the assessment of recent iodine *intake*. For epidemiological studies, such as population-based surveys, the *median* urinary iodine concentration can be used to classify that *population's* iodine status. Adequate iodine status is indicated by a population median urinary iodine concentration greater than 0.79 $\mu\text{mol/L}$ (100 $\mu\text{g/L}$). However, the urine iodine test is not an appropriate test to diagnose iodine deficiency in individuals. Urine iodine levels have a low predictive value in an individual because urinary iodine concentration varies substantially between days and seasons, as well as within a day (up to three-fold) as a consequence of circadian rhythm and due to differences in fluid intake. Because the thyroid gland can store large amounts of iodine (12 to 16 mg in an iodine sufficient individual), a "low" urine iodine concentration no more indicates iodine deficiency than a low urinary sodium indicates sodium deficiency. It is recommended, however, that iodine status can be reliably estimated if 10 repeat random urine samples are collected. Iodine concentration in serum or whole blood provides no useful information relevant to iodine nutritional status.

Manganese

Absorption, Transport, Metabolism, and Excretion

Dietary manganese is absorbed from the small intestine. Diets high in iron, calcium, magnesium, phosphates, fiber, phytic acid, oxalate, and tannins from tea can reduce the absorption. Once absorbed, manganese is transported to the liver bound to albumin; it is then exported to other tissues bound to transferrin and possibly to α_2 -macroglobulin. Excretion of manganese occurs primarily via bile into feces, with urine output being very low and not sensitive to dietary intake.

Functions

Manganese is a constituent of many important metalloenzymes. Mn^{2+} ions can be replaced by Mg^{2+} , Co^{2+} , and other cations during the activation of some enzymes. Some important manganese-dependent enzymes are discussed.

Superoxide Dismutase (SOD). Manganese-dependent SOD is a mitochondrial enzyme that is an important factor in limiting oxygen toxicity. The enzyme catalyzes the breakdown of the superoxide radical O_2^- to H_2O_2 , which is then removed by catalase and glutathione peroxidase.

Pyruvate Carboxylase. This enzyme is required to catalyze the formation of phosphoenolpyruvate (PEP), from pyruvate, a key reaction in the hepatic synthesis of glucose.

Arginase. Arginase is the terminal enzyme in the urea cycle, hydrolyzing L-arginine to urea and ornithine and completing the deamination of amino acids. Arginase is most concentrated in the liver, but is also found in other tissues. The activity of arginase affects the production of nitric oxide by limiting the availability of L-arginine required for synthesis of nitric oxide synthetase.

Glycosyl Transferases. These enzymes are responsible for the sequential addition of carbohydrate molecules to proteins to form proteoglycans, and ultimately connective tissue and cartilage.

Deficiency

Overt manganese deficiency has not been documented in humans eating natural diets. Symptoms in experimentally induced manganese deficiency in animal studies include impaired growth and reproductive function, skeletal abnormalities, impaired glucose tolerance, and cholesterol synthesis.

Prolidase deficiency in infants is a rare genetic disorder that is known to be associated with abnormalities of manganese biochemistry. One study suggests there is low arginase activity due to a defect in the supply of manganese for enzyme activation.

Toxicity

Prolonged exposure to manganese-containing dust or fumes at work is well recognized, with neurologic symptoms resembling Parkinson disease developing slowly over a period of months or years. Patients with severe liver disease may have neurologic and behavioral signs of manganese neurotoxicity resulting from failure to excrete manganese in bile. Manganese deposition in the globus pallidus results in T₁-weighted magnetic resonance imaging (MRI) signal hypersensitivity. By causing deficits in neurotransmitter production, manganese ions may be partially responsible for symptoms of postsystemic hepatic encephalopathy. Deposition of manganese in the brain has been demonstrated in children with biliary atresia, in adult cirrhotic patients and patients receiving manganese intravenously during TPN, especially those with cholestasis. A study in adults that compared the effects of increasing doses of manganese in patients receiving home parenteral nutrition showed a good correlation between blood manganese, MRI intensity, and T₁ values in the globus pallidus.

Increases in serum manganese to greater than 1.6 µg/L (>30 nmol/L) or in blood manganese to greater than 20 µg/L (>360 nmol/L) are indices of manganese retention.

Laboratory Assessment of Status

Manganese status should be monitored in at-risk patients. Serum manganese, lymphocyte Mn SOD activity, and blood arginase are potentially useful when possible nutritional depletion is assessed. Blood or serum manganese in combination with brain MRI scans and neurologic assessment detect excessive exposure.

Chromium

Chromium occurs in biology as Cr³⁺ or Cr⁶⁺, each having markedly different properties. The element has no redox or acid-base properties, but in the Cr⁶⁺ form it is a strong oxidant that can cause tissue damage (e.g., chromic acid), although it is normally rapidly reduced to Cr³⁺.

Absorption, Transport, Metabolism, and Excretion

Absorption is increased marginally by ascorbic acid, amino acids, oxalate, and other dietary factors. After absorption, chromium binds to plasma transferrin with an affinity similar to that of iron. It then concentrates in human liver, spleen, other soft tissue, and bone. Urine chromium is the main route for excretion.

Functions

While symptoms have been reported in severely chromium-deficient rats (impaired growth, reduced life span, corneal lesions, alterations in carbohydrate, lipid, and protein metabolism), studies by other groups yielded inconsistent results.

Deficiency

Chromium is proposed to play a role in impaired glucose tolerance, diabetes, and cardiovascular disease. Clinical signs attributed to chromium deficiency were described in a few patients receiving TPN for a prolonged period using fluids that did not supply sufficient chromium. All had similar presentations, with previously stable patients developing insulin-resistant glucose intolerance, weight loss, and in some cases neurologic deficits. Addition of substantial amounts of Cr³⁺ to the intravenous fluids (150 to 200 µg/day) reversed glucose intolerance and reduced insulin requirements with eventual improvement in neurologic symptoms. These cases influenced the US Food and Nutrition Board to designate chromium as an essential trace element, although this is not universally accepted.

Toxicity

Hexavalent chromium is a recognized carcinogen, and industrial exposure to fumes and dusts containing this metal is associated with increased incidence of lung cancer, dermatitis, skin ulcers, and hypersensitivity reactions. Chromium picolinate is a widely used dietary supplement, and this compound may cause renal and hepatic damage when used at high doses.

In addition, markedly increased concentrations (up to 1000-fold) have been observed in both plasma and urine in patients with problem hip prostheses.

Laboratory Assessment of Status

Measurement of chromium in blood plasma or serum, the diet, in oral and intravenous nutritional support regimens requires great care to prevent contamination before and during analysis. Increased amounts of chromium in urine confirm recent occupational or environmental exposure. Monitoring urine chromium during trials that use pharmacologic dosages of chromium confirms compliance and detects potential toxicity.

Cobalt

Cobalt (Co) is essential for humans as an integral part of vitamin B₁₂ (cobalamin). No other function in the human body is known. Non-vitamin B₁₂ cobalt does not interact with the body vitamin B₁₂ pool.

Increased exposure from industrial uses, particularly with hard metal blades, leads to high mean urinary Co concentrations. Increases are also associated with hip prostheses for which concentrations can be markedly raised with no apparent clinical evidence of overt toxicity; however, there is some emerging evidence of cobalt toxicity with wear from metal-on-metal hip prostheses.

Erythropoiesis can be stimulated by inorganic cobalt ions (Co²⁺), even in nonanemic subjects, and cobalt chloride was

once administered at daily doses of 25 to 50 mg for use as an antianemic agent and Co^{2+} therapy proved effective in stimulating erythropoiesis in both nonrenal and renal anemia. The mode of action is to stabilize hypoxia-inducible transcription factors that increase the expression of the erythropoietin gene. Because the mass of Hb is a critical factor in aerobic sports, use of cobaltous salts is tempting for athletes and horse racing trainers to stimulate erythropoiesis. But there are risks to health with severe organ damage, primarily in the heart and the sensory systems, the gastrointestinal tract, and the thyroid.

Molybdenum

Absorption, Transport, Metabolism, and Excretion

Molybdenum is efficiently absorbed over a wide range of dietary intakes, mainly as molybdate, although competitive inhibition of absorption by sulfate reduces intestinal uptake. Concentrations in whole blood are about $1.0 \mu\text{g/L}$ (10 nmol/L), and some 80% to 90% or more of molybdenum is bound to red cell proteins. Transport of small amounts in plasma may involve α_2 -macroglobulin. Urine output directly reflects the dietary intake of molybdenum.

Functions

Several important mammalian enzymes, sulfite oxidase, xanthine dehydrogenase, and aldehyde oxidase require molybdenum as a cofactor. The organic component is a molybdopterin complex. Sulfite oxidase is probably the most important enzyme in relation to human health, catalyzing the last step in the degradation of sulfur amino acids by oxidizing sulfite to sulfate and transferring electrons to cytochrome *c*. Xanthine dehydrogenase and aldehyde oxidase hydroxylate heterocyclic substances, such as purines and pteridines.

Deficiency

Molybdenum deficiency has not been observed in healthy people consuming a normal diet. A single case report described a patient receiving prolonged parenteral nutrition

during treatment for severe Crohn disease who developed an intolerance to intravenous amino acids, especially L-methionine. Clinical signs included tachycardia, visual defects, neurologic irritability, and eventually coma. Symptoms improved on discontinuation of amino acid infusion. Biochemical abnormalities included high methionine and low uric acid concentrations in plasma. Treatment with ammonium molybdate ($300 \mu\text{g/day}$, IV) improved the clinical and biochemical abnormalities.

Very rare, usually fatal, recessive inherited diseases result from defects in the biosynthesis of molybdenum cofactor. Symptoms include failure to thrive and seizures with lens dislocations and cerebral atrophy developing later. Diagnosis is made by detection of excess sulfite in urine.

Toxicity

Molybdenum compounds have low toxicity in humans. Reports have described increased blood uric acid in those with occupational exposure and in Armenian populations that have an abnormally high dietary intake (10 to 15 mg/day). A single report of acute toxicity from self-administration of 300 to $800 \mu\text{g/day}$ with a cumulative total of 13.5 mg over 18 days led to acute psychosis and seizures but is inconsistent with another study in healthy men given as much as $1500 \mu\text{g/day}$ for 24 days with no adverse effects reported. Excess molybdenum intake prevents copper absorption through formation of an insoluble thiomolybdate-copper complex. This is the basis for using ammonium molybdate in the management of Wilson disease.

Laboratory Assessment of Status

Whole blood and serum or plasma molybdenum concentrations are too low to be reliably used to detect deficiency. However, urinary output is responsive to increases or decreases in input. Measuring urate or sulfite in the urine is the most valuable means of confirming molybdenum cofactor disorder or possible molybdenum deficiency.

POINTS TO REMEMBER

Vitamins

Vitamin A	Retinol	Antioxidant; important role in vision
Vitamin E	Tocopherols	Antioxidant; multiple functions including bone metabolism
Vitamin K	Phylloquinones	Coagulation; bone metabolism
Vitamin B ₁	Thiamine, aneurin	Coenzyme for decarboxylation and transketolation reactions; involved in carbohydrate metabolism
Vitamin B ₂	Riboflavin	Prosthetic group for oxidation-reduction reactions
Vitamin B ₃	Niacin	Hydrogen acceptors (as NAD and NADP) in many oxidation-reduction reactions
Vitamin B ₅	Pantothenic acid	Coenzyme A required for metabolism of carbohydrates, fats, and proteins
Vitamin B ₆	Pyridoxine	Coenzyme for enzymes involved in metabolism of various amino acids
Vitamin B ₇	Biotin, vitamin H	Coenzyme for carboxylation reactions involved in gluconeogenesis and lipogenesis
Vitamin B ₉	Folate	Required for the interconversions of amino acids and the biosynthesis of purines and pyrimidines
Vitamin B ₁₂	Cobalamin	Required for erythropoiesis, methylation processes necessary for DNA metabolism, and is a cofactor for various enzymes
Vitamin C	Ascorbic acid	Connective tissue formation; antioxidant

POINTS TO REMEMBER—cont'd**Trace Elements**

Copper	Catalytic component of numerous enzymes and has structural roles
Selenium	Component of numerous selenocysteine-containing proteins such as glutathione peroxidase and iodothyronine deiodinase
Zinc	Component of numerous metalloenzymes and proteins including transcription factors
Iodine	Important role in thyroid hormone synthesis
Manganese	Constituent of many important metalloenzymes such as superoxide dismutase
Chromium	Implicated roles in impaired glucose tolerance, diabetes, and cardiovascular disease
Cobalt	Integral component of vitamin B ₁₂ (cobalamin)
Molybdenum	Cofactor for several enzymes such as sulfite oxidase and xanthine dehydrogenase

REVIEW QUESTIONS

- Which enzyme activity is decreased as a result of vitamin B₁ deficiency?
 - Glutathione reductase
 - Glutathione peroxidase
 - Transketolase
 - Methyltetrahydrofolate reductase
- Which of the following statements best describes the effects of systemic inflammatory response (SIR) on vitamin status?
 - SIR causes a decrease in the vitamins A, E, B₂, B₆, C, D, and carotenoids.
 - SIR causes an increase in the vitamins A, E, B₂, B₆, C, D, and carotenoids.
 - SIR does not have an appreciable effect on any vitamins in blood circulation.
 - SIR causes a decrease in albumin and CRP that affect vitamin status.
- Which of the following statements best accounts for vitamin A deficiency?
 - It is dependent on renal functioning.
 - It is not caused by liver disease.
 - It may result due to decreased retinol binding protein (RBP) concentration in circulating blood.
 - Circulating retinol always correlates with total body vitamin A stores.
- Which of the following is a major cause of fat-soluble vitamin deficiency?
 - Decreased fat intake
 - Hemolytic disease
 - Renal insufficiency
 - Malabsorption syndromes
- Which of the listed vitamin deficiencies is not associated with the disease state?
 - Xerophthalmia—vitamin A
 - Beriberi—vitamin B₁
 - Wernicke-Korsakoff syndrome—vitamin B₂
 - Hartnup disease—niacin
- Which of the following enzymes does not require selenium for functionality?
 - Glutathione peroxidase
 - Selenophosphate synthetase
 - Glutathione reductase
 - Iodothyronine deiodinase
- Which of the following best facilitates the diagnosis of copper dysfunction as in Wilson disease?
 - Liver biopsy
 - Urine copper output
 - Urine copper post penicillamine challenge
 - Serum copper
- Which of the following conditions does not result in low serum copper and ceruloplasmin?
 - Menkes syndrome
 - Wilson disease
 - Keshan disease
 - Aceruloplasminemia
- How would you investigate a patient suspected of taking excess supplements of essential trace elements such as Cu, Zn, and/or Se? By measuring:
 - different organo inorganic species.
 - urine output corrected for creatinine.
 - impact on other analytes for, for example, renal and/or liver function.
 - whole blood and plasma content of the named traced elements.

Hemoglobin, Iron, and Bilirubin

Christina Ellervik, Maria Domenica Cappellini, Stanley Lo, Dorine W. Swinkels

OBJECTIVES

- Define the following:
 - Anemia of chronic disease
 - Bilirubin
 - Conjugated (direct) bilirubin
 - Ferritin
 - Hereditary hemochromatosis
 - Hemoglobin
 - Hemoglobinopathy
 - Jaundice
 - Kernicterus
 - Soluble transferrin receptor (sTfR)
 - Thalassemia
 - Transferrin
 - Transferrin saturation
 - Transfusion induced iron overload
 - Unconjugated (indirect) bilirubin
 - Urobilinogen
- Describe the structure and physiological role of hemoglobin.
- State the function of hemoglobin and its significance in health and disease.
- List four different types of hemoglobin and state the makeup of the globin chains in each.
- List four different types of thalassemia and state the globin deficiency and genetic defect in each.
- Compare the differences between hemoglobinopathy and thalassemia with regard to causes and laboratory values.
- List analytical methods used to assess the presence of a hemoglobinopathy or thalassemia.
- Describe the principle of the cyanmethemoglobin method of hemoglobin determination.
- Describe iron food sources.
- Describe iron uptake, transport, distribution, and storage.
- Describe systemic and cellular iron regulation.
- List the three major disorders of iron metabolism.
- Describe and contrast causes, clinical and laboratory findings for iron deficiency, hereditary hemochromatosis, and iron distribution disorder (anemia of chronic disease).
- Compare the causes of primary, secondary, and juvenile hemochromatosis.
- State the principle of chromogenic serum iron determination and the clinical significance of the results.
- Define total iron-binding capacity (TIBC) and state how TIBC value is determined.
- Describe how to calculate transferrin saturation (TSAT).
- List analytical methods used to assess serum ferritin, iron, transferrin, hepcidin, and soluble transferrin receptor.
- Describe how biological and pre-analytical variation impact laboratory findings for serum ferritin, iron, transferrin.
- Describe the biochemistry of bilirubin including transport in blood, conjugation in the hepatocyte, and hydrolysis in the intestine.
- List and describe two causes of hyperbilirubinemia in the neonate.
- State the principle of the diazo method of total bilirubin analysis; state what is required in this reaction to measure direct bilirubin.

KEY WORDS AND DEFINITIONS

Anemia of chronic disease Anemia of inflammation.

Biliary atresia A condition characterized by failure of a fetus to develop an adequate pathway for bile to drain from the liver to the intestine.

Bilirubin A yellow bile pigment that is a breakdown product of heme mainly formed from the degradation of erythrocyte hemoglobin in reticuloendothelial cells.

Carboxyhemoglobin A form of hemoglobin in which the sites usually bound to oxygen are bound to carbon monoxide.

Complete blood count (CBC) The determination of the quantity of each type of blood cell in a milliliter of blood, often including the amount of hemoglobin, the hematocrit, and the proportions of various white cells. In certain countries it is referred to as the “full blood count.”

Conjugated bilirubin Bilirubin that has been taken up by the liver cells and conjugated to form the water-soluble bilirubin diglucuronide.

Direct bilirubin The fraction of bilirubin that reacts with the diazo reagent in the absence of alcohol.

Dubin-Johnson syndrome An autosomal recessive disorder that causes an increase of conjugated bilirubin in the serum.

Ferritin The iron/apoferritin complex, which is one of the chief forms in which iron is stored in the body; it occurs in the (1) gastrointestinal mucosa, (2) liver, (3) spleen, (4) bone marrow, and (5) reticuloendothelial cells.

Gilbert syndrome An inborn error of bilirubin metabolism causing predominantly unconjugated hyperbilirubinaemia.

Heme Any quadridentate chelate of iron with the four pyrrole groups of a porphyrin, further distinguished as ferroheme or ferriheme, referring to the chelates of Fe(II) and Fe(III), respectively.

Hemochromatosis A rare genetic disorder caused by deposition of hemosiderin in the parenchymal cells, resulting in tissue damage and dysfunction of the liver, pancreas, heart, and pituitary. Also called *iron overload disease*.

Hemoglobin(Hb) The oxygen-carrying pigment of the erythrocytes, formed by the developing erythrocyte in bone marrow. It is a conjugated protein containing four heme groups and globin, with the property of reversible oxygenation.

Hemoglobinopathy Any inherited disorder caused by abnormalities of hemoglobin, resulting in conditions such as sickle cell anemia, hemolytic anemia, or thalassemia.

Hemosiderin An intracellular storage form of iron; the granules consist of an ill-defined complex of ferric hydroxides, polysaccharides, and proteins having an iron content of about 33% by weight.

Hemosiderosis A focal or general increase in tissue iron stores without associated tissue damage. Hepatic and pulmonary forms of hemosiderosis are characterized by abnormal quantities of hemosiderin in the liver and lungs, respectively.

Hepcidin Hepcidin is a peptide hormone produced by the liver and regulates systemic iron.

Hereditary hemochromatosis A genetically heterogeneous group of inherited disorders of iron metabolism characterized by failure to prevent excessive amounts of iron from entering the circulatory pool and accumulating in the tissues.

Hereditary persistence of fetal hemoglobin A condition characterized by continued production of fetal hemoglobin beyond the point when it is normally replaced by hemoglobin A.

Hyperbilirubinemia Excessive concentrations of bilirubin in the blood, which may lead to jaundice;

the hyperbilirubinemias are classified as conjugated or unconjugated, according to the predominant form of bilirubin in the blood.

Icterus A condition characterized by hyperbilirubinemia and the deposition of bile pigments in the skin, mucous membranes, and sclera, with resulting yellow appearance of the patient; also called *jaundice*.

Indirect bilirubin Free bilirubin that has not been conjugated with glucuronic acid.

Jaundice A condition characterized by hyperbilirubinemia and deposition of bile pigment in the skin, mucous membranes, and sclera, with resulting yellow appearance of the patient; also called *icterus*.

Kernicterus A clinical syndrome of the neonate resulting from high concentrations of unconjugated bilirubin that passes the immature blood-brain barrier of the newborn and causes degeneration of cells of the basal ganglia and hippocampus.

Ligandin A hepatic transport protein; its measurement in serum and urine may be a means of estimating the severity of hepatocellular necrosis.

Methemoglobin A form of hemoglobin where its iron atom is changed from the ferrous to the ferric state.

Myoglobin A heme-containing protein found in red skeletal muscle.

Sickle cell anemia An autosomal dominant type of hemolytic anemia that is caused by the presence of hemoglobin S with abnormal sickle-shaped erythrocytes (*sickle cells*).

Soluble transferrin receptor A circulating truncated form of the transferrin receptor used in the diagnosis of iron deficiency.

Thalassemia A heterogeneous group of hereditary hemolytic anemias having a decreased rate of synthesis of one or more hemoglobin polypeptide chains and classified according to the chain involved (α , β , δ); the two major categories are α - and β -thalassemia.

Thalassemia major The homozygous form of β -thalassemia, a severe condition evident from the neonatal period with complete absence of hemoglobin A.

Thalassemia minor The heterozygous form of β -thalassemia; it is usually asymptomatic, although hemoglobin A synthesis may be retarded and there is sometimes moderate anemia and splenomegaly.

Transferrin A beta globulin that carries iron in the blood.

Transferrin saturation The ratio of serum iron to total iron binding capacity, expressed as a ratio or percentage.

Transfusion-induced iron overload Iron overload caused by transfusion.

Unconjugated bilirubin Free bilirubin that has not been conjugated with glucuronic acid.

Urobilinogen A colorless compound formed in the intestines by the reduction of bilirubin.

Fig. 28.1 Model of the hemoglobin tetramer with the α -chain subunits facing the reader. Each subunit contains a molecule of heme attached to an atom of iron.

HEMOGLOBIN

Biochemistry

Hemoglobin (Hb) is a globular protein with a diameter of 6.4 nm and a molecular mass of approximately 64,500 Da. Hb consists of four globin subunits: two α - and two non- α -chains (β -, γ -, or δ -chains). The **heme** portion is an iron-containing chelate with the globin portion consisting of two pairs of polypeptide globin chains, designated α and non- α . The four globin chains form a thick-walled globular shell surrounding a central cavity, in which the heme portion, attached by interaction of the histidine residues of the globin chains to the iron in heme, is suspended (Fig. 28.1). The heme iron is normally in the ferrous ($2+$) oxidation state.

Globin Structure of Normal and Fetal Hemoglobin

In healthy human adults, Hb A is composed of two normal α - and two normal β -polypeptide chains and is represented symbolically as $\alpha_2\beta_2$; it represents at least 96% of the total Hb contained in a sample of whole blood. Hb A₂ is typically approximately 2.5% to 3.0% of total Hb; it contains two α - and two δ -chains and is designated as $\alpha_2\delta_2$. HbA2' is considered a variant of Hb A₂ and is the result of a glycine-to-arginine substitution in the 16th position of the δ -chain. It rarely forms more than 3% of the total Hb. Fetal Hb (Hb F) predominates during fetal life but rapidly diminishes during the first year of postnatal life. In healthy adults, less than 1% of Hb is Hb F. It consists of two α - and two γ -chains ($\alpha_2\gamma_2$).

Modified Hemoglobins

In addition to the Hbs discussed previously, carboxyhemoglobin, **methemoglobin**, and sulfhemoglobin are other Hbs whose structure has been environmentally or chemically modified.

Each of the modified Hbs has a characteristic spectral pattern, as shown in Fig. 28.2. These spectral characteristics form the basis of analysis in the many co-oximeters and blood gas

Fig. 28.2 Spectrophotometric absorption curves for oxyhemoglobin, methemoglobin, and cyanmethemoglobin. Oxyhemoglobin and cyanmethemoglobin are used in measuring the concentration of hemoglobin (Hb). The peak at 630 nm, which is distinctive for methemoglobin, is abolished by the addition of cyanide, and the resultant decrease in absorbance is directly proportional to the methemoglobin concentration. All heme proteins exhibit their maximum absorbance in the Soret band region of 400 to 440 nm. Because the absorbance of Hb in the Soret region is approximately 10 times the absorbance at 540 nm, the Soret peaks have been omitted from this diagram. The absorbance curve for methemoglobin is greatly influenced by small changes in pH. The curve given here was obtained at a pH of 6.6.

analyzers that provide, in a single analysis, the simultaneous quantitative measurement of carboxyhemoglobin, methemoglobin, and sulfhemoglobin. The spectral scans are performed using multidiode arrays covering a number of wavelengths, followed by patented calculations that discriminate between normal and modified Hbs.

Carboxyhemoglobin. **Carboxyhemoglobin** is formed by the preferential attachment of carbon monoxide instead of oxygen to Hb, compromising the oxygen-carrying ability of hemoglobin. Carboxyhemoglobin concentrations are increased in smokers and employees with certain

Fig. 28.3 Normal oxygen dissociation curve of hemoglobin (Hb). Changes in 2,3-diphosphoglycerate (2,3-DPG) concentration in the erythrocyte greatly influence the position of the curve. As the concentration of 2,3-DPG increases, the curve shifts to the right. pO_2 , Partial pressure of oxygen. (From Duhm, J. [1972]. The effect of 2,3-DPG and other organic phosphates on the Donnan equilibrium and the oxygen affinity of human blood. In M. Roth, & P Astrup [Eds], *Oxygen affinity of hemoglobin and red cell acid base status [Alfred Benzon Symposium, IV]*. Copenhagen, Denmark: Alfred Benzon Foundation.)

environmental exposures. Carboxyhemoglobin saturation that varies from 15% to 25% may be associated with dizziness, headaches, and nausea, and greater than 50% saturation is considered life threatening. The half-life of carboxyhemoglobin is 4 to 6 hours.

Methemoglobin. The Fe of heme is normally in the reduced ferrous state (Fe^{2+}). Under alkaline conditions, the Fe is oxidized to the ferric state (Fe^{3+}) by toxic agents, such as nitrates (found in some well waters), aniline dyes, chlorates, drugs (e.g., quinones, phenacetin, and sulfonamides), or local anesthetics (e.g., procaine, benzocaine, and lidocaine). This oxidation converts the heme to hematin and the Hb to methemoglobin. Patients with methemoglobin are cyanotic because methemoglobin is unable to reversibly bind oxygen. Methemoglobin is normally reduced to Hb in the cell by the reduced form of the nicotinamide-adenine dinucleotide-cytochrome reductase system.

Sulfhemoglobin. Sulfhemoglobin is produced by the reaction of sulfur-containing compounds with heme to form an irreversible chemical alteration and oxidation of Hb by the introduction of sulfur in one or more of the porphyrin rings. The most common cause of sulfhemoglobinemia is exposure to drugs, such as phenacetin and sulfonamides. Sulfhemoglobin cannot transport oxygen, and cyanosis is noted at low concentrations.

Physiological Role

The Fe of heme is in the ferrous state (Fe^{2+}) and is able to combine reversibly with oxygen to act as the major oxygen-carrying moiety. The term *cooperativity* is used to describe the interaction of globin chains in such a way that oxygenation of one heme group enhances the probability of oxygenation

of the other heme group. The *Bohr effect* refers to reduction of oxygen affinity, with a decrease in pH from the physiologic range (7.35 to 7.45) to 6.0 and is another result of this cooperativity. Because the pH of the tissue decreases as a result of the presence of the end products of anaerobic metabolism, carbon dioxide (CO_2) and carbonic acid, the delivery of oxygen to the exercising tissue is enhanced. The oxygen dissociation curve of normal blood Hb is sigmoidal (Fig. 28.3). Physiologically, the CO_2 reversibly combines with the amino terminal groups of Hb to form carbamated Hb, which facilitates the removal of approximately 10% of the CO_2 that forms because of metabolism in the tissue to the lungs. Removal and transport of CO_2 from the tissue are enhanced by the preference for the attachment of more CO_2 by carbamated Hb.

Clinical Significance

The **thalassemia** syndromes and hemoglobinopathies are clinical disorders related to Hb pathophysiology. Although they may have some similar clinical manifestations, they form two distinct disease groups of genetic origin. The thalassemias originate from insufficient or absent globin chain production due to gene deletion or nonsense mutations, which are mutations that affect the transcription or stability of mRNA products. The name *thalassemia* is derived from the Greek word for “sea,” *thalassa*, because early cases of β -thalassemia were described in children of Mediterranean origin.

Hemoglobinopathies, the most common single gene disorder in the world, are structural Hb variants arising from mutations in the globin genes, which result in substitutions or disruptions in the normal amino acid residue sequence in one or more of the globin chains of Hb.

The thalassemias and hemoglobinopathies occur worldwide and are particularly prevalent in South East Asia, Southern China, Mediterranean countries (particularly Greece and the Greek Cypriot part of Cyprus), India, the Middle East, Africa, and the islands of the South Pacific. With increasing migration, the thalassemias—once considered rare genetic diseases in Northern Europe, Australia, and North America—are now becoming more common all over the world.

Thalassemia Syndromes

Thalassemias are identified by the globin chain in which a production deficiency occurs. For example, α - and β -thalassemias result from a deficiency in α - or β -globin chain production, respectively. They are further clinically classified depending on the extent of globin chain production and the resultant severity of the anemia. All the thalassemias have a similar pattern of inheritance: in most cases the gene defects are transmitted in a Mendelian autosomal fashion. Thus, the severe symptomatic varieties result from the interaction of more than one genetic determinant. The inheritance of α -thalassemia is more complicated because it involves the products of the linked pairs of α genes ($\alpha\alpha$).

Alpha-thalassemias. The α -thalassemias arise from deficiencies in production of the α -globin chains and are caused by deletions or (less frequently) point mutations in one or more of the four α -globin genes. There are two major classes of α thalassemias: α^0 in which both α genes are inactivated ($-/-$), and α^+ thalassemias, in which only one of the pair is defective either due to α deletion or to α mutation. The conventional nomenclature for the point mutations of an α -gene is “ $\alpha^T\alpha$,” and for deletion, it is “ $-\alpha$.” The clinical spectrum of α thalassemias correlates well with the number of the affected α -genes (i.e., from normal to the loss of all four genes). The inheritance of a normal allele ($\alpha\alpha$) with one of the α^+ or α^0 results, most frequently, in an “ α -thalassemia minor” ($-/\alpha\alpha$; $-\alpha/\alpha\alpha$; $-\alpha^T/\alpha\alpha$; $\alpha^T\alpha/-\alpha$; $-\alpha/-\alpha$) (Table 28.1). The **complete blood count (CBC)** in patients with α -thalassemia minor shows a mildly reduced Hb with low mean corpuscular volume (MCV) and mean corpuscular hemoglobin (MCH). Alpha-thalassemias are common in areas where β -thalassemia is also found at a high frequency. Thus, the coinheritance of α - and β -thalassemia traits may occur and even ameliorate the hematological parameters. *Alpha-Thalassemia silent* describes an α -thalassemia trait with a single α -globin chain gene deletion or mutation ($-\alpha/\alpha\alpha$; $\alpha^T\alpha/\alpha\alpha$).

Hemoglobin Bart's results from deletion of all four α -globin genes, with the subsequent inability to produce any α -globin chains, leading to failure of synthesis of Hb A, F, or A₂. In the fetus, an excess number of γ -globin chains join together to form unstable tetramers known as Hb Bart's (γ^4). Mothers who carry a fetus with Hb Bart's usually present clinically between 20 and 26 weeks' gestation with pregnancy-induced hypertension, polyhydramnios, and hydrops fetalis.

TABLE 28.1 The Alpha-Thalassemias

Condition	Affected Number of Alpha-Globin Genes	Phenotype
Silent carrier	One	Asymptomatic or occasional low red blood cell indices
Alpha-thalassemia trait	Two	Mild microcytic and hypochromic anemia
HbH disease	Three	Mild-to-moderate anemia, splenomegaly, jaundice
Alpha-thalassemia major/Hb Bart's hydrops	Four genes	Most severe form Hb Bart's hydrops Death in utero or at birth

Hb, Hemoglobin.

Data from Vichinsky, E. P. (2009). Alpha thalassemia major—new mutations, intrauterine management, and outcomes. *Hematology American Society of Hematology Education Program*, 35–41.

Hemoglobin H disease. This disorder is usually caused by a three α -globin gene deletion ($-/-\alpha$) and is characterized by a chronic anemia of variable severity.

Beta-thalassemias. The β -thalassemias result from a reduction in the synthesis of the β -globin chain. The high frequency of β -thalassemia in the tropics is believed to reflect an advantage of heterozygotes against *Plasmodium falciparum* malaria.

The clinical classification of β -thalassemia includes: **thalassemia major** (TM; transfusion-dependent), **thalassemia intermedia** (TI; of intermediate severity, nontransfusion-dependent) and **thalassemia minor** (asymptomatic). The severity of the clinical manifestations correlates well with the degree of imbalance of globin chains, depending on the β -globin gene defects and their interaction. The production of β -globin chains is quantitatively reduced to different degrees, whereas the synthesis of α -globin continues as normal, resulting in an accumulation of excess unmatched α -globin chains in the erythroid precursors. Clinical manifestations of β -thalassemia range from mild anemia to severe life-threatening disease that requires lifelong transfusions (Fig. 28.4).

Beta-thalassemia (beta-thalassemia major). Beta-TM results from mutations that interfere with translation or are involved in the initiation, elongation, or termination of globin chain synthesis. Mutations that interfere with translation account for almost 50% of all β -thalassemia mutations. Included in this are frame shift or nonsense mutations that produce premature termination codons, which result in incomplete translation of the β -globin gene and nonproduction of the β -globin chain, leading to β -thalassemia. Clinical presentation usually occurs at younger than 1 year of age, with features such as small size for age, abdominal girth expansion, and failure to thrive. Physical examination of the

Fig. 28.4 Clinical complications in thalassemia major and in thalassemia intermedia. *IOL*, Iron overload; *NTDT*, non-transfusion-dependent thalassemia; *PHT*, pulmonary hypertension; *TDT*, transfusion-dependent thalassemia; *β-TM*, β -thalassemia major. (Modified from Musallam, K., Rivella, S., Vichinsky, E., & Rachmilewitz, E. A. [2013]. Non-transfusion-dependent thalassemias. *Haematologica*, 98, 833–844.)

patient may reveal frontal bossing (an unusually prominent forehead) caused by thickening of the cranial bones, pallor, and prominence of the cheek bones, which in older children obscures the base of the nose and exposes the teeth. These features are a result of marrow expansion (up to a 30-fold increase) caused by ineffective erythropoiesis with production of highly unstable α -globin tetramers, leading to a sequence of events responsible for bone marrow expansion, anemia, hemolysis, splenomegaly, and increased Fe absorption. Typical CBC results include severe anemia with Hb concentration between 3 and 6.5 g/dL (30 and 65 g/L), MCV of 48 to 72 fL, and MCH of 23 to 32 pg, and varying size of red blood cells (RBCs) (anisocytosis).

Beta-thalassemia intermedia. TI is a clinical term used to describe patients with anemia and splenomegaly, but who do not have the full spectrum of clinical severity found in TM. Most TI patients are homozygotes or compound heterozygotes for mild-to-moderate β -gene mutations (β^+/β^+ ; β/β^+), less commonly, only a single β -globin gene is affected. Mildly affected patients are almost completely asymptomatic until adult life, experiencing only mild anemia and spontaneously

maintaining Hb levels between 7 and 10 g/dL (70 to 100 g/L). In adult life, Hb is significantly reduced to values between 6 and 10 g/dL (60 to 100 g/L)

Beta-thalassemia minor (beta-thalassemia trait). Patients with β -thalassemia minor are often asymptomatic, except at times of hematopoietic stress, such as infection or pregnancy, when they can become more anemic. The CBC on patients with a β -thalassemia trait shows mild anemia with low normal or decreased Hb concentration and hematocrit, decreased MCV (<80 fL) and MCH (<25 pg), and variable red cell distribution widths.

Delta/beta-thalassemia. The $\delta\beta$ -thalassemias are the result of deletions that affect various parts of the β -globin locus.

Hereditary persistence of fetal hemoglobin. The term **hereditary persistence of fetal hemoglobin (HPFH)** is used to describe a group of genetic conditions in which the concentration of Hb F is increased above the upper limit of the reference interval because of a reduction in β -globin synthesis and a compensatory increase in δ -globin synthesis. HPFH is divided into *deletional* and *nondeletional* HPFH.

Fig. 28.5 Peripheral blood smear from patients with (A) homozygous hemoglobin (Hb) E and (B) homozygous Hb S.

Hemoglobinopathies

Nomenclature. Hb variants are named using (1) letters (Hbs S, D, E, and so on), (2) the family name of the index case (Hb Lepore), (3) the place of discovery of the variant or place of origin of the propositus (Hb Edmonton), or (4) the name of the river (Hb Saale) flowing through the city in which the propositus lived. In some cases, both a letter and a name are used, as in Hb J-Baltimore, indicating that the Hb is classified as having electrophoretic mobility similar to that of other J Hbs, but differs from them in amino acid sequence, and was originally discovered in Baltimore. The term *AS trait* (sometimes abbreviated to *S trait*) is used to describe a heterozygous state in which one of the β -globin chains is S and the other is A. In instances in which no normal β -globin chain is present (e.g., Hb SD), the β -globin chain present in the higher concentration is usually, although not always, placed first. A systematic nomenclature system is now used alongside the variant name to describe the affected chain and location on the chain and the amino acid substitution. For example, Hb Spanish Town [$\alpha 27(\beta 8)^{\text{Glu} \rightarrow \text{Val}}$], a Hb variant named after a district in Kingston, Jamaica, and found in Jamaicans of African descent, results from a substitution of valine for glutamic acid in position 27 of the α -globin chain, which is located in position 8 of the B helix of the α -chain.

Classification of hemoglobin variants. Hb variants are classified according to the type of mutation. Single point mutations in α -globin chains give rise to substitution of one amino acid residue. As an example, Hb San Diego [$\beta 109(\text{G11})^{\text{Val} \rightarrow \text{Met}}$] has a methionine residue instead of the normal valine at position 109 of the β -chain.

Types of hemoglobin variants. Types of Hb variants include (1) deletion, (2) insertion, (3) deletion/insertion, (4) elongation, and (5) hybrid/fusion/crossover Hbs.

Hemoglobin S. Hemoglobin S [$\beta 6(\text{A3})^{\text{Glu} \rightarrow \text{Val}}$] in the heterozygous or homozygous state is the most widespread of the Hb variants and arises from a substitution of valine for glutamic acid at position 6 in the A helix of the β -globin chain. Approximately 8% of African Americans are heterozygous for Hb S, and homozygous Hb S is found in 1 in 500 newborns

in this group. The widespread distribution of the single point gene mutation responsible for the synthesis of Hb S in areas where *P. falciparum* malaria is endemic is due to the protection of Hb S heterozygotes from the worst manifestations of this malaria. The homozygous condition is described as **sickle cell anemia** or sickle cell disease because of the sickle-shaped RBCs that occur when a sickle cell crisis occurs (Fig. 28.5). It is sometimes written as $\beta^{\text{S}}\beta^{\text{S}}$.

Analytical Methods

Thalassemias and hemoglobinopathies are diagnosed and monitored using multiple assays. The methods used are divided into presumptive identification (e.g., CBC, high-performance liquid chromatography [HPLC], and electrophoresis) and definitive identification (DNA sequencing and mass spectrometry). In addition to these tests, the Fe status of the patient should be ascertained by the measurement of ferritin or by the Fe/total Fe-binding capacity/saturation index. Information on the ethnicity and/or nationality of the patient also provides useful information.

Ethylenediaminetetraacetic acid (EDTA) whole blood should be collected and testing should be performed within 5 days of collection, and samples should be stored at 4°C.

Techniques

Analytical techniques used to measure RBCs and their indices, Hb, and related compounds include (1) determination of CBC, (2) electrophoresis, (3) immunoassay, (4) separation techniques such as HPLC, capillary electrophoresis, and mass spectrometry, (5) molecular techniques such as DNA analysis, and (6) specific tests for specific variants.

Complete blood count. A CBC, also known as a full blood count, a full blood examination, or a blood panel, consists of (1) numbers of RBCs (erythrocytes), (2) numbers of white blood cells, (3) numbers of platelets, (4) a measure of Hb, (5) and various cell indices (Table 28.2). Knowledge of red cell indices and the information obtained from microscopic examination of a peripheral blood film is vital to the diagnosis of both α - and β -thalassemias.

TABLE 28.2 Definition of the Parameters That Constitute a Complete Blood Count

Parameter	Definition
WBC	The number of WBCs in the blood
WBC differential count	The number (or percentage) of each type of WBC present in the blood: neutrophils, basophils, eosinophils, lymphocytes, monocytes
RBC count	The number of RBCs in the blood
Hct	The Hct is the proportion of blood volume that is occupied by RBCs
Hb	The protein molecule in RBCs that carries oxygen
MCV	The MCV is the average volume of RBCs
Mean corpuscular Hb	The average amount of Hb in the average RBC
Mean corpuscular Hb concentration	The average concentration of Hb in a given volume of blood
Red cell distribution width	A measurement of the variability of RBC size
Platelet count	The calculated number of platelets in a volume of blood
Platelet distribution width	A measurement of the variability of platelet size
Plateletcrit	The proportion of blood volume that is occupied by platelets
Mean platelet volume	The average volume of platelets

Hb, Hemoglobin; Hct, hematocrit; MCV, mean corpuscular volume; RBC, red blood cell; WBC, white blood cell count.

Electrophoresis. Electrophoresis using agarose gel under alkaline conditions (pH 9.2) is the most common initial screening method for the detection and preliminary identification of hemoglobinopathies. Visualization of separated Hb bands is achieved by using a protein-binding stain, such as Amido Black or Ponceau S. Hb bands stain blue with Amido Black and reddish pink with Ponceau S.

At alkaline pH, Hbs migrate according to electrical charge, with Hb H moving the fastest (closest to the anode). The order of migration (fastest to slowest) is Hb H, Hb N, Hb I, Hb J, Hb A, Hb F, Hb S, and Hb C. Hb D and Hb G comigrate with Hb S, and Hb E, Hb O, and Hb A₂ comigrate with Hb C. Hemoglobin Constant Spring migrates slightly toward the cathode. An easy way to remember the sequence is Hb A goes to the anode, whereas Hb C migrates to the cathode. Hb F and Hb S follow after Hb A in alphabetical order.

Electrophoresis at pH 6.4 using a citrate buffer is performed when an abnormal band is noted on alkaline Hb electrophoresis. The same Hb variants separated on agarose electrophoresis at pH 6.4 and stained with acid violet are shown in the *right panel* of Fig. 28.6. The order of migration (cathode to anode, fastest to slowest) is Hb F, Hb A, Hb S, and Hb C. Hb D, Hb G, Hb I, Hb J, Hb O, Hb A₂, and Hb E comigrate with Hb A.

Specific types of electrophoresis that are used for Hb analysis include isoelectric focusing, electrophoresis, and capillary electrophoresis.

Fig. 28.6 Alkaline (*left*) and acid (*right*) electrophoresis of various hemoglobinopathies. Lane 1, hemoglobin (Hb) S, Hb FA control. Lane 2, Hb S, Hb F, HbCA control. Lane 3, transfused sickle cell (SC) disease. Lane 4, SC disease. Lane 5, Hb A (normal). Lane 6, Hb Presbyterian. Lane 7, Hb S. Lane 8, raised Hb A₂ (β-thalassemia trait). Lane 9, Hb J Baltimore. Lane 10, Hb C.

Isoelectric focusing electrophoresis. Isoelectric-focusing electrophoresis (IEF) has greater resolving power than conventional electrophoresis, but it is more expensive, time-consuming, and technique-dependent to perform. Commercial IEF gels are made of cellulose acetate or polyacrylamide with the pH gradient produced by the inclusion of amphoteric materials of different pHs in bands in the gel. Locations of the Hb bands are identified using stains similar to those used in conventional electrophoresis. The bands or zones produced by IEF (Fig. 28.7) are more clearly defined than those seen with conventional electrophoresis, and reliable quantification of separated Hbs may be made at high concentrations using densitometry.

Capillary isoelectric focusing electrophoresis. Capillary IEF combines the detection sensitivity of capillary electrophoresis with the resolution qualities and existing extensive data on Hb variant separation by immunoelectrophoresis and the automated sampling and digital data acquisition techniques developed for chromatography. With this approach, the hemolysate is introduced into the capillary chamber using low-pressure injection and then is focused at high voltage (typically ≈30 kV and 0.5 to 1.5 μA), during which it is essential to maintain adequate cooling. The separated Hbs are then eluted, using low-pressure and simultaneous voltage, past a single-wavelength spectrophotometric detector set to read at 415 nm or a dual-wavelength detector set at 415 and 450 nm.

Capillary electrophoresis. The introduction of commercial capillary electrophoresis instrumentation for the separation of Hbs has made this technique available to clinical laboratories. Separation in an alkaline buffer at a specific pH using high voltages is based on charge difference, electrolyte pH, and electro-osmotic flow. Hb measurement is commonly performed at a wavelength of 415 nm, and identification is based on retention time.

Fig. 28.7 A diagram of isoelectric focusing patterns for a variety of hemoglobin (Hb) variants. The conditions shown represent heterozygotes (traits), unless otherwise indicated. The width of the bars approximates the relative density of the bands observed. The acid anodic (pH 6) side is to the *right*, and the alkaline cathodic (pH 8) side is to the *left*. The same pattern is observed in homozygous patients with HbS disease who have received HbA by transfusion.

High-performance liquid chromatography. HPLC using a column packed with cation-exchange resin provides—in a single analytical protocol—the quantification of Hb F and Hb A₂. With it, the initial identification of an Hb variant on the basis of elution time may be made. It has also been used to detect α -thalassemia phenotypes.

After injection and subsequent adsorption onto the particles of a cation-exchange resin, molecules of Hb are eluted using gradient elution. The detection of eluted Hbs is achieved by monitoring the effluent solvent stream using a dual-wavelength photometer (usually set to measure at wavelengths of 415 and 690 nm) (Fig. 28.8).

Electrospray Mass Spectroscopy

Electrospray mass spectrometry is becoming an accepted method for the characterization of Hb variants involving substitution of one or more amino acids in the globin protein chains. Tandem mass spectrometry (MSMS) has been used for newborn screening for sickle cell disease and thalassemias.

Several mass spectrometry-based approaches, sometimes using laborious preparative steps, have been described. (1) Measurement of the mass of intact globin chains and the relative proportion of β and δ globin chains. Alpha or β variants are followed up by peptide-based analysis, based on tryptic digestion of whole blood, using electrospray MSMS in multiple reaction monitoring (MRM) mode to confirm identity. (2) Ultra-performance liquid chromatography coupled with MSMS using predetermined tryptic peptides to screen for clinically important structural variants. (3) Mass measurement of intact globin chains without complex pre-analytical sample digestion/separation procedures followed by top-down electron transfer dissociation (ETD) fragmentation of selected globin chains for the confirmation of variants. These techniques offer a faster and more specific detection and sequence confirmation of clinically significant Hb variants than conventional methods, but they require special instrumentations and skills for interpretation.

DNA Analysis

DNA analysis is used in the investigation of thalassemias and hemoglobinopathies to identify specific individuals at risk and those who may benefit from genetic counseling in populations with a known high incidence of disease. For example, DNA analysis has been used to do the following:

1. Diagnose α^0 - and α^+ -thalassemia.
2. Investigate potentially life-threatening disorders of Hb synthesis in the fetus; it is performed at less than 10 weeks' gestation on chorionic villus samples.
3. Characterize the β -thalassemia genotype.
4. Screen at-risk populations for clinically significant Hb variants.
5. Distinguish between conditions that have similar laboratory and clinical presentations but are the result of different genetic conditions.

Specific Tests

Tests that are used to measure Hbs and related analytes include those for Hb H, Hb S, unstable Hbs, and globin chains.

Determining hemoglobin H. Hb H, an insoluble tetramer consisting of four β -globin chains due to decreased production of α -globin chains. If the tetramers are oxidized, precipitation occurs, which may be viewed microscopically. In the laboratory, this oxidation is achieved by staining unfixed cells with freshly prepared methylene blue or brilliant cresyl blue at 37°C.

Sickling and hemoglobin S solubility tests. Sickling tests are useful in confirming the presence of Hb S in a sample after initial electrophoresis at alkaline pH. When Hb S is oxygenated, it is fully soluble. When Hb S is deoxygenated, polymerization occurs, forming deformed red cells with a characteristic rigid sickle shape. In the laboratory, deoxygenation and lysis of RBCs is achieved using a solution of sodium metabisulfite in a phosphate buffer. The addition of the sodium metabisulfite reagent to an Hb S-containing blood sample induces the typical sickle shape of RBCs (which is the basis of the sickling test by microscopic investigation).

Fig. 28.8 High-performance liquid chromatography chromatograms obtained on the bio-rad variant β -thal short program for (A) hemoglobin (Hb) Bart's; (B) β 0-thalassemia major; (C) B+thalassemia homozygous E; (D) HbH; (E) homozygous S; (F) S trait; (G) homozygous C; (H) C trait; and (I) HbS-HbG Philadelphia. (From Clarke, G. M., Trefor, N., & Higgins, T. N. [2000]. Laboratory investigation of hemoglobinopathies and thalassemias: review and update. *Clinical Chemistry*, 46, 1284–1290.)

of the blood film preparation), and it also causes turbidity (which is the basis of the solubility test). In the Hb S solubility test, this turbidity is visualized by holding a lined card or a card with writing on it behind the reaction test tube (Fig. 28.9). A positive sample is not transparent, whereas a negative sample is. False negative results are obtained on anemic patients (Hb <8 g/dL; or <80 g/L) or on samples with hematocrit less than 15% (0.15). False positive results are found in samples with (1) Heinz bodies, (2) high concentrations of monoclonal protein, (3) hyperlipidemia, or (4) cold agglutinins. The test is subjective, and the combination of two identification techniques, such as HPLC and alkaline electrophoresis, may eliminate the necessity to perform this test on a routine basis.

Tests for unstable hemoglobins. These tests use heat or isopropanol to precipitate the unstable Hb and must be performed on fresh blood. More than 100 unstable Hbs are mainly the result of the interchange of nonpolar amino acid residues for polar amino acid residues in positions in the α - or β -globin chain associated with the heme cleft.

IRON

Iron is involved in the function of all cells. It can accept and donate electrons, depending on its oxidation state: ferrous iron (Fe[II]) or ferric iron (Fe[III]). Iron is mostly locked into Fe protoporphyrin (heme) and Fe-sulfur clusters, which serve as enzyme cofactors. Hemoproteins are involved in numerous

Fig. 28.9 Solubility test for hemoglobin (Hb) S. Deoxyhemoglobin S (left tube) is insoluble in 2.3 mol/L phosphate buffer. In contrast, normal hemolysate (right tube) is sufficiently transparent that print can easily be read through it.

biological functions, such as oxygen binding and transport (Hbs), oxygen metabolism (catalases, peroxidases), cellular respiration, and electron transport (cytochromes). Proteins containing nonheme Fe are important for fundamental cellular processes such as DNA synthesis, cell proliferation and differentiation (ribonucleotide reductase), gene regulation, drug metabolism, and steroid synthesis. However, Fe can also cause damage, because Fe(II) catalyzes the generation of highly reactive hydroxyl radicals ($\cdot\text{OH}$) from hydrogen peroxide (H_2O_2) ($\text{Fe}^{2+} + \text{H}_2\text{O}_2 \rightarrow \text{Fe}^{3+} + \text{HO}^- + \text{HO}\cdot$), which is called the “Fenton reaction.” These hydroxyl radicals damage cellular membranes, proteins, and DNA. A large number of scavenger molecules protect cells against Fe-mediated tissue damage. Proteins sequester Fe to reduce this threat. Iron circulates in a form bound to plasma **transferrin**, which is needed to offer the highly insoluble Fe(III) to cells via the transferrin receptor. Iron can safely be stored within cells in the form of ferritin and hemosiderin. Under normal circumstances, only small amounts of Fe exist outside this physiologic sink, although stored Fe can be mobilized for reuse. Many diseases arise from imbalances in Fe homeostasis. Too much Fe accumulates in **hereditary hemochromatosis** (HH) and in the Fe-loading anemias, which are often aggravated by multiple transfusions. In iron-deficiency anemia (IDA), insufficient amounts of Fe are available for heme synthesis. In **anemia of chronic disease** (ACD), Fe is redistributed to macrophages to promote resistance to infections.

Iron Metabolism

Systemic and Cellular Iron Regulation

The control of Fe homeostasis acts at both the cellular and the systemic level, and involves a complex system of

different cell types, transporters, and signals. To maintain systemic Fe homeostasis, communication between cells that absorb Fe from the diet (duodenal enterocytes), consume Fe (mainly erythroid precursors), and store Fe (hepatocyte and tissue macrophages) must be tightly regulated. Each of these cell types plays an essential role in the homeostatic Fe cycle. Hepcidin controls Fe absorption and macrophage Fe release. Hepcidin is synthesized in the liver upon changes in body Fe needs, anemia, hypoxia, and inflammation, and is secreted in the circulation. It counteracts the function of ferroportin, a major cellular Fe exporter protein in the membrane of macrophages and the basolateral site of enterocytes, by inducing its internalization and degradation **Fig. 28.10**.

Body Iron Distribution

See **Table 28.3** for average distribution of body iron.

Ferritin. **Ferritin** consists of a protein shell surrounding an iron core. Ferritin consists of an apoferritin shell composed of 24 subunits that are either L (light) or H (heavy) ferritin chains, and an interior ferric oxyhydroxide (FeOOH) crystalline core. Ferritin occurs in nearly all body cells and stores iron in a form that is shielded from body fluids and is therefore unable to cause oxidative damage. Ferritin in hepatocytes and macrophages provides a reserve of iron that is available for synthesis of Hb and other heme proteins. In healthy men, ≈ 1000 mg of storage iron is present, mostly as ferritin. In healthy premenopausal women, storage iron ranges up to ≈ 300 mg. Relative to tissues, minute quantities of relatively iron-poor ferritin are also present in serum in concentrations roughly proportional to total body iron stores. However, when elevated, serum ferritin does not always correlate with body iron content. Relatively large amounts of ferritin may be released into plasma as the result of diverse pathological conditions among which are infections, chronic inflammatory diseases, chronic liver diseases, the metabolic syndrome, and nonalcoholic steatohepatitis (NASH).

Hemosiderin. **Hemosiderin**, a terminus of the intracellular storage iron pathway, is formed when ferritin is aggregated and partially deproteinized in secondary lysosomes. Like ferritin, hemosiderin is usually found predominantly in cells of the (1) liver, (2) spleen, and (3) bone marrow. Unlike ferritin, hemosiderin is insoluble in aqueous solutions.

Tissue iron. Numerous cellular enzymes and coenzymes require iron as an integral part of the molecule or as a cofactor. These include *peroxidases* and *cytochromes*, all of which are heme proteins, like Hb. Other enzymes, such as *aconitase* and *ferredoxin*, contain iron that is coordinated with sulfur in a so-called iron-sulfur cluster. These enzymes and coenzymes occur in all nucleated cells of the body and form the *tissue iron compartment*, normally ≈ 150 mg of iron (see **Table 28.3**).

Myoglobin. **Myoglobin** very closely resembles a single Hb subunit and contains a single heme per molecule.

The labile iron pool. A fraction of the circulating non-transferrin-bound iron (NTBI) is redox-active and

Fig. 28.10 Systemic iron (Fe) homeostasis. The largest flux of Fe takes place in the recycling of Fe from senescent erythrocytes out of (A) macrophages to incorporation in (B) erythroid precursors in the bone marrow. Values for the different tissues and fluxes are approximate. The (D) liver and (C) reticuloendothelial macrophages function as major iron stores. Only 1 to 2 mg Fe is absorbed and lost every day. Importantly, the total amount of Fe in the body can only be regulated by absorption, whereas Fe loss occurs only passively from sloughing of skin and mucosal cells, as well as from blood loss. Hepcidin, a recently identified antimicrobial, β -defensin-like peptide secreted by the liver, decreases the plasma Fe concentration by inhibiting Fe export by ferroportin from (A) duodenal enterocytes and (C) reticuloendothelial macrophages. As a consequence, an increase in hepcidin production results in a decrease in plasma Fe concentrations. Hepcidin expression of the hepatocyte is regulated by circulating and stored Fe, inflammatory stimuli, the erythroid Fe demand, and hypoxia, by pathways involving expression of *HFE*, *TfR2*, hemojuvelin (*HJV*), and *TMPRSS6* genes. In *HFE*-, transferrin receptor (*TfR*)-2, and *HJV*-related hereditary hemochromatosis, hepcidin production is low despite increased liver Fe, which results in inappropriately increased Fe absorption. Defects in the *TMPRSS6* gene, encoding for matriptase-2, result in Fe refractory iron-deficiency anemia. The letters A, B, C, and D refer to sites with special functions in iron metabolism. (From Swinkels, D. W., Janssen, M. C., Bergmans, J., & Marx, J. J. [2006]. Hereditary hemochromatosis: genetic complexity and new diagnostic approaches. *Clinical Chemistry*, 52, 950–968.)

TABLE 28.3 Iron Content of Compartments in an Average Male

Compartment	Iron Content (mg)
Hemoglobin	2500
Storage iron ^a	1000
Myoglobin	130
Other cellular iron-containing proteins	150
Transport (transferrin)	3
Total	3000–5000

^aSum of parenchymal and reticuloendothelial iron stored in ferritin or hemosiderin.

designated labile plasma Fe. Although there are methods for measuring serum NTBI and labile plasma Fe, insufficient standardization and clinical correlation currently limit clinical use of these measurements.

Iron transport. Iron is transported from one organ to another in the plasma by the transport protein *apotransferrin*. The apotransferrin/ Fe^{3+} complex is called mono-ferric or diferric (=holo) transferrin. When transferrin binds to the *transferrin receptor* of cells, the transferrin/receptor complex is internalized into an endosome that becomes acidified, releasing the iron from transferrin. Iron is then converted to ferrous iron (Fe^{2+}) by a ferredoxinase, and transported to the cytosol via the divalent metal transporter DMT1. The apotransferrin is then transported back to the cell surface, ready to transport another transferrin molecule to the interior of the cell. This series of reactions has been designated the *transferrin cycle*.

Regulation of iron homeostasis

Systemic iron regulation. The total body iron content can only be regulated by absorption from the upper intestinal tract, whereas iron loss occurs only passively from sloughing

of skin and mucosal cells, as well as from blood loss. **Hepcidin**, a peptide hormone produced by the liver, regulates systemic iron. It decreases the iron absorption from the diet as well as iron export from macrophages. As a consequence, elevated hepcidin levels result in a decrease of plasma iron concentration.

Normal iron balance. The average daily American diet contains 10 to 15 mg of iron, much of it in the form of (1) heme proteins, (2) Hb, and (3) myoglobin in meat. Normally, ≈ 1 to 2 mg of iron is absorbed each day, mostly by the duodenum. To be absorbed, inorganic iron must be in the ferrous state (Fe^{2+}). Dietary heme is taken up via an unknown transport system.

Proteins that affect iron homeostasis. Many proteins influence iron homeostasis. Mutations in genes that encode these proteins may cause several inherited iron disorders, among which are iron overload or iron deficiency. [Table 28.4](#) summarizes the effects of some of these proteins on iron homeostasis.

Clinical Significance

Iron deficiency, Fe overload, and ACD are the most prevalent disorders of Fe metabolism. Iron disorders may be classified

according to (1) pathophysiology (see [Table 28.4](#)), (2) heritability (genetic or acquired), or (3) as being “primary,” (e.g., resulting from a defect in an Fe metabolism-related protein) or “secondary” (e.g., the consequences of defects in other proteins).

Iron Deficiency

Iron deficiency and IDA—defined when anemia and Fe deficiency coexist—are global health problems and common medical conditions seen in everyday clinical practice.

Iron deficiency is particularly a disorder of children and premenopausal women in low- and middle-income countries, but it can also occur in men, and in developed countries in people of all ages. In children, Fe deficiency is frequently caused by the increased physiologic needs for dietary Fe for growth and development. In adults, and especially premenopausal women, Fe deficiency is almost always the result of chronic blood loss or childbearing.

Iron-deficiency anemia is associated with impaired quality of life, work productivity, aerobic exercise capacity, and fatigue, and there is also a relationship between Fe status and depression and cognitive functioning. Iron deficiency

also affects immune function and the susceptibility to infections. Furthermore, Fe deficiency is a predictor of mortality in patients with chronic kidney disease and heart failure; treating Fe deficiency in patients with heart failure improves quality of life.

Iron-deficiency anemia is generally an acquired condition due to blood losses, malabsorption, insufficient Fe intake, or a combination of these. Some patients with chronic disease are especially vulnerable to develop absolute Fe deficiency (e.g., patients with gastrointestinal tumors because of blood losses). Patients with advanced chronic kidney disease also have a negative Fe balance as a result of reduced dietary intake, impaired absorption from the gut, and increased Fe losses. In addition, patients with chronic kidney disease also often have a functional Fe deficiency because the available circulating Fe cannot keep pace with the requirements of erythropoiesis.

In patients with iron refractory iron-deficiency anemia (IRIDA), an inherited form of IDA due to a defect in the

TMPRSS6 gene encoding for the protein matriptase-2, the iron deficiency does not improve with oral Fe supplementation. This disorder is an indication for intravenous iron treatment.

Many different measurements have been advocated for the diagnosis of Fe deficiency. Overall, a low ferritin level is a sensitive and specific indicator of Fe deficiency uncomplicated by other diseases. A **transferrin saturation** (<15% to 20%) indicates an Fe supply that is insufficient to support normal erythropoiesis (Tables 28.5 and 28.6). Hb below normal combined with iron deficiency defines IDA. **Soluble transferrin receptor (sTfR)** is helpful in the investigation of the pathophysiology of anemia, to distinguish IDA from ACD and to detect functional iron deficiency. In the different stages of iron deficiency, the various biochemical and hematological tests efficiently complement each other and help characterize the severity in the individual patient (Fig. 28.11).

Anemia of Chronic Disease

ACD, also named anemia of inflammation, is a common disorder. It is often observed in patients with infectious and inflammatory diseases, among whom are patients with chronic kidney disease, inflammatory bowel disease, chronic heart failure, malignancies, and hepatic diseases. It is an acquired Fe distribution disorder with relatively low circulating Fe levels, despite the presence of adequate total body Fe stores. The pathogenesis of ACD includes shortened erythrocyte survival, impaired marrow function, and disturbances of Fe metabolism. In ACD, the release of Fe from cells to the circulation is inadequate to support heme formation, and Fe is sequestered in reticuloendothelial macrophages. The ACD is typically normocytic and normochromic. Patients with ACD have anemia, low Fe, low transferrin, low transferrin saturation (TSAT), normal or moderately elevated ferritin, elevated hepcidin, and mostly normal sTfR concentrations.

Iron Overload

Iron overload disorders are typically insidious, causing progressive and sometimes irreversible tissue damage before clinical symptoms develop. Fe overload disorders can be categorized according to whether the underlying pathophysiological defect is in the hepcidin-ferroportin axis, erythroid maturation, or in Fe transport. There are also some less common disorders that do not fit into one of these categories (see Table 28.4). Iron overload may also develop as a consequence of multiple RBC transfusions and parenteral Fe supplementation.

Disorders of the hepcidin-ferroportin axis. Each of the six disorders in this group has a primary form of Fe overload and is a subtype of HH (primary) (see Table 28.4). Five of the six different HH disorders may lead to a classical HH phenotype: normal Hb, elevated ferritin and TSAT, and tissue Fe overload (see Tables 28.5 and 28.6). The pathophysiology of these five conditions is similar, with an increased Fe absorption exceeding the needs of the body, which leads to increased Fe stores due to inadequate hepcidin-mediated down-regulation of ferroportin. This leads to Fe deposition in parenchymal organs (e.g., the liver and the pancreas).

Initial clinical symptoms of tissue Fe overload are often nonspecific and vague: fatigue and joint pain. In later stages, disease manifestations may include diabetes mellitus, hypogonadism and other endocrinopathies, liver cirrhosis, cardiomyopathy, skin pigmentation, and in cirrhotic patients, increased susceptibility of liver cancer. Early diagnosis and therapeutic phlebotomy can prevent the development of tissue damage, reduce morbidity and mortality, and provide long-term survival similar to the general population. Phlebotomy is the treatment for HH.

The most common form of HH is attributed to variants in the *HFE*-gene. The best described variants in *HFE*-hemochromatosis are (1) the variant in the cDNA of *HFE* at position 845, a G to A nucleotide change resulting in a cysteine to tyrosine replacement (p.Cys282Tyr or C282Y); and (2) the variant at *HFE* cDNA position 187, a C to G nucleotide change resulting in a histidine to asparagine replacement in the protein (p.His63Asp or H63D). Of the Caucasian population, approximately 1 in 200 are *HFE* C282Y homozygotes,

and approximately 1 in 10 carries the variant. In patients with Fe overload and of European ancestry, nearly 80% have been found to be homozygous for the C282Y variant in *HFE*. A smaller proportion (5%) are compound heterozygous for the C282Y/H63D variants. Although 38% to 76% of C282Y homozygous people have been found to develop raised serum Fe parameters, such as ferritin and TSAT, disease penetrance is 2% to 38% in men and 1% to 10% in women, presumably because menstrual blood loss and childbearing protects them from Fe overload. Also, both disease severity and clinical expression correlate well with the degree of Fe overload, but are heterogeneous among patients, depending not only on the age of diagnosis but also on other genetic and dietary modifiers that remain still largely unknown. Among C282Y/H63D compound heterozygotes the risk of disease progression is low, and documented Fe overload disease is rare. Furthermore, C282Y/H63D compound heterozygous hemochromatosis patients with clinical disease expression, frequently have additional risk factors for Fe overload or liver disease. Homozygosity for H63D is also rarely associated with **hemochromatosis** and is not considered a disease-associated genotype. Most patients with HFE-associated HH do not present until middle age (and women not until after menopause).

Disorders of erythroid maturation. This class of disorders represents forms of secondary Fe overload, and includes the Fe-loading anemias, among which are thalassemia syndromes (especially the β -thalassemias), sideroblastic anemias, and the congenital dyserythropoietic anemias. These diseases are characterized by ineffective erythropoiesis (i.e., by apoptosis of erythroid precursors), failure of erythroid maturation, and consequent expansion of the number of erythroid precursor cells in the bone marrow.

Disorders of iron transport and iron acquisition. The common pathophysiologic feature of these disorders is insufficient delivery and acquisition of transferrin-bound Fe to the RBC precursors in the bone marrow for heme synthesis, despite Fe stores. The resulting Fe-restrictive erythropoiesis, anemia, and hypoxia all contribute to low hepcidin-induced Fe overload.

Other forms of iron overload. Chronic erythrocyte transfusion is the most common cause of this group of disorders. **Transfusion-induced iron overload** is common in patients with severe β -TM and sickle cell disease. Transfusion-induced iron overload also occurs in persons with (1) severe aplastic anemia, (2) Blackfan-Diamond syndrome, (3) Fanconi anemia, (4) acute leukemia, (5) autoimmune hemolytic anemias, and (6) myelodysplasia with refractory anemia.

Rarely, iron overload develops in persons who ingest large quantities of supplemental iron. Iron overload also occurs in persons with renal insufficiency as a result of excessive intravenous supplements.

Analytical Methods

Several methods are used to measure iron and related analytes. These include methods for (1) serum iron, (2) iron-binding capacity, (3) transferrin saturation, (4) serum ferritin, (5) hepcidin, (6) sTfR, and (7) red cell indices.

Methods for Serum Iron, Total Iron-Binding Capacity, Transferrin, and Transferrin Saturation

Except when atomic absorption spectroscopy is used, hemolysis has very little effect on serum iron assay results because Hb iron is not released from heme by acid treatment. Markedly hemolyzed specimens should be rejected for analysis. Because iron is ubiquitous, scrupulous care is necessary to ensure that glassware, water, and reagents do not become contaminated with extraneous iron.

Iron is released from transferrin by decreasing the pH of the serum. It is reduced from Fe^{3+} to Fe^{2+} and then is complexed with a chromogen such as bathophenanthroline or ferrozine.

Such iron/chromogen complexes have extremely high absorbance at the applicable wavelength, which is proportional to the iron concentration.

Transferrin can be measured directly by immunological techniques. Alternatively, in mostly Anglo-Saxon countries, transferrin is quantified in terms of the amount of iron it will bind, a measure called total iron binding capacity (TIBC).

Serum unsaturated iron-binding capacity (UIBC) and TIBC are determined by the addition of sufficient Fe^{3+} to saturate iron-binding sites on transferrin. Excess Fe^{3+} is removed, e.g., by adsorption with (1) light magnesium carbonate (MgCO_3) powder, (2) a silica column, or (3) anion exchange resin, and the assay for iron content is then repeated. From this second measurement, the TIBC is obtained.

Many automated chemistry analyzers now measure UIBC and calculate TIBC, rather than measuring it directly. UIBC is measured by adding a known excess concentration of iron to serum. By leaving the pH near neutral, only the iron that did not bind to transferrin is measured upon the addition of an iron-binding chromogen. TIBC is calculated by adding the UIBC to the serum iron level.

The combination of total serum Fe and either TIBC or transferrin measurement allows the calculation of the saturation of transferrin with Fe:

$$\text{Transferrin saturation (\%)} = (100 \times \text{serum iron}) / \text{TIBC}$$

Transferrin concentration can be used to derive TIBC, and indirectly, TSAT. Because 1 mol of transferrin (average molecular mass 79,570 Da) has the capacity to bind two atoms of Fe (atomic mass 55.84 Da), the theoretically derived formulas for calculating transferrin (and TSAT) from TIBC and vice versa are:

$$\begin{aligned} \text{Transferrin} \left(\frac{\text{g}}{\text{L}} \right) &= 0.007 \times \text{TIBC} \left(\frac{\mu\text{g}}{\text{L}} \right) \\ \text{TIBC} \left(\frac{\mu\text{g}}{\text{dL}} \right) &= \text{transferrin} \left(\frac{\text{mg}}{\text{dL}} \right) \times 1.41 \\ \text{TIBC} \frac{\mu\text{mol}}{\text{L}} &= \text{transferrin} \left(\frac{\text{g}}{\text{L}} \right) \times 25.2 \end{aligned}$$

$$\left(\begin{array}{l} \text{TSAT (\%)} = \frac{([\text{SerumFe}(\mu\text{g/dL})])}{([\text{transferrin}(\text{mg/dL})])} \times 70.9 \\ \text{TSAT (\%)} = \frac{([\text{SerumFe}(\mu\text{mol/L})])}{([\text{transferrin}(\text{mg/dL})])} \times 398 \end{array} \right)$$

These mathematical derivations have some weaknesses. The results of immunological measurements of transferrin concentration correlate with those of the TIBC assay. Note that the relationship is not entirely linear as a small portion of iron in serum is bound to proteins other than transferrin. Therefore calculated TIBC values are slightly greater than the amount of transferrin-bound iron. However, these small differences are of no practical or clinical consequence.

Reference intervals. Reference intervals for serum iron differ by as much as 35% between commercial methods. Therefore, a generic reference interval cannot be applied, and each laboratory should independently define its own reference intervals that are appropriate for the laboratory's method and local population. The reference value used for TSAT also differs between laboratories. The approximate and most used reference interval is 15% to 45%. There is day-to-day variation of serum iron and TSAT in many healthy people.

Clinical relevance. The serum iron concentration refers to the Fe^{3+} bound to serum transferrin and does not include the iron contained in serum as free Hb and ferritin. In clinical situations, serum Fe measurements are often combined with TIBC or transferrin, to calculate the TSAT that is considered more useful for clinical interpretation.

The serum iron concentration or TSAT is decreased in many, but not all, patients with IDA and with chronic inflammatory disorders (see Table 28.4). Elevated serum iron or TSAT occur (1) in iron overload such as HH, (2) in patients with aplastic anemia, (3) in children with acute iron poisoning, (4) after oral or parenteral iron use, and (5) as the result of acute liver injury.

Because only about one-third of the iron-binding sites of transferrin are occupied by Fe^{3+} in healthy individuals, serum transferrin has much reserve iron-binding capacity (UIBC). TIBC is a measurement of the maximum concentration of iron that transferrin binds. TIBC or transferrin is increased in subjects with iron deficiency and is decreased in those with chronic inflammatory disorders, chronic liver diseases, and malnutrition. In many persons with untreated HH, TIBC is slightly decreased.

Methods for Serum Ferritin

Serum ferritin assay may be performed by several commercially available methods, including: (1) immunoradiometric assay, (2) enzyme linked immunosorbent assay (ELISA), (3) immunochemiluminescence assays, and (4) immunofluorometric methods.

Reference intervals. Reference intervals for serum ferritin concentrations are summarized in Tables 28.5 and 28.6. Reference intervals and diagnostic cutoffs differ distinctly between laboratories. This can be attributed to variation in definition of reference population, variation in assay techniques and limited use of reference materials for calibration.

Clinical relevance. Under normal conditions serum ferritin concentrations are usually proportional to the body's iron content. The circulating protein is largely apoferritin. The plasma ferritin concentration declines very early in the development of iron deficiency—long before changes are observed in (1) blood Hb concentration, (2) RBC size, or (3) serum

iron concentration. Thus, the measurement of serum ferritin concentration is used as a highly sensitive indicator of iron deficiency that is uncomplicated by other concurrent disease. On the other hand, many chronic diseases cause increased serum ferritin levels (see Table 28.4). Elevated ferritin has a low specificity for parenchymal iron overload and most subjects with elevated serum ferritin levels do not have HH or other iron overload disorders.

Since an elevated TSAT facilitates parenchymal iron deposition, the combination of high TSAT with hyperferritinemia can be observed in HH and transfusion-induced iron overload.

In subjects with proven hemochromatosis or iron overload, serum ferritin measurements are useful gauges to the progress of phlebotomy therapy in achieving iron depletion.

Methods for Hepcidin

Currently, several in-house and commercial immunochemical assays and laboratory-developed mass spectrometry assays have been shown to provide reliable hepcidin results. Some of the mass spectrometry assays have been thoroughly validated and are used in patient care, but most assays are labeled for “research use only.”

Reference interval. Because hepcidin assays are not harmonized and standardized, there are no universal reference intervals or decision limits.

Clinical relevance. The measurement of hepcidin has provided important insights into the pathophysiology of Fe disorders, among which are HH, anemia of inflammation, and IRIDA. Proof-of-concept studies highlight hepcidin as a promising tool in the diagnosis of IRIDA, and the guidance of iron supplementation therapy. The recent identification of commutable reference material, allows future harmonization.

Method for Soluble Serum Transferrin Receptor

Soluble or serum transferrin receptor (sTfR1 or sTfR)—a truncated form of the transferrin receptor—is a single polypeptide chain with a molecular mass of 84.9 kDa that can be measured by a variety of standard immunoassay techniques. The automated homogeneous immunoturbidimetric assay is characterized by a high sample throughput and excellent precision. In addition, sTfR concentrations can be assessed by fluoroimmunoassays and immunofluorometric assays, which are based on immunoreactants labeled with fluorescent probes. The high sensitivity of fluorescence measurement combined with the sensitivity of the probe to changes in its environment offered the possibility of monitoring the concentration of sTfR directly in the reaction mixture.

Reference intervals. Current commercial methods for the assay of sTfR are characterized by different reference intervals.

Clinical relevance. Soluble TfR is useful in the investigation of the pathophysiology of anemia, to distinguish IDA from ACD and to detect functional Fe deficiency. Cell membranes of developing erythroid cells, especially the erythroblasts, in bone marrow are rich in transferrin receptors (TfRs) to which the Fe-transferrin complex binds. The number of TfRs increases in the presence of high erythroid proliferation

rates and low Fe supplies, and decreases in bone marrow hypoplasia and suppression. These variations in the quantity of TfRs in erythropoietic tissue are also reflected in changes in sTfR.

Red Blood Cell Indices

MCV, MCH, and MCH concentration (MCHC) are indices that are included in the CBC test. One of their uses is to characterize the RBCs of patients with anemia. Low values of MCV and MCH are indicators of IDA. MCV, MCH, and MCHC are slightly higher for untreated HH patients compared to healthy individuals.

Gold Standard Assessment of Body Iron

Bone marrow examination. The absence of stainable bone marrow Fe is the most commonly accepted reference criterion of Fe deficiency. One way of evaluating Fe stores is by examining a bone marrow aspirate for hemosiderin within reticuloendothelial cells. In Fe deficiency, marrow hemosiderin is absent; in the anemia of chronic disorders, Fe is always present. Fe stores are greatly increased in TM and in sideroblastic anemias. However, this method for quantification of Fe stores may be misleading when Fe stores are not normally distributed between reticuloendothelial and parenchymal tissues as occurs in ACD. Another way of evaluating bone marrow Fe includes evaluation of Fe in the erythroblasts, which represents the useable and functional Fe stores. Differentiation between functional Fe deficiency and quantitative deficiency of Fe stores is important, especially in areas of high infection pressure. Bone marrow examination for the sole purpose of assessing Fe stores is rarely justifiable. It may be helpful in the diagnosis of unexplained forms of anemia and if there are concerns that a high serum ferritin value is not a true reflection of body Fe stores.

BILIRUBIN

Hb, iron, and **bilirubin** are analytes that collectively may be viewed in terms of a manufacturing process in which the raw material (iron) is incorporated with other raw materials in a multistage complex process leading to a finished product (Hb). This finished product has a limited life span, after which degradation into the waste product (bilirubin) occurs. Within this process, many exquisite mechanisms are found: (1) biochemical control, (2) conservation, and (3) synthesis. For example, this process may be disrupted by (1) a deficiency in the supply of raw material, (2) a lack of control or synthesis mechanisms, (3) excessive loss of finished product, or (4) excessive conversion to or deficiency in the elimination of waste products. These disruptions lead to the clinical disorders of (1) hemoglobinopathies, (2) thalassemias, (3) IDAs, (4) liver disease, and (5) various genetic diseases.

Bilirubin is the orange-yellow pigment derived mainly from senescent (*aging*) RBCs. It is extracted and metabolized mainly in the liver and is excreted in bile and urine. The chemistry, biochemistry, clinical significance, and analytical methods for bilirubin are briefly reviewed in this section.

Fig. 28.12 Bilirubin IX α structure. (A) A linear molecular representation of unconjugated bilirubin. (B) The preferred structure of unconjugated bilirubin IX α , Z-Z configuration. The structure is stabilized by hydrogen bonding. The “ridge” involves carbon atoms 8 through 12.

Chemistry

The proposed structure of bilirubin is shown in the upper portion of Fig. 28.12. However, the insolubility of the bilirubin molecule in water and its solubility in a variety of nonpolar, lipid solvents are not predicted from this linear tetrapyrrole structure. X-ray crystallography showed bilirubin assuming a ridge-tiled configuration, stabilized by six intramolecular hydrogen bonds. This Z-Z (*trans*) conformation (see Fig. 28.12) prevents the interaction of bilirubin with polar groups in aqueous media. When exposed to light, the Z-Z configuration is converted by rupture of the intramolecular double bonds to the E-E (*cis*) conformation, which is more water soluble than the Z-Z conformation. Thus light-exposed forms of bilirubin are more water soluble and are readily excreted in the bile. This is the rationale for irradiating jaundiced newborns with 450 nm light.

Biochemistry

Bilirubin IX α is produced from the catabolism of heme. For each mole of heme, one mole each of carbon monoxide, bilirubin, and ferric iron is produced. Daily bilirubin production from all sources in humans averages from 250 to 300 mg. Approximately 85% of the total bilirubin produced is derived from the heme moiety of Hb released from senescent erythrocytes that are destroyed in the reticuloendothelial system. The remaining 15% is produced from RBC precursors destroyed in the bone marrow and from the catabolism of other heme-containing proteins.

In blood, bilirubin is bound to albumin and is transported to the liver. It dissociates from albumin at the membrane of the hepatocyte and is transported across the membrane into the liver (Fig. 28.13). Inside the liver cells, bilirubin is

Fig. 28.13 At a glance. Bilirubin uptake, metabolism, and transport in the hepatocyte. (From Gollan, J. L., & Schmid, R. [1982]. Bilirubin update: formation, transport, and metabolism. In H. Popper, & F. Schaffner [Eds.], *Progress in liver diseases*. Vol 7. Chapter 15. Philadelphia: WB Saunders.)

reversibly bound to soluble proteins known as **ligandins** or **protein Y**. Inside the hepatocytes, bilirubin is rapidly conjugated with glucuronic acid to produce bilirubin monoglucuronide and diglucuronide, which then are excreted into bile (see Fig. 28.13). The microsomal enzyme bilirubin uridine diphosphate (UDP)–glucuronyltransferase (EC 2.4.1.17) catalyzes the formation of bilirubin monoglucuronide. In adults, virtually all bilirubin excreted in bile is in the form of glycosidic conjugates.

In the intestine, bilirubin glucuronides are hydrolyzed by the catalytic action of β -glucuronidase from the (1) liver, (2) intestinal epithelial cells, and (3) bacteria. The **unconjugated bilirubin** is then reduced by anaerobic intestinal microbial flora to form a group of three colorless tetrapyrroles collectively called **urobilinogens**. In the lower intestinal tract, the three urobilinogens are spontaneously oxidized to produce the bile pigments, which are orange–brown and the major pigments of stool.

Clinical Significance

Jaundice is a condition characterized by **hyperbilirubinemia** and deposition of bile pigment in the (1) skin, (2) mucous membranes, and (3) sclera, with a resulting yellow appearance of the patient; it is also called **icterus**. Defects in bilirubin metabolism resulting in jaundice occur at each step of the metabolic pathway (see Fig. 28.13). Bilirubin disorders are characterized by elevations in conjugated or unconjugated bilirubin in the absence of other abnormal liver tests. For more information on disorders of bilirubin metabolism and other conditions associated with increased bilirubin, readers are referred to the 6th edition of the *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics*.

Jaundice in the Neonate

Disorders that cause jaundice in the neonate are classified as unconjugated or conjugated hyperbilirubinemia (Box 28.1).

Unconjugated hyperbilirubinemia. Unconjugated hyperbilirubinemia poses a risk for development of **kernicterus** (acute bilirubin encephalopathy), especially in low-birth-weight infants. It is possible to prevent this syndrome by phototherapy and exchange transfusion in infants with elevated unconjugated bilirubin concentrations. Causes of unconjugated hyperbilirubinemia in the neonate are (1) physiological jaundice of the newborn, (2) hemolytic disease owing to Rh or ABO incompatibility, and (3) breast milk hyperbilirubinemia.

Physiological jaundice of the newborn. Babies frequently become jaundiced within a few days of birth; this condition is known as *physiological jaundice of the newborn*. Unconjugated bilirubin concentrations reach a peak within 3 to 5 days of birth and remain elevated for less than 2 weeks. Factors contributing to physiological jaundice include (1) increased bilirubin load in the newborn caused by the shortened life span of RBCs; (2) decreased conjugation of bilirubin resulting from relative lack of glucuronyltransferase (conjugating enzyme) in the first few days after birth; and (3) exposure of breast-feeding infants to pregnanediol, nonesterified fatty acids, and other inhibitors of bilirubin conjugation present in breast milk.

Physiological jaundice of the newborn is treated with phototherapy; exposure to light of approximately 450 nm disrupts intramolecular hydrogen bonds in the bilirubin molecule and yields several photoisomers that are more water soluble than the Z-Z-isomer and thus are excreted in the bile. Exchange transfusions are rarely necessary.

Guidelines for managing newborns with hyperbilirubinemia were introduced in 2004. These guidelines were developed to

BOX 28.1 Physiologic Classification of Jaundice

Unconjugated Hyperbilirubinemia

Increased Production of Unconjugated Bilirubin From Heme

Hemolysis

- Hereditary
- Acquired

Ineffective erythropoiesis

Rapid turnover of increased red blood cell mass (in the neonate)

Decreased Delivery of Unconjugated Bilirubin (in Plasma) to Hepatocyte

Right-sided congestive heart failure

Portocaval shunt

Decreased Uptake of Unconjugated Bilirubin Across Hepatocyte Membrane

Competitive inhibition

- Drugs
- Others

Gilbert syndrome

Sepsis, fasting

Decreased Storage of Unconjugated Bilirubin in Cytosol (Decreased Y and Z Proteins)

Competitive inhibition

Fever

Decreased Biotransformation (Conjugation)

Neonatal jaundice (physiologic)

Inhibition (drugs)

Hereditary (Crigler-Najjar)

- Type I (complete enzyme deficiency)
- Type II (partial deficiency)

Hepatocellular dysfunction

Gilbert syndrome

Conjugated Hyperbilirubinemia (Cholestasis)

Decreased Secretion of Conjugated Bilirubin Into Canaliculi

Hepatocellular disease

- Hepatitis
- Cholestasis (intrahepatic)

Dubin-Johnson syndrome and Rotor syndrome

Drugs (estradiol)

Decreased Drainage

Extrahepatic obstruction

- Stones
- Carcinoma
- Stricture
- Atresia

Sclerosing cholangitis

Intrahepatic obstruction

- Drugs
- Granulomas
- Primary biliary cirrhosis
- Bile duct paucity
- Tumors

Fig. 28.14 Bhutani nomogram to assess risk of hyperbilirubinemia in newborns. (From Subcommittee on Hyperbilirubinemia. [2004]. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics*, 114, 297.)

assess the newborn's risk for hyperbilirubinemia prior to their discharge. The increase in bilirubin concentration from the time of birth prior to discharge from the hospital is monitored using

a nomogram similar to the Bhutani nomogram (Fig. 28.14). The total bilirubin concentration is plotted versus the time (hours) to determine the newborns risk for hyperbilirubinemia.

Conjugated hyperbilirubinemias

Biliary atresia. **Biliary atresia** is a condition in which the bile ducts either fail to develop or develop abnormally. It occurs in one in 10,000 births, and females are more frequently affected. Having no exit to the intestine, bile accumulates inside the liver and eventually escapes into the blood, causing mixed hyperbilirubinemia. Other possible causes include (1) certain viral infections, (2) α_1 -antitrypsin deficiency, and (3) trisomy 17 or 18.

Extrahepatic biliary atresia, which is more common than the intrahepatic type, may involve all or part of the extrahepatic biliary tree. If jaundice persists beyond 14 days of age, a direct or **conjugated bilirubin** measurement must be performed to exclude biliary atresia. If bilirubin is elevated, the urine should be tested for bile. Early identification of this condition is essential if these infants are to benefit from the operation of portoenterostomy, which should be performed no later than 60 days after birth. If portoenterostomy is not successful, liver transplantation is the treatment of choice. Children rarely live beyond 3 years unless the lesion is surgically correctable.

Analytical Methods

Serum bilirubin is measured in body fluids by spectrophotometric or chromatographic methods. For a description of additional methods and materials, the reader is referred to the 6th edition of the *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics*.

Diazo Methods

The reaction of bilirubin with diazotized sulfanilic acid, known as the *diazo reaction*, is the basis of the most widely used methods for measuring bilirubin. The observation that the reaction was slow in sera from jaundiced infants and required an accelerator (ethanol) to proceed, and that it was rapid in bile and in adult sera with the addition of ethanol led to the terms **indirect bilirubin** and **direct bilirubin**, respectively.

The reaction of the coupling of bilirubin with a diazo compound is shown in Fig. 28.15. In this example, diazotized sulfanilic acid reacts with bilirubin to produce two azodipyroles, which are reddish purple at neutral pH and blue at low or high pH values. Numerous variations of this method have been developed. All use one of a variety of “accelerators,” which facilitate the reaction of unconjugated (indirect) bilirubin with the diazo reagent. The most commonly used accelerators are (1) caffeine, (2) dyphylline, and (3) several surface-active agents (surfactants).

Total Bilirubin

The diazo method to quantitate total bilirubin in serum was described by Jendrassik and Grof, and later modified by Doumas and colleagues.

In this procedure, serum is added to an aqueous solution of caffeine and sodium benzoate (accelerator), which displaces unconjugated bilirubin from its association sites on albumin. Formation of hydrogen bonds with caffeine

Fig. 28.15 The reaction of bilirubin glucuronide with diazotized sulfanilic acid to produce isomers I and II of azobilirubin B. Unconjugated bilirubin reacts in the same way to produce isomers I and II of azobilirubin A.

renders the bilirubin water soluble and facilitates its reaction with diazotized sulfanilic acid. After a 10-minute incubation period at room temperature, alkaline tartrate is added, and absorbance of the alkaline azobilirubin is measured at 598 nm. This method is currently the reference method for measuring total bilirubin in serum.

Direct bilirubin. Bilirubin monoconjugates and diconjugates (mainly glucuronides), and δ -bilirubin, because they are water soluble, react with the diazo reagents in the absence of accelerators. A reliable method for direct bilirubin should not

measure any unconjugated bilirubin. To prevent the unconjugated bilirubin from reacting, it is necessary to keep the pH of the reaction mixture near 1.0. A preferred manual method for direct bilirubin is available. Ditaurobilirubin (bilirubin

conjugated with taurine and available as the disodium salt)—a water-soluble synthetic material—is used by instrument manufacturers for calibrating direct bilirubin methods; it is also present in quality control and proficiency-testing materials.

REVIEW QUESTIONS

- Heme is a:
 - Chelate of iron with the four pyrrole groups of a porphyrin.
 - Conjugated protein and an oxygen-carrying pigment of the erythrocytes.
 - Protein found in red skeletal muscle that releases oxygen.
 - Colorless compound formed in the intestines by the reduction of bilirubin.
- The role of hemoglobin is to:
 - Transport iron between organs.
 - Store iron and readily release it when body iron stores are low.
 - Reversibly bind oxygen.
 - Conjugate bilirubin in the liver.
- What is bilirubin conjugated to in a hepatocyte to form conjugated bilirubin?
 - Cholic acid
 - Glycogen
 - Bile acid
 - Glucuronic acid
- In an individual with suspected β -thalassemia, which of the following laboratory results would correctly indicate the presence of this disease?
 - Increased hemoglobin concentration, mean corpuscular volume (MCV) and mean corpuscular hemoglobin concentration (MCHC) with the peripheral blood smear showing increased macrocytes and Howell-Jolly bodies
 - Decreased hemoglobin concentration, MCV and MCHC with the peripheral blood smear indicating microcytosis, target cells, and polychromasia
 - Decreased hemoglobin concentration, increased MCV and MCHC and persistence of hemoglobin F with the peripheral blood smear indicating spherocytosis and nucleated red blood cells
 - Increased hemoglobin concentration and normal MCV and MCHC with a normal peripheral blood smear
- Which of the following is associated with low serum iron and high total iron binding capacity (TIBC) or transferrin?
 - Hemochromatosis
 - Iron-deficiency anemia
 - Iron intoxication
 - Anemia of chronic disease
- This readily soluble iron/protein complex is the form in which iron is stored in tissues:
 - Ferritin
 - Transferrin
 - Hemosiderin
 - Hemoglobin
- The correct formula for determining the percent of transferrin saturation % is:
 - $MCV < 70 \text{ mL} = \text{increased transferrin}$
 - $\text{Total iron binding capacity} \div \text{serum iron}$
 - $\text{Total iron binding capacity} \times 100$
 - $[\text{Serum iron: TIBC}] \times 100$
- The major difference between thalassemia and hemoglobinopathy is that:
 - In thalassemia the globin chains of hemoglobin are structurally altered.
 - In thalassemia the serum level of conjugated bilirubin is dramatically increased.
 - In a hemoglobinopathy the globin chains of hemoglobin are structurally altered.
 - In a hemoglobinopathy the globin chains of hemoglobin are insufficiently produced.
- Anemia of chronic disease is characterized by:
 - Elevated transferrin saturation (TSAT) and elevated or normal ferritin
 - Elevated TSAT and low or normal ferritin
 - Low TSAT and low or normal ferritin
 - Low TSAT and elevated or normal ferritin
- Symptomatic hereditary hemochromatosis is best characterized by:
 - Elevated TSAT and elevated ferritin
 - Normal TSAT and elevated ferritin
 - Elevated TSAT and normal ferritin
 - Normal TSAT and normal ferritin
- Hemolytic disease in a newborn results from maternal-fetal Rh incompatibility. This produces physiological jaundice that is characterized by:
 - Unconjugated hyperbilirubinemia.
 - Conjugated bilirubinemia.
 - Hemosiderosis.
 - Hemoglobinopathy.
- Extrahepatic biliary atresia:
 - Is characterized by the lack of bile ducts within the liver.
 - Is less common than intrahepatic biliary atresia.
 - Is characterized by a mixed hyperbilirubinemia.
 - Produces jaundice that can be observed within the first few days of life.
- Bilirubin:
 - In the conjugated form is highly toxic to the nervous system when elevated.
 - In the plasma is bound to albumin before conjugation in hepatocytes.
 - Becomes conjugated to cholic acid in the hepatocyte.
 - All of the above.

Porphyryns and Porphyrias

Michael N. Badminton, Sharon D. Whatley, Aasne K. Aarsand

OBJECTIVES

1. Define the following terms:
 - 5-Aminolevulinic
 - Heme
 - Porphyrin
 - Porphobilinogen (PBG)
 - Porphyria
 - Zinc protoporphyrin
2. Summarize the biosynthetic pathway of heme, including intracellular sites of each synthetic step, rate-limiting step, and enzyme, and incorporation into hemoglobin.
3. List six functions of heme.
4. Compare and contrast the acute and nonacute porphyrias, including causes, symptoms, and laboratory analyses; describe the screening tests that differentiate between the two categories of porphyria.
5. List and categorize seven porphyrias; state the major elevated intermediates involved in each.
6. List the abnormalities of porphyrin metabolism that are unrelated to porphyria.
7. Explain the effects of lead toxicity on the heme biosynthetic pathway and on iron status.
8. List the specimen collection and storage requirements for samples undergoing porphyrin analysis.
9. Describe the laboratory methods of analysis for the following:
 - Porphobilinogen
 - 5-Aminolevulinic acid
 - Porphyrins in urine, stool, blood, and plasma
 - DNA assessments
10. Analyze and solve case studies related to abnormal porphyrin metabolism and lead toxicity.

KEY WORDS AND DEFINITIONS

Acute intermittent porphyria (AIP) An autosomal dominant hepatic porphyria caused by mutation in the *HMBS* gene (locus: 11q23.3), which encodes hydroxymethylbilane synthase.

Acute porphyrias Inherited disorders of heme biosynthesis, characterized by acute attacks of neurovisceral symptoms; potentially life threatening; diagnosed by elevated urine porphobilinogen (PBG).

5-Aminolevulinic acid (ALA) Immediate precursor of porphobilinogen; two molecules of ALA combine to form one molecule of porphobilinogen.

Congenital erythropoietic porphyria (CEP) An autosomal recessive porphyria due to mutation in the *UROS* gene (locus: 10q25.2–q26.3), which encodes uroporphyrinogen-III synthase.

Coproporphyrin A porphyrin with four methyl and four propionic acid side chains attached to the tetrapyrrole backbone.

Cutaneous porphyrias Disorders of heme biosynthesis in which accumulations of porphyrins in the skin cause skin damage on exposure to sunlight.

Erythropoietic protoporphyria (EPP) An autosomal recessive disorder due to mutation in the *FECH* gene

(locus: 18q21.3), which encodes ferrochelatase, causing a partial deficiency of the enzyme.

Ferrochelatase (FECH) A mitochondrial enzyme of the lyase class that catalyzes the insertion of ferrous iron into protoporphyrin IX to form heme.

Hereditary coproporphyria (HCP) An autosomal dominant hepatic porphyria caused by mutations of the *CPOX* gene (locus: 3q12) that result in partial deficiency of coproporphyrinogen oxidase activity.

Porphobilinogen (PBG) Immediate precursor of the porphyrins; a pyrrole ring with acetyl, propionyl, vinyl, and aminomethyl side chains; four molecules of PBG condense to form one molecule of 1-hydroxymethylbilane, which is then converted successively to uroporphyrinogen-III, coproporphyrinogen-III, protoporphyrinogen-IX, protoporphyrin-IX, and heme.

Porphyryns Any of a group of compounds containing the porphyrin structure; four pyrrole rings connected by methylene bridges in a cyclical configuration, to which a variety of side chains are attached.

Porphyria cutanea tarda (PCT) The most common form of porphyria, characterized by cutaneous photosensitivity.

Porphyrias A group of mainly inherited metabolic disorders that result from partial deficiencies of the enzymes of heme biosynthesis, which cause increased formation and excretion of porphyrins, their precursors, or both.

Porphyrin precursors ALA and PBG, the biosynthetic intermediates, are metabolized to porphyrinogens and porphyrins.

Protoporphyrin A porphyrin with four methyl, two vinyl, and two propionic acid side chains attached to the tetrapyrrole backbone.

Upregulation A process by which the cell increases the quantity of a cellular component such as a specific protein or RNA.

Uroporphyrin A porphyrin with four acetic acid and four propionic acid side chains attached to the tetrapyrrole backbone.

Variegate porphyria (VP) An autosomal dominant hepatic porphyria due to mutation in the *PPOX* gene (locus: 1q22), which encodes protoporphyrinogen oxidase.

X-linked erythropoietic protoporphyria An erythropoietic porphyria caused by mutations in the *ALAS2* gene (locus Xp11.21) that result in increased ALA synthase activity.

Zinc protoporphyrin (ZPP) A normal but minor by-product of heme biosynthesis found in the red blood cell; when insufficient Fe^{2+} is available for heme biosynthesis, increased ZPP is formed.

The **porphyrias** are a group of uncommon, inherited diseases resulting from either partial deficiency in one of the enzymes of heme biosynthesis or, in one disorder, increased activity of the rate-controlling enzyme of erythroid heme synthesis. Each disorder is associated with a specific pattern of overproduction of pathway intermediates, which are excreted in excessive amounts in urine, feces, or both. The clinical consequences depend on the nature of the heme precursors that accumulate. In the **acute porphyrias**, excess **porphyrin precursors** (5-aminolaevulinic acid [ALA] and **porphobilinogen [PBG]**) are associated with potentially fatal acute neurovisceral attacks that are often provoked by various commonly prescribed drugs or hormonal factors. In the nonacute porphyrias, and in those acute porphyrias in which skin lesions occur, accumulation of **porphyrins** results in photosensitization of sun-exposed skin. Diagnosis depends on laboratory investigations to demonstrate the pattern of heme precursor accumulation and excretion specific for each type of porphyria through examination of appropriate specimens using adequately sensitive and specific methods. DNA analysis is rarely necessary for diagnosis of symptomatic cases, but is the method of choice when investigating healthy at-risk relatives. Abnormalities of porphyrin accumulation and excretion also occur in a wide variety of other disorders that are collectively more common than the porphyrias. Recognition of secondary porphyrin disorders is important to avoid diagnostic errors.

PORPHYRIN CHEMISTRY

In this section, porphyrin structure, nomenclature, and chemical characteristics are reviewed.

Structure and Nomenclature

The basic porphyrin structure consists of four monopyrrole rings connected by methene bridges to form a tetrapyrrole ring (Fig. 29.1). The porphyrin compounds of relevance to the porphyrias differ in the substituents

occupying peripheral positions 1 through 8 (Fig. 29.2). Variation in the distribution of the same substituents around the peripheral positions of the tetrapyrrole ring gives rise to porphyrin isomers, which are depicted by Roman numerals (e.g., I, II, III). The reduced form of a porphyrin, known as a **porphyrinogen** (see Fig. 29.1), differs by the absence of six hydrogens (four from the methylene bridges and two from ring nitrogens). Porphyrinogens are unstable in vitro and spontaneously oxidize to the corresponding porphyrins. Under the lower cellular oxygen tension, porphyrinogens are sufficiently stable to act as intermediates of the heme biosynthetic pathway; aromatization to **protoporphyrin** at the penultimate step requires protoporphyrin oxidase.

Chelation of Metals

The arrangement of four nitrogen atoms in the center of the porphyrin ring enables porphyrins to chelate various metal ions. Protoporphyrin that contains iron is known as heme; ferroheme refers specifically to the Fe^{2+} complex and ferriheme to Fe^{3+} . Ferriheme associated with a chloride counterion is known as hemin, or hematin when the counterion is hydroxide.

Fig. 29.1 Porphyrin and porphyrinogen structures: numbers 1 to 8 represent various substituents, the nature and order of which determine the type of porphyrin or porphyrinogen. Numbering system and ring designations are based on the Fischer system.

Fig. 29.2 Biosynthetic pathway of porphyrins and heme. C_{et} — $\text{CH}_2\text{CH}_2\text{COOH}$; C_{m} — CH_2COOH ; Me , — CH_3 ; Vn , — $\text{CH}=\text{CH}_2$. ALA, 5-Aminolevulinic acid; CoA, coenzyme A; PBG, porphobilinogen.

Spectral Properties

Porphyrins, named from the Greek root for “purple” (“porphyrā”), owe their color to the conjugated double-bond structure of the tetrapyrrole ring. Porphyrinogens have no conjugated double bonds and are therefore colorless. Porphyrins show particularly strong absorbance near 400 nm, often called the Soret band, and as a result of this exposure, display a characteristic orange–red fluorescence in the range of 550 to 650 nm. Absorbance and fluorescence are altered by substituents around the porphyrin ring and by metal binding. Zinc chelation shifts the fluorescence emission peak of protoporphyrin to shorter wavelengths and reduces the fluorescence intensity. The strong binding of iron alters the character of protoporphyrin to the extent that heme lacks significant fluorescence.

HEME BIOSYNTHESIS

The complex tetrapyrrole ring structure of heme is built up in a stepwise fashion from precursors succinyl–coenzyme A (CoA) and glycine (see Fig. 29.2). The pathway is present in all nucleated cells and it has been estimated that daily synthesis of heme in humans is 5 to 8 mmol/kg body weight. The pathway is compartmentalized, with some steps occurring in the mitochondrion and others in the cytoplasm.

Enzymes of Heme Biosynthesis

The genes for all enzymes of human heme biosynthesis have been characterized (Table 29.1) and enzyme structures determined by x-ray crystallography.

5-Aminolevulinic Acid Synthase (EC 2.3.1.37)

5-Aminolevulinic acid synthase (ALAS), the initial enzyme of the pathway is mitochondrial and has a housekeeping (ALAS1) and erythroid (ALAS2) isoenzyme. It catalyzes the formation of ALA (sometimes referred to as aminolevulinic acid to emphasize its ionic nature at physiological pH) from succinyl–CoA

and glycine and requires a pyridoxal phosphate cofactor, which forms a Schiff base with the amino group of glycine at the enzyme surface. The carbanion of the Schiff base displaces CoA from succinyl–CoA with the formation of α -amino- β -ketoadipic acid, which is then decarboxylated to ALA. The activity of ALAS is rate limiting as long as the catalytic capacities of other enzymes in the pathway are normal.

5-Aminolevulinic Acid Dehydratase (EC 4.2.1.24)

Aminolevulinic acid dehydratase (ALAD) (also known as PBG synthase) is a cytoplasmic enzyme that catalyzes the formation of the monopyrrole PBG from two molecules of ALA with the elimination of two molecules of water. The enzyme requires zinc as a cofactor and reduced sulfhydryl groups at the active site, and is therefore susceptible to inhibition by lead.

Hydroxymethylbilane Synthase (EC 2.5.1.61)

Hydroxymethylbilane synthase (HMBS) (also known as PBG deaminase) is a cytoplasmic enzyme that catalyzes the formation of one molecule of the linear tetrapyrrole 1-hydroxymethylbilane (HMB; also known as preuroporphyrinogen) from four molecules of PBG with the release of four molecules of ammonia. The enzyme is susceptible to allosteric inhibition by intermediates farther down the heme biosynthetic pathway, notably coproporphyrinogen-III and protoporphyrinogen-IX.

Uroporphyrinogen-III Synthase (EC 4.2.1.75)

Uroporphyrinogen synthase (UROS) is a cytoplasmic enzyme that rearranges and cyclizes HMB to form uroporphyrinogen-III. Each pyrrole ring of HMB contains a methylcarboxylate and an ethylcarboxylate substituent, which are in the same orientation. By the rotation of zero, one, or two alternate or two adjacent pyrrole rings, it is possible to arrive at four different isomers (I to IV). Apart from closing the ring structure, the enzyme rotates the D-ring via a spirane intermediate, producing type III, the only isomer which can contribute to

TABLE 29.1 Human Enzymes and Genes of Heme Biosynthesis

Enzyme	Monomer Mol Mass (kDa) ^{ab}	Chromosomal Location of Gene	Gene Size (kb)	Expression
ALAS1	70.6	3p21.2	17	Ubiquitous
ALAS2	64.6	Xp11.21	22	Erythroid cells
ALAD	36.3	9q32	13	Ubiquitous and erythroid-specific mRNAs
HMBS	37.0	11q23.3	10	Ubiquitous and erythroid-specific isoforms
UROS	29.5	10q26.1–q26.2	34	Ubiquitous and erythroid-specific mRNAs
UROD	40.8	1p34.1	3	Ubiquitous
CPOX	40.3	3q11.2–q12.1	14	Ubiquitous
PPOX	50.8	1q23.3	5	Ubiquitous
FECH	47.8	18q21.3	45	Ubiquitous

^aALAD is a homo-octamer, and HMBS and UROS are monomers; all other enzymes are homodimers.

^bMolecular masses for ALAS1, ALAS2, CPOX, and FECH include presequences that are cleaved during mitochondrial import.

ALAD, Aminolevulinic acid dehydratase; ALAS, aminolevulinic acid synthase; CPOX, coproporphyrinogen oxidase; FECH, ferrochelatase; HMBS, hydroxymethylbilane synthase; mRNA, messenger ribonucleic acid; PPOX, protoporphyrinogen oxidase; UROD, uroporphyrinogen decarboxylase; UROS, uroporphyrinogen synthase.

heme biosynthesis. HMB is unstable, and in those porphyrias in which excess HMB accumulates, cyclization occurs non-enzymatically forming the type I isomer. Normally, only minimum amounts of uroporphyrinogen-I are produced.

Uroporphyrinogen Decarboxylase (EC 4.1.1.37)

The last cytoplasmic enzyme in the pathway catalyzes the decarboxylation of all four carboxymethyl groups to form the tetracarboxylic coproporphyrinogen. The enzyme can use I and III isomers of uroporphyrinogen as substrate. Decarboxylation commences on ring D and proceeds stepwise through rings A, B, and C with formation of heptacarboxylate, hexacarboxylate, and pentacarboxylate intermediates at a single active site. Decreased uroporphyrinogen decarboxylase (UROD) activity causes accumulation of these intermediates in addition to its substrate, uroporphyrinogen. At high substrate concentrations, decarboxylation occurs by a random mechanism.

Coproporphyrinogen Oxidase (EC 1.3.3.3)

Coproporphyrinogen oxidase (CPOX), which is located in the mitochondrial intermembrane space, catalyzes the sequential oxidative decarboxylation of the 2- and 4-carboxyethyl groups to produce the more lipophilic protoporphyrinogen-IX, with formation of a tricarboxylic intermediate, harderoporphyrinogen. Oxygen is required as the oxidant and the enzyme requires sulfhydryl groups for activity, making it a target for inhibition by metals. The enzyme is specific for the type III isomer only. The product of the enzyme differs from the substrate in that replacement of two of the carboxyethyl groups by vinyl groups introduces a third substituent into the molecule. The number of possible isomeric forms is therefore increased, and conventionally the numbering system changes, so that the III isomer becomes the IX isomer. In UROD-deficient states, one of the ethylcarboxylate groups of the accumulated pentacarboxylate porphyrinogen is decarboxylated by CPOX to form the isocoporphyrin series of porphyrins.

Protoporphyrinogen Oxidase (EC 1.3.3.4)

Protoporphyrinogen oxidase (PPOX), a flavoprotein located in the inner mitochondrial membrane, catalyzes the removal of six hydrogens (four from methylene bridges and two from ring nitrogens) to form protoporphyrin-IX. Although nonenzymatic oxidation also occurs in vitro, under the low cellular oxygen tension, PPOX is essential for oxidation to occur. The protoporphyrin produced is the only porphyrin that functions in the heme pathway. Other porphyrins are produced by nonenzymatic oxidation and represent porphyrinogens that have irreversibly escaped from the pathway.

Ferrochelatase (EC 4.99.1.1)

Ferrochelatase (FECH) (also known as heme synthase) is an iron-sulfur protein located in the inner mitochondrial membrane. This enzyme inserts ferrous iron into protoporphyrin to form heme. During this process, two hydrogens are displaced from the ring nitrogens. Other metals in the divalent state also act as substrates, yielding the corresponding chelate

(e.g., incorporation of Zn^{2+} into protoporphyrin to yield **zinc protoporphyrin [ZPP]**). In iron-deficient states, Zn^{2+} successfully competes with Fe^{2+} in developing red cells, so that the concentration of ZPP in erythrocytes increases. In lead poisoning, impaired iron delivery or utilization within the mitochondrion has the similar effect of increasing erythrocyte ZPP. Other dicarboxylic porphyrins also serve as substrates (e.g., mesoporphyrin).

REGULATION OF HEME BIOSYNTHESIS

Heme supply in all tissues is controlled by the activity of mitochondrial ALAS. Two isoforms of ALAS are known. The ubiquitous isoform, ALAS1, is encoded by a gene on chromosome 3p21 and is expressed in all tissues. Because it has a half-life of approximately 1 hour, changes in its rate of synthesis produce short-term alterations in enzyme concentration and cellular ALAS activity. Synthesis of ALAS1 is under negative feedback control by heme. In the liver, ALAS1 is induced by a wide variety of drugs and chemicals that induce microsomal cytochrome P450-dependent oxidases (CYPs). This effect is thought to be mediated mainly by direct transcriptional activation of drug-responsive nuclear receptors, rather than occurring secondary to depletion of an intracellular regulatory heme pool. The induction of ALAS1 is prevented by heme, which acts by destabilizing messenger ribonucleic acid (mRNA) for ALAS1, by blocking mitochondrial import of pre-ALAS1, by increased proteolysis and possibly by inhibiting transcription. In addition, ALAS1 activity is regulated by a transcriptional co-activator, PGC-1 α ; an effect that links the rate of hepatic heme synthesis with nutritional status.

The erythroid isoform, ALAS2, is encoded by a gene on chromosome Xp11.21 and is expressed only in erythroid cells. Its activity is regulated by two distinct mechanisms. Transcription is enhanced during erythroid differentiation by the action of erythroid-specific transcription factors, and mRNA concentrations are regulated by iron. Iron deficiency in erythroid cells promotes specific binding of iron regulatory proteins to an iron-responsive element in the 5' untranslated region (UTR) of ALAS2 mRNA with consequent inhibition of translation.

Function of Heme

Heme functions as a prosthetic group in various proteins in which, depending on the function of the protein, the iron shifts freely between the 2⁺ and 3⁺ valency states. Heme synthesis (70% to 80%) occurs in the bone marrow and approximately a further 15% in the liver. Heme-containing proteins participate in a variety of redox reactions, including:

1. Oxygen transport (by hemoglobin in the blood) and storage (by myoglobin in muscle)
2. Mitochondrial respiration (by cytochromes b_1 , c_1 , and a_3)
3. Enzymatic destruction of peroxides (by catalase and peroxidase)
4. Drug metabolism (by microsomal cytochrome P-450 mixed function oxidases)

TABLE 29.2 Adult Reference Intervals

Specimen	Analyte	Reference Interval (SI Units)	Reference Interval (Traditional Units)
Urine	Porphobilinogen	<1.5 $\mu\text{mol}/\text{mmol}$ creatinine <10 $\mu\text{mol}/\text{L}$	<3.0 mg/g creatinine <0.23 mg/dL

^aPercentage of total coproporphyrin.

Laboratories should verify that these ranges are appropriate for use. Further guidance is provided in [Chapter 5](#).
wt, Weight.

- Desaturation of fatty acids (by microsomal cytochrome b_5)
- Tryptophan metabolism (by tryptophan oxygenase)

Reactions of nitric oxide (NO) are often mediated by the reaction of heme with NO in control enzymes such as guanylate cyclase.

Other naturally occurring tetrapyrrole derivatives include vitamin B_{12} and chlorophyll, each of which contains an atom of chelated cobalt and magnesium, respectively.

SOLUBILITY AND EXCRETION OF HEME PRECURSORS

Typically, only minute quantities of heme precursors accumulate in the body. The route of excretion largely depends on solubility. The porphyrin precursors ALA and PBG are water soluble and are excreted almost exclusively in urine as is uroporphyrinogen. PBG polymerizes readily, particularly at high concentrations in acid solution to form primarily the I-isomer of uroporphyrin. The last intermediate of the pathway, protoporphyrin (and also protoporphyrinogen), is insoluble in water and is excreted in the feces via the biliary tract. The other porphyrins are of intermediate solubility and appear in both urine and feces. Coproporphyrinogen-I is taken up and excreted by the liver in preference to the III isomer, so that coproporphyrinogen-I predominates in feces and coproporphyrinogen-III in urine. All porphyrinogens in the urine or feces are slowly oxidized to the corresponding porphyrins.

Once in the gut, porphyrins are susceptible to modification by gut flora. The two vinyl groups of protoporphyrin are reduced to ethyl groups, hydrated to hydroxyethyl groups, or removed, giving rise to a variety of secondary porphyrins. Gut flora can also metabolize heme (from dietary, gut cell lining or gastrointestinal bleeding) to produce a variety of

dicarboxylic porphyrins. In addition, some bacteria are capable of de novo synthesis of porphyrins.

The differing solubility of individual porphyrins is of importance not only in determining the route of excretion from the body, but also in the design of analytical methods for their extraction and fractionation. At pH 7, the carboxyl groups are ionized, and the molecule has a net negative charge. Below pH 2, the pyrrole nitrogens and the carboxyl groups become protonated so that the molecule has a net positive charge. At physiologic pH, the solubility of a given porphyrin is determined by the number of substituent carboxyl groups. **Uroporphyrin** has eight carboxylate groups and is the most soluble porphyrin in aqueous media. Protoporphyrin has only two carboxylate groups, is insoluble in water, but dissolves readily in lipid environments, and binds readily to the hydrophobic regions of proteins such as albumin. **Coproporphyrin**, with four carboxylate groups, has intermediate solubility. Reference ranges for porphyrins and porphyrin precursors in blood, urine and feces are reported in [Table 29.2](#).

THE PORPHYRIAS

The porphyrias are a group of metabolic disorders associated with a disturbance of heme biosynthesis ([Table 29.3](#)). All are inherited in monogenic patterns, apart from some forms of **porphyria cutanea tarda (PCT)** and rare erythropoietic porphyrias associated with malignant myeloid disorders. Each type of porphyria is defined by the association of characteristic clinical features with a specific pattern of accumulation of heme precursors that reflects increased formation of the substrate of the enzyme that is partially deficient or becomes secondarily rate-limiting in that type of porphyria ([Table 29.4](#)). The porphyrias are characterized clinically by two main features; skin

TABLE 29.3 Main Types of Human Porphyrria

Disorder	Defective Enzyme	Prevalence ^a (Per Million)	Neurovisceral Crises	Skin Lesions	Inheritance
Acute Porphyrrias					
ADP	ALAD	—	+	—	AR
AIP	HMBS	5.9	+	—	AD

VP	PPOX	3.2	+	+ ^{b,c}	AD
Nonacute Porphyrrias					
CEP	UROS	0.3	—	+ ^c	AR
PCT	UROD	40	—	+ ^c	Complex (20% AD)
EPP	FECH	9.2	—	+ ^d	AR
XLEPP	ALAS2	0.15	—	+ ^d	XL

^aEstimated prevalence of clinically overt disease.

^bSkin lesions and neurovisceral crises may occur alone or together.

^cFragile skin, bullae.

^dAcute photosensitivity without fragile skin, bullae.

AD, Autosomal dominant; ADP, ALA dehydratase deficiency porphyria; AIP, acute intermittent porphyria; ALAD, aminolevulinic acid dehydratase; ALAS, Aminolevulinic acid synthase; AR, autosomal recessive; CEP, congenital erythropoietic porphyria; CPOX, coproporphyrinogen oxidase; EPP, erythropoietic protoporphyria; FECH, ferrochelatase; HCP, hereditary coproporphyria; HMBS, hydroxymethylbilane synthase; PCT, porphyria cutanea tarda; PPOX, protoporphyrinogen oxidase; UROD, uroporphyrinogen decarboxylase; UROS, uroporphyrinogen; VP, variegate porphyria; XL, X-linked; XLEPP, X-linked erythropoietic protoporphyria.

TABLE 29.4 Porphyrrias: Patterns of Overproduction of Heme Precursors During Clinically Overt Phase of Disease

Porphyrria	Urine PBG/ALA	Urine Porphyrins	Fecal Porphyrins	Erythrocyte Porphyrins	Plasma Fluorescence Emission Peak
ADP	ALA	Copro-III	Not increased	ZPP	—
AIP	PBG>ALA	Mainly uroporphyrin from PBG	Normal or increased ^a Copro-III/I ratio normal	Not increased	615–622 nm ^b
CEP	Not increased	Uro-I, Copro-I	Copro-I	ZPP, Proto, Copro-I, Uro-I	615–620 nm
PCT	Not increased	Uro, Hepta ^c	Isocopro, Hepta, Penta	Not increased	615–622 nm
HCP	PBG>ALA ^d	Copro-III, uroporphyrin from PBG	Copro-III, Copro-III/I ratio increased	Not increased	615–622 nm ^b
VP	PBG>ALA ^d	Copro-III, uroporphyrin from PBG	Proto IX>Copro-III ^e X-porphyrin Copro-III/I ratio increased	Not increased	624–628 nm
EPP	Not increased	Not increased	±Proto ^f	Proto	626–634 nm ^g
XLEPP	Not increased	Not increased	±Proto	Proto, ZPP ^h	626–634 nm ^g

^aSlight increase only unless uroporphyrin is present.

^bNot always increased.

^cOther methylcarboxylate-substituted porphyrins are increased to a smaller extent; uroporphyrin is a mixture of type I and III isomers; heptacarboxylate porphyrin is mainly type III.

^dPBG and ALA may be normal when only skin lesions are present.

^eCoproporphyrin-III/I ratio increased, but usually less than in overt HCP.

^fNot increased in about 40% of patients.

^gProtoporphyrin (Proto) bound to globin. If hemolysis is present the peak shifts to the left (i.e., at 626–628 nm or is quenched).

^hZn-protoporphyrin (ZPP) 20%–60% of total erythrocyte protoporphyrin.

ADP, ALA dehydratase deficiency porphyria; AIP, acute intermittent porphyria; ALA, aminolevulinic acid; CEP, congenital erythropoietic porphyria; EPP, erythropoietic protoporphyria; HCP, hereditary coproporphyria; PBG, porphobilinogen; PCT, porphyria cutanea tarda; VP, variegate porphyria; XLEPP, X-linked erythropoietic protoporphyria.

lesions in sun-exposed areas and acute neurovisceral attacks, typically comprising of (1) abdominal pain, (2) peripheral neuropathy, and (3) mental disturbance. The skin lesions are caused by porphyrin-catalyzed photodamage, of which singlet oxygen is the main mediator. Acute attacks are associated

with increased formation of ALA and consequently PBG from induced activity of hepatic ALAS1 and partial hepatic heme deficiency, often in response to induction of hepatic CYPs by drugs and other factors, such as hormones. The relationship of these biochemical changes to the neuronal dysfunction that

underlines all clinical features of the acute attack is uncertain. The leading hypothesis for pathophysiology is that ALA, or a product of ALA or PBG, is neurotoxic, possibly through interference with the gamma amino butyric acid (GABA) receptor pathway. As listed in Table 29.3, the porphyrias are classified as acute (in which acute neurovisceral attacks occur), or non-acute.

Acute Porphyrrias

Acute porphyrias include (1) ALA dehydratase deficiency porphyria (ADP), (2) **acute intermittent porphyria (AIP)**, (3) **variegate porphyria (VP)**, and (4) **hereditary coproporphyria (HCP)**. These disorders are autosomal dominant except for the very rare disorder, ADP, which is autosomal recessive.

The inherited defect in each of the autosomal dominant acute porphyrias (see Table 29.3) is a mutation leading to complete or near complete inactivation of one of the pairs of allelic genes that encode the enzyme whose partial deficiency causes the disorder. Heme supply is maintained at normal or near normal concentration by **upregulation** of ALAS1, with a consequent increase in the substrate concentration for the defective enzyme. These compensatory changes vary between tissues; they are most prominent in the liver and are undetectable in most other organs. They also vary between individuals with some showing no evidence of overproduction of heme precursors, and others having biochemically manifest disease with or without clinical symptoms.

Low clinical penetrance is a prominent feature of all the autosomal dominant acute porphyrias. Family studies indicate that many affected individuals are asymptomatic throughout life.

All the autosomal dominant acute porphyrias show extensive allelic heterogeneity but founder mutations are present in some populations and explain the high frequency of VP in South Africans of Dutch descent and of AIP in Sweden.

Clinical Features

The life-threatening, acute neurovisceral attacks that occur in AIP, VP, and HCP are clinically identical. Acute attacks are very rare before puberty, and usually occur first between the ages of 15 and 40, and are more common in women. Precipitating factors have been identified in about two-thirds of patients who present with acute attacks. The most important are drugs; alcohol, especially binge drinking; the menstrual cycle; calorie restriction; infection; and stress. Drugs known to provoke acute attacks include barbiturates, sulfonamides, progestogens, and some anticonvulsants, but many others have been implicated in the precipitation of acute attacks (www.porphyrria-europe.org).

The main clinical features are summarized in Table 29.5. Acute attacks almost always start with abdominal pain that rapidly becomes very severe and may also be present in the back and thighs. Vomiting, constipation, tachycardia, and hypertension, are frequent with convulsions as a consequence of hyponatremia or secondary to central nervous system

TABLE 29.5 Clinical Features of an Acute Neurovisceral Attack of Porphyria

Symptom/Sign	Percentage of Acute Attacks
Abdominal pain	85–90
Nonabdominal pain	25–70
Vomiting and nausea	30–90
Constipation/diarrhea	50–80
Psychologic symptoms (insomnia, anxiety, depression, confusion, hallucinations)	20–85
Acute encephalopathy (headache, somnolence, seizures, altered con- sciousness)	2–20
Motor neuropathy (muscle weakness, pain, low/ absent tendon reflexes)	10–90
Hemi/tetraparesis	30–40
Respiratory paralysis	10–55
Sensory neuropathy	10–40
Hypertension	40–75
Tachycardia (>80/min)	30–85
Hyponatremia (<135 nmol/L)	30–60

Data modified from Harper, P., & Sardh, E. (2014). Management of acute intermittent porphyria. *Expert Opinion on Orphan Drugs*, 2(4), 349–368.

involvement. Pain may dissipate within a few days, but in severe cases a predominant motor neuropathy develops that may progress to flaccid quadriplegia. The acute phase may be accompanied by mental confusion with abrupt changes in mood, hallucinations, and other psychotic features. Persistent psychiatric illness is not a feature of the acute porphyrias, although mild anxiety or depression may be present in some patients. Abdominal pain usually resolves within 2 weeks, but recovery from neuropathy may take many months and is not always complete. Most patients have one or a few attacks followed by complete recovery and prolonged remission. About 5% have repeated acute attacks, which, in women, may be premenstrual.

Skin lesions similar to those of PCT and other bullous porphyrias are present in about 80% of patients with clinically manifest VP (see Table 29.3). About 60% of patients with this condition present with skin lesions alone. The skin is less commonly affected in HCP; skin lesions without an acute attack are uncommon and usually are provoked by intercurrent cholestasis.

Long-term complications of acute porphyria include chronic renal failure, hypertension, and primary hepatocellular carcinoma.

Management of Families

The diagnosis of autosomal dominant acute porphyria should be followed by an investigation of the patient's family to identify affected, often asymptomatic relatives, so they can be advised to avoid drugs and other factors known to provoke potentially fatal acute attacks.

POINTS TO REMEMBER

Acute porphyrias

- Present clinically after puberty.
- Low clinical penetrance means that there is usually no family history.
- Clinical effects are due to autonomic, central, and motor neuropathy.
- Common precipitants are prescribed drugs, hormonal fluctuations, excess alcohol consumption, starvation, infection, and stress.
- Diagnosed by demonstrating increased PBG excretion in a random urine sample.
- Mild hyponatremia is common.

Nonacute Porphyrias

The nonacute porphyrias fall into two categories depending on whether patients have bullous skin lesions (PCT, **congenital erythropoietic porphyria [CEP]**) or acute photosensitivity (**erythropoietic protoporphyria [EPP]**, **X-linked erythropoietic protoporphyria [XLEPP]**).

Porphyria Cutanea Tarda

PCT is by far the most common porphyria. The disease occurs at all ages in both sexes with onset usually during the fifth and sixth decades. Lesions on sun-exposed skin, particularly the backs of the hands, the forearm, and the face, are present in all patients. These lesions are identical to those seen in the other bullous porphyrias (see [Table 29.3](#)). Increased mechanical fragility of the skin, with trivial trauma leading to erosions, is present in virtually all patients.

A combination of skin lesions with liver damage is strongly associated with alcohol abuse, estrogens, infection with hepatotropic viruses, particularly hepatitis C (HCV), smoking, and mutations in the hemochromatosis (*HFE*) gene. PCT may also complicate HIV infection. Hepatic iron overload in combination with at least one of the other associated factors are present in almost all patients.

PCT results from decreased activity of UROD in the liver, which is understood to be secondary to a UROD inhibitor, porphomethene, generated by iron dependent partial oxidation of uroporphyrinogen. This inhibition leads to the overproduction of uroporphyrin and other carboxymethyl-substituted porphyrins, which accumulate in the liver and skin, where they act as photosensitizers. This iron dependence explains why patients with iron overload disorders, such as haemochromatosis, develop PCT. Two main types of PCT can be identified in most populations; about 80% of patients have the sporadic (type I) form of PCT, in which the enzyme defect is restricted to the liver and is a result of viral illness (e.g., HCV) or exogenous substances (e.g., hepatic iron overload, alcohol excess). The *UROD* gene appears to be normal. The rest have familial (type II) PCT, which is inherited in an autosomal dominant manner. In this

form, the mutation of one *UROD* gene leads to half-normal UROD activity in all tissues. However, the hepatic enzyme activity has to be 20% or less of normal for porphyrins to accumulate and cutaneous symptoms to appear. This further reduction in activity is dependent on the additional triggering factors associated with liver damage outlined above and explains the low penetrance of familial PCT. PCT may also be caused by exposure to certain polyhalogenated aromatic hydrocarbons, such as hexachlorobenzene and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin.

Congenital Erythropoietic Porphyria

CEP is the least common but most severe of the **cutaneous porphyrias**. The clinical features vary in severity from hydrops fetalis with death in utero—through the onset in infancy of severe skin lesions with transfusion-dependent hemolytic anemia—to mild skin lesions, resembling PCT.

With age, progressive scarring (particularly if erosions become infected), and atrophic changes lead to photomutilation with erosions of the terminal phalanges; destruction of ears, nose, and eyelids; and alopecia. Accumulation of porphyrin in bone is visible as erythrodontia—brownish-red teeth that fluoresce in UVA light. The skin changes are usually accompanied by hemolytic anemia and splenomegaly. Hemolysis may be fully compensated or mild, but in some patients, anemia is severe enough to require repeated transfusion.

CEP is an autosomal recessive disease resulting from decreased UROS activity (see [Table 29.3](#)). Patients are homoallelic or heteroallelic for mutations in the *UROS* gene or, rarely, the *GATA1* gene, which encodes an erythroid transcription factor.

Erythropoietic Protoporphyria and X-Linked Erythropoietic Protoporphyria

The protoporphyrias are characterized by life-long acute photosensitivity caused by accumulation of protoporphyrin-IX in the skin. In EPP, overproduction of protoporphyrin-IX results from decreased activity of FECH. EPP is an autosomal recessive disease where most individuals are compound heterozygotes for a *FECH* mutation that abolishes or severely decreases FECH activity and a hypomorphic *FECH* c.315-48C allele (rs2272783). In approximately 4% of EPP families, affected individuals are heteroallelic or homoallelic for *FECH* mutations. In XLEPP gain-of-function mutations in *ALAS2*, usually deletions within the C-terminal region lead to formation and accumulation of protoporphyrin in excess of the amount required for hemoglobinization. XLEPP is inherited in an X-linked pattern with expression of disease in males and most females. The symptoms of XLEPP are clinically indistinguishable from EPP.

Patients with either form of protoporphyria present with acute photosensitivity characterized by burning pain, which normally starts between birth and the age of 6 years. Onset after the age of 40 years is very rare; most cases are due to acquired FECH deficiency associated with myelodysplasia. Exposure to sun is followed by an intensely painful, burning,

prickling, itching sensation in the skin, usually within 5 to 30 minutes, which is most frequently on the face and the backs of the hands. Symptoms persist for several hours up to days and are not relieved by shielding the skin from light. Recurrent sun exposure leads to chronic skin changes, such as shallow linear scars over the bridge of the nose and elsewhere on the face, and the skin may become thickened and waxy, especially over the knuckles. Seasonal palmar keratoderma is present in about 3% of patients.

The most severe complication of protoporphyria is progressive hepatic failure, which is caused by the accumulation of protoporphyrin in the liver. About 15% of patients have abnormal biochemical tests of liver function, particularly increased aspartate aminotransferase; however, only about 5% of patients develop liver failure. Protoporphyria may also increase the risk of cholelithiasis, due to high concentrations of protoporphyrin in the bile.

POINTS TO REMEMBER

Cutaneous Porphyrrias

- Porphyrins absorb light with wavelengths around 400 nm.
- The absorbed radiant energy is either
 - Released as red fluorescent light, or
 - Interacts with molecular oxygen to create reactive oxygen species.
- The skin lesions are therefore caused by porphyrin-catalyzed photodamage.
- Photosensitivity can occur in any porphyria where porphyrin ring structures accumulate; that is, all the porphyrias except AIP and ADP.
- Symptoms manifest clinically as an immediate or delayed photosensitivity dependent on the type of porphyrins that accumulate and their localization within the skin.
- Protection of the skin from sunlight is essential to reduce symptoms.

Abnormalities of Porphyrin Metabolism Not Caused by Porphyrria

Abnormalities of porphyrin metabolism or excretion, or both, may occur in a number of conditions other than the porphyrias. A number of other conditions need to be considered when porphyrin results are interpreted from patients in whom porphyria is suspected. Many are more common than the porphyrias. These disorders include exposure to various toxins, for example lead, hereditary tyrosinemia, renal and hepatobiliary disorders, hematological disorders, and situations where there is increased heme in the gastrointestinal system (diet, bleeding, bacteria). These abnormalities and their causes are detailed in Table 29.6. Conversely, there are a number of conditions that can give rise to skin lesions identical to those that characterize bullous porphyrias, such as PCT, but in which no abnormality in accumulation or excretion of porphyrins can be demonstrated. This is usually described as “pseudoporphyria” and is mainly associated with photosensitization from prescribed drugs, sunbeds, and end-stage renal failure.

TABLE 29.6 Secondary Disorders of Porphyrin Metabolism

Sample	Increased Heme Precursors	Clinical Conditions
Urine	Coproporphyrin Aminolevulinic acid	Liver dysfunction, fever, drugs, alcohol Lead poisoning, hereditary tyrosinemia I
Feces	Protoporphyrin, other dicarboxylic porphyrins	Intestinal bleed, high protein intake
Plasma	Uroporphyrin coproporphyrin	Renal failure Liver dysfunction
Erythrocytes	Zinc protoporphyrin	Iron deficiency anemia Lead poisoning

LABORATORY DIAGNOSIS OF PORPHYRIA

Laboratory investigation is essential for the diagnosis and exclusion of the porphyrias in patients with symptoms of acute porphyria, typical cutaneous lesions, and in relatives of patients known to have porphyria because none of the clinical features are sufficiently distinctive to allow diagnosis on clinical grounds alone.

Patients With Symptoms of Porphyrria

In patients with current symptoms caused by porphyria, the excessive production of heme precursors is always present. Diagnosis depends on demonstrating specific patterns of overproduction of heme precursors (see Table 29.4) and is usually straightforward, provided appropriate specimens are examined for the relevant intermediates using adequately sensitive techniques. Although the porphyrias are uncommon disorders, the variability of the associated clinical features may make it necessary to consider them as differential diagnoses in many clinical situations. Therefore it is important to apply diagnostic strategies that not only allow for the diagnosis of a porphyria, but also adequately exclude the diagnosis. The diagnostic strategy of choice depends on the mode of presentation.

Patient Presenting With Suspected Acute Attack

Failure to correctly diagnose an attack of acute porphyria not only delays appropriate life-saving treatment but may result in unnecessary surgery or administration of drugs that aggravate the attack with potentially fatal consequences. A false diagnosis of porphyria may be equally serious because of delayed vital surgery or other treatment, and may also lead to analgesic (including opiate) misuse and dependency. The essential first-line investigation is the measurement of urinary PBG by an adequately sensitive and specific method. Testing for ALA is often performed along with PBG. Based on the currently available evidence, PBG excretion is always increased during an acute attack of AIP, HCP, or VP, usually to a concentration that exceeds 10 times the upper reference limit. Normal PBG excretion,

at a time when symptoms are present, provides very strong evidence against any type of acute porphyria as their cause, except for the very rare ADP. In ADP, PBG is normal or only slightly elevated, while ALA is markedly increased. The same pattern may be observed in lead poisoning. Further investigation is usually indicated by the finding of increased urinary coproporphyrin, which is a biochemical feature of both conditions (Tables 29.4 and 29.6).

Differentiation between the acute porphyrias. Management of the attack is the same regardless of the type of porphyria, so further investigation is not a matter of urgency. However, differentiation between the acute porphyrias is necessary for deciding which gene to examine by DNA analysis and for the selection of appropriate tests for use in family studies, as well as assessing for risk of skin symptoms. The absence of skin lesions does not exclude VP or HCP (see Table 29.3).

Once the diagnosis of acute porphyria has been established, the most efficient diagnostic strategy uses plasma fluorescence scanning and fecal porphyrin fractionation with coproporphyrin III and I separation to differentiate between AIP, VP, and HCP (see Table 29.4).

Investigation of an asymptomatic patient with past symptoms consistent with an acute attack. Diagnosis may be less straightforward when a patient presents for investigation after all clinical symptoms have resolved. Appropriate investigations include those described earlier.

If all these tests are normal, the patient may have AIP in remission, but is most likely to have had a nonporphyric illness with symptoms mimicking those of acute porphyria. If clinical suspicion remains high, mutational analysis of *HMBS*, supplemented by assay of *HMBS* activity in mutation-negative patients, may help to distinguish these possibilities.

Patients With Cutaneous Symptoms

Active skin lesions of cutaneous porphyrias require increased circulating porphyrins to reach the skin. Thus, analysis of plasma porphyrins by fluorescence emission spectroscopy is usually the first step when diagnosing cutaneous porphyrias (Fig. 29.3). Urine ALA and PBG have no role in the diagnosis of cutaneous porphyrias. The route of further investigation to identify the specific porphyria is dictated by the clinical presentation.

Patients with acute photosensitivity without skin fragility or bullae. When suspecting EPP/XLEPP, the essential investigation consists of the measurement of erythrocyte protoporphyrin concentration using a sensitive fluorometric method. Screening tests using solvent extraction of blood or fluorescence microscopy of erythrocytes are unreliable. If the erythrocyte (proto)porphyrin concentration is within the reference interval, EPP/XLEPP is excluded. If the concentration is increased, it is important to determine whether the increase is caused mainly by free protoporphyrin, as in EPP, both free and ZPP as in XLEPP, or primarily by ZPP, as in iron deficiency and lead toxicity (Tables 29.4 and 29.6).

DNA analysis is required to confirm the diagnosis of XLEPP in patients with an increased percentage of ZPP or in patients with a family history suggestive of XLEPP.

Fig. 29.3 Fluorescence emission spectra (excitation, 405 nm) of dilutions in phosphate-buffered saline (PBS) of plasma from a normal individual and from patients with various porphyrias. EPP, Erythropoietic protoporphyrin; PCT, porphyria cutanea tarda; VP, variegata porphyria.

Patients with bullae/fragility/scarring. Clinically indistinguishable skin lesions occur in PCT, VP, HCP, CEP (see Table 29.3), hepatoerythropoietic porphyria (HEP), and other rare variants. In addition, identical skin lesions characterize pseudoporphyria, in which porphyrin metabolism is normal. Initial investigations should include the fluorescence emission spectroscopy of plasma. If this is normal, then porphyria is excluded as the cause of any active skin lesions.

A positive plasma porphyrin fluorescence scan with any increase in total urinary porphyrin should be further investigated by the determination of individual porphyrins in urine and feces using a technique capable of resolving all porphyrins of clinical interest, including isomers. The pattern observed in each of these porphyrias is unique (see Table 29.4).

Patients may present for investigation after their skin lesions have healed. In PCT, excretion and plasma porphyrin concentrations return to normal during remission, but the proportions of individual porphyrins in urine and feces may remain abnormal for longer than the total porphyrin concentrations, and the determination of individual porphyrins may suggest the diagnosis. The plasma fluorescence scan in VP and fecal coproporphyrin-III excretion in HCP remain abnormal during clinical remission.

Asymptomatic Relatives of Patients With Porphyria

Depending on the type of porphyria, investigating healthy at-risk relatives may be beneficial.

Presymptomatic Diagnosis of Autosomal Dominant Acute Porphyrrias

The screening of family members to identify asymptomatic individuals who have inherited AIP, VP, or HCP, and therefore are at risk for acute attacks, is an essential part of the management of families with these disorders. Screening may be carried out by metabolite measurement, enzyme assay, and/or DNA analysis, although the use of metabolite and enzyme assays are limited by the low negative predictive value of these tests. Mutation detection by DNA analysis is the method of choice for family studies unless a mutation cannot be identified in the proband, as it allows asymptomatic disease to be excluded with certainty.

Erythropoietic Protoporphyrria

In EPP caused by mutations in the *FECH* gene, testing the unaffected parent for the presence of the hypomorphic *FECH* c.315-48C allele is helpful in assessing the risk that a future child will have clinically overt disease; the presence of this allele increases the risk from about 1 in 100 to 1 in 4. In XLEPP, mutational analysis of the *ALAS2* gene may be required to identify female carriers, who show phenotypic and biochemical heterogeneity, reflecting the degree of X-chromosomal inactivation of the mutant gene.

Other Porphyrrias

Family investigation has a more limited role in the clinical management of other porphyrias. In PCT, the autosomal dominant familial form has been identified by erythrocyte UROD assay or mutational analysis, but as yet little evidence suggests that family studies are necessary unless requested by anxious relatives, as the identification of a mutation does not alter the management of the patient or family.

For severe homozygous or compound heterozygous porphyrias, such as CEP, ADP, HEP, and homozygous dominant acute porphyrias, mutation analysis may be required if prenatal diagnosis in subsequent pregnancies is indicated.

LABORATORY ANALYSIS

The analytical methods used to diagnose and monitor porphyria are briefly described here. Full descriptions can be found in *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics*, 6th edition.

Preanalytical Aspects

Specimen Collection and Stability

For porphyrin analysis, all samples must be protected from light, as urinary porphyrin concentrations have been observed to decrease by up to 50% if kept in the light for 24 hours. Urinary porphyrins and PBG are best analyzed in fresh, random (10 to 20 mL) samples collected without preservative. Very dilute urine (creatinine <2 mmol/L) is unsuitable for analysis and it may be helpful to request an early morning urine sample to ensure it is appropriately concentrated.

Urine often is of normal color in the nonacute porphyrias, except in CEP, when it is usually red, occasionally to such an

extent that it is mistaken for hematuria. During an acute attack, urine may be a red-brown color because of the presence of uroporphyrin and other pigments formed by the nonenzymatic polymerization of PBG. This color may be evident immediately, or develop progressively during handling and storage.

About 5 to 10 g wet weight of feces is adequate for porphyrin measurements. Diagnostically, important changes in concentration are unlikely to occur within 36 hours at room temperature, and samples are stable for many months at -20°C.

Blood, anticoagulated with ethylenediaminetetraacetic acid (EDTA), shows no loss of protoporphyrin for up to 8 days at room temperature, and for at least 8 weeks at 4°C in the dark.

Quality Management and External Quality Assessment

Participation in external quality assessment (EQA) schemes, preferably assessing the total testing process, and the use of internal quality control (IQC), is particularly important for porphyria-related analyses. IQC is available commercially for urine analytes (porphyrin, ALA and PBG) but not fecal, plasma, or erythrocyte porphyrins. The European Porphyria Network (EPNET) operates a clinical EQA scheme, assessing the total testing process for porphyria-related analyses in all sample types. A specialized analytical EQA scheme covering all sample types is operated by the Royal College of Pathologists of Australasia with the European Molecular Quality Network (EMQN) providing a quality scheme for the molecular testing of the porphyria genes.

Methods for Porphyrins and Porphyrin Precursors in Urine and Feces

The water-soluble metabolites, PBG and ALA, are excreted by the kidneys and usually are measured in the urine in the clinical laboratory.

Porphobilinogen

Most methods for PBG are based on the reaction of Ehrlich's reagent (dimethylaminobenzaldehyde in acidic solution) with the α -methene carbon of the pyrrole ring to form a colored product variously described as "rose red" or "magenta," which has a characteristic absorption spectrum with a peak at 553 nm and a shoulder at 540 nm. Porphyrins do not contain any α -methene hydrogens and so do not react. Some other substances in urine may react with the reagent to give red products, notably urobilinogen, may inhibit the reaction, or are pigmented themselves and so mask the red chromogen. All need to be removed. This is best achieved by ion-exchange chromatography (first described by Mauzerall and Granick), but methods for accurate quantification of PBG based on this procedure are time-consuming. Methods based on high-performance liquid chromatography (HPLC) and tandem-mass spectrometry that are sufficiently sensitive to measure PBG in plasma have also been described.

There are a number of qualitative methods. The Watson-Schwartz and Hoesch methods have been criticized for poor detection limits and interferences whereas modified Mauzerall-Granick methods that use ion exchange resin reduced the time taken to perform the test to 10 minutes and produced a semi-quantitative result. If a qualitative or semiquantitative screening

Fig. 29.4 Absorption spectrum of acidified urine showing the procedure for measurement of corrected absorbance (A) of the porphyrin peak.

test is used, it is essential to include appropriate controls and to confirm all positive test results using a specific quantitative method. Commercial methods for the measurement of both PBG and ALA, based on that of Mauzerall and Granick, are available (Bio-Rad Laboratories, Hercules, CA, United States; Recipe Clinical Diagnostics, Munich, Germany).

5-Aminolevulinic Acid

It is possible to measure **5-aminolevulinic acid (ALA)** directly but it is more generally converted into an Ehrlich-reacting pyrrole through condensation with a reagent, such as acetylacetone, after separation from PBG by two-stage anion-exchange chromatography (see above).

Analysis of Porphyrins in Urine and Feces

The methods for porphyrin fractionation are complex and time-consuming and are not available in every laboratory. Consequently, simple qualitative screening tests are often used to differentiate the majority of specimens that do not require further investigation from the few that justify fractionation of the individual porphyrins. Screening tests in which extracts of urine or feces are examined visually for typical red-pink fluorescence of porphyrins are not sensitive analytically and should not be used. Methods based on spectrophotometric scanning of acidified urine (Fig. 29.4) or fecal extracts for the presence of the Soret band are recommended and yield semiquantitative information. Quantitative fluorometric methods are also available.

All methods for the fractionation of porphyrins are based on varying solubilities of individual porphyrins caused by their different β -substituents and, to a lesser extent, on the substituent order around the macrocycle. Methods include (1) differential

extraction with solvents, (2) paper and thin-layer chromatography, and (3) HPLC. Solvent extraction methods should not be used because they yield only limited and sometimes misleading information. Reversed-phase HPLC with fluorometric detection, the current method of choice, separates all porphyrins of clinical interest, including isomers and metal chelates, without the need for prior methylation. Representative HPLC chromatograms associated with porphyrin excretion patterns in several different porphyrias are shown in Fig. 29.5

Analysis of Blood Porphyrins

The methods described here require a spectrofluorometer with a red-sensitive photomultiplier. If such equipment is not available locally, samples must be referred to a specialized laboratory.

The most widely used method for erythrocyte total porphyrin is based on double extraction and fluorometry. If erythrocyte (proto)porphyrin concentration is increased, it is important to differentiate between free protoporphyrin, as in EPP, or ZPP, as in iron deficiency and lead toxicity (Fig. 29.6). This requires extraction with a neutral solvent, such as ethanol or acetone, to prevent the demetalation caused by strong acids, followed by fluorescence spectroscopy or HPLC to distinguish free protoporphyrin from ZPP (fluorescence emission maxima 630 nm and 587 nm, respectively).

Analysis of Plasma Porphyrins

Plasma porphyrins may be determined by fluorescence emission spectroscopy of saline-diluted plasma or HPLC analysis of deproteinized extracts. The fluorescence emission method offers the advantages of simplicity and inclusion of porphyrins that are bound covalently to plasma proteins and HPLC analysis cannot, from a diagnostic point of view, replace that method. Porphyrins at neutral pH fluoresce in the 610 to 640 nm region; the wavelength of maximum emission depends primarily on the porphyrin structure, but it is also influenced by the nature of the porphyrin-protein complex (see Fig. 29.3). Plasma fluorescence emission spectroscopy is an essential front-line investigation for suspected cutaneous porphyria.

POINTS TO REMEMBER

Diagnostics

- Identification of individual porphyrias usually requires analysis of urine, feces, and blood samples.
- All specimens must be protected from light.
- Symptomatic porphyria is always associated with increased production of porphyrins and porphyrin precursors.
 - Active acute autosomal dominant porphyria can be diagnosed by measuring increased PBG in a random urine sample.
 - Active cutaneous porphyrias can be diagnosed as a first step by finding a positive plasma porphyrin fluorescence emission screen in a freshly separated plasma sample.
- EPP cannot be diagnosed by urine porphyrin analysis, a blood sample for erythrocyte protoporphyrin analysis is essential.
- Fluorescent porphyrin analysis requires a red-sensitive photomultiplier for detection.
- Laboratories specializing in porphyria diagnosis must register with an appropriate EQA Scheme.

Fig. 29.5 Representative high-performance liquid chromatography chromatograms for (A) working standard, (B) normal feces, (C) normal urine, (D) feces—hereditary coproporphyria, (E) urine—congenital erythropoietic porphyria, (F) feces—variegate porphyria, (G) urine—porphyria cutanea tarda, and (H) feces—porphyria cutanea tarda chromatographic conditions. Peaks are (1) uroporphyrin-I, (2) uroporphyrin-III, (3) heptacarboxylate porphyrin-I, (4) heptacarboxylate porphyrin-III, (5) hexacarboxylate porphyrin, (6) pentacarboxylate porphyrin, (7) coproporphyrin-I, (8) coproporphyrin-III, (9) deuteroporphyrin-IX, (10) mesoporphyrin-IX, (11) protoporphyrin-IX, (12) hydroxyisocoproporphyrin, and (13) isocoproporphyrin.

Fig. 29.6 Fluorescence emission spectra (excitation at 405 nm) of ethanolic extracts of erythrocytes from a normal individual and with iron deficiency (A) and from patients with erythropoietic protoporphyria (EPP) or X-linked protoporphyria (XLEPP) (B). Note that different scales are used.

Enzyme Measurements

Assay of individual enzymes of the heme biosynthetic pathway is rarely required for the assessment of patients

with symptoms of porphyria. However, measurement of enzyme activities may be useful for family studies when it is not possible to identify the individual mutation, or when DNA analysis is not available. Erythrocytes are a convenient source of cytoplasmic enzymes (ALAD, HMBS, UROS, and UROD); however, assay of the mitochondrial enzymes (CPOX, PPOX, and FECH) requires nucleated cells, and sampling thus requires specialized techniques.

DNA Analysis

DNA analysis is required in the porphyrias mainly for family screening, for identifying the pattern of inheritance in families with EPP, and as an aid in assessing the prognosis in CEP. As most mutations are restricted to one or a few families, identification of a mutation in a new family almost always requires analysis of the entire gene.

Analysis of a gene for the presence of a mutation is most commonly carried out using direct sequencing and gene dosage analysis of genomic DNA. Unclassified variants continue to be identified in the porphyria genes, and these need to be assessed individually. Once the mutation that causes porphyria in a family has been identified, relatives are screened for its presence by direct sequencing of the region containing the mutation, or by some other mutation-specific method (see Chapter 48).

The clinical sensitivity of mutation detection in most porphyrias is above 90%, provided gene dosage analysis is included in the analysis.

POINTS TO REMEMBER

Genetic Testing in Acute Porphyria

- The main purpose is to identify family members who are at risk of an acute attack.
- The type of acute porphyria must be determined biochemically in the index case.
- The pathogenic mutation must be identified in the relevant gene.
- Family members should be appropriately counseled and offered testing for the presence of the familial mutation.
- Following appropriate counseling and consent, the testing of children is clinically justifiable.
- Patients with a predictive diagnosis of acute porphyria should be counseled on the avoidance of agents or behaviors that can trigger acute attacks.

REVIEW QUESTIONS

1. The precursors of the tetrapyrrole ring structure of porphyrin are:
 - a. 5-aminolevulinic acid and iron.
 - b. acetyl CoA and porphyrin.
 - c. succinyl CoA and glycine.
 - d. zinc and protoporphyrinogen.
2. The important initial screening test that allows for differentiation between the two categories of porphyria is:
 - a. serum coproporphyrin.
 - b. urine aminolevulinic acid (ALA) and porphobilinogen (PBG).
 - c. serum zinc protoporphyrin.
 - d. red blood cell zinc protoporphyrin.

3. Another name for protoporphyrin that contains iron is:
 - a. heme.
 - b. PBG.
 - c. coproporphyrin.
 - d. ferrochelatase.
4. The skin lesions and photosensitivity observed in patients with nonacute cutaneous porphyrias are the result of:
 - a. autonomic neuropathy.
 - b. excessive production of ALA.
 - c. accumulation of porphyrins in the liver.
 - d. excess presence of porphyrins in skin that generate oxygen radicals.
5. In lead toxicity, what replaces iron as a substrate for ferrochelatase to be incorporated into protoporphyrin?
 - a. Carbon dioxide
 - b. Zinc
 - c. Copper
 - d. Lead
6. The most common of all the porphyria disorders is:
 - a. variegate porphyria.
 - b. acute intermittent porphyria.
 - c. porphyria cutanea tarda.
 - d. congenital erythropoietic porphyria.
7. The initial steps of heme synthesis occur in the:
 - a. mitochondrion.
 - b. cytosol.
 - c. endoplasmic reticulum.
 - d. cell nucleus.
8. The best specimen type for analyzing porphobilinogen is:
 - a. heparinized plasma separated and frozen immediately after collection.
 - b. a 24-hour urine collection collected in a dark brown container and preserved with 0.1% HCl.
 - c. a fresh early morning urine specimen collected without preservative and protected from light.
 - d. blood anticoagulated with EDTA and protected from light.
9. Erythropoietic protoporphyria is characterized by which of the following symptoms?
 - a. Flaccid quadriparesis caused by the accumulation of porphobilinogen in muscle
 - b. Lifelong acute photosensitivity caused by protoporphyrin-IX accumulation in skin
 - c. Liver damage and hepatic siderosis caused by iron accumulation in cells
 - d. Severe abdominal pain and peripheral neuropathy caused by the induction of hepatic cytochromes
10. The reduced form of a porphyrin is known as a:
 - a. protoporphyrin.
 - b. heme molecule.
 - c. pyrrole ring.
 - d. porphyrinogen.

Therapeutic Drug Monitoring

Michael C. Milone, Leslie M. Shaw*

OBJECTIVES

1. Review basic principles of applied pharmacokinetics and drug monitoring
2. Discuss the rationale for drug monitoring and some of the pitfalls of applying it in the clinical setting
3. List drugs that are commonly monitored during their use

KEY WORDS AND DEFINITIONS

Antiepileptic A substance to prevent or alleviate seizures.

Applied pharmacokinetics The use of pharmacokinetic principles to guide the clinical application of therapeutic drugs.

Beta-blocker A drug that induces adrenergic blockade at either P1- or P2-adrenergic receptors or at both.

Bioavailability The fraction of a drug absorbed into the systemic circulation relative to the same drug administered intravenously.

Biotransformation The chemical alteration of a xenobiotic within the body that generally enhances the xenobiotic's aqueous solubility and excretion.

Dose-response relationship The relationship between the dose of an administered drug and the response of the organism to the drug.

Drug half-life The time required for one-half of an administered drug to be lost through metabolism and elimination.

Drug interactions The effects of one drug on the intestinal absorption, metabolism, or action of another drug.

Enzyme induction Increased synthesis of an enzyme in response to an inducer or other stimulus.

First-pass effect Extensive metabolism of a drug with a high hepatic extraction rate by the liver before it reaches the systemic circulation.

Generic drug A drug not protected by a trademark. Also, the scientific name as opposed to the proprietary, brand name.

Immunophilin A generic term for an intracellular protein that binds immunosuppressive drugs such as cyclosporine, FK 506, or rapamycin.

Immunosuppressant An agent capable of suppressing immune responses.

Pharmacodynamics The study of the biochemical and physiological effects of drugs and the mechanisms of their actions, including the correlation of actions and effects of drugs with their chemical structure; also, such effects on the actions of a particular drug or drugs.

Pharmacokinetics The activity or fate of drugs in the body over a period of time, including the processes of absorption, distribution, localization in tissues, biotransformation, and excretion.

Therapeutic drug monitoring The process of using drug concentration or other pharmacodynamics biomarkers to guide drug dosing.

Toxicology Subdiscipline of pharmacology concerned with adverse effects of chemicals on living systems.

Xenobiotics A chemical substance foreign to the biological system.

The ability of medicines to both heal and hurt has been recognized since ancient times. Immortalized by the writing of the Renaissance Swiss-German physician, Paracelsus over 500 years ago:

All things are poison and nothing is without poison, only the dose makes that a thing is not a poison.

*The authors gratefully acknowledge the contributions by Christine L.H. Snozek, Gwendolyn A. McMillan, and Thomas P. Moyer on which this chapter is based.

The challenge in medicine is therefore to determine the optimal dose of medicine that will help a patient with limited associated harm.

Studies in the 1990s identified adverse events associated with drug therapy as ranking within the top 10 causes of death in the United States. Although many severe or fatal events may not be preventable, more than one-third appear to be preventable. In addition to the tragic life-and-death consequences of adverse drug events (ADEs), failed drug therapy also has a significant economic impact. The estimated cost

of ADEs ranges from \$17 to \$29 billion in the United States alone. Just examining hospital-associated ADEs, the average cost of treating each preventable event is estimated to be greater than \$3000 in addition to the increased length of stay. The causes of preventable drug-related adverse events vary; however, inadequate monitoring of therapy represents major sources of preventable ADEs contributing to as much as 40% of these events. Improving monitoring strategies is therefore likely to have an important impact on both health and its associated cost.

There are many ways in which drug therapy can be monitored. Clinical signs and symptoms of toxicity are often an effective way to detect toxicity or treatment failure. **Beta-blockers** represent a typical example. Blood pressure and heart rate monitoring can be used to assess the efficacy and toxicity of these drugs. Both are also easily measurable in the clinical setting and even at home. As a result, there is little need to perform monitoring beyond these straightforward clinical assessments.

The efficacy and toxicity of some drugs, however, can be much more difficult to monitor based on clinical signs and symptoms alone. Insulin treatment in diabetes represents a case in point. The consequences of inappropriate insulin treatment are insidious, potentially life threatening, and very difficult to detect. Excessive insulin can lead to an acute decrease in blood glucose culminating in coma, permanent brain injury, and death. Inadequate insulin dosing, although not as acutely life threatening, leads over time to vascular disease, end-stage renal failure, blindness, and neuropathy, which result in significant morbidity and mortality. Laboratory testing of blood glucose, a direct biomarker of insulin's mechanism of action, provides an ideal means to monitor insulin therapy and prevent these complications. It is so important in diabetes therapy that it has driven the commercial development of simple, point-of-care (POC) devices that patients can use to routinely monitor their therapy at home. Biomarkers of drug efficacy or toxicity like blood glucose, although highly desirable, are not always available. In the absence of a useful drug effect biomarker, measuring the drug itself provides a potential surrogate.

Therapeutic drug monitoring (TDM) is the traditional term used for the activity of measuring drug concentrations to tailor the dose of the medication to an individual. There is an implicit assumption in TDM of a relationship between drug concentrations and efficacy or toxicity outcomes. The use of TDM and **applied pharmacokinetics** to guide drug therapy began in the 1960s, coincident with the development of robust analytical techniques. Since that time, TDM has become the standard of care for monitoring therapy with many drugs including antiepileptic drugs (AEDs), immunosuppressive drugs (ISDs), and antibiotics. TDM is a complex process that involves several members of the health-care team including pharmacists, laboratory professionals, and physicians. To justify the costs associated with TDM, it must improve clinical outcome and reduce the overall cost of drug therapy. Prospective, randomized, concentration-controlled trials (RCCTs) of TDM are limited; however, some of these

RCCTs show that concentration control can improve efficacy and reduce drug therapy toxicity. The cost-effectiveness of TDM is lacking for most drugs, but TDM has been shown to improve the costs of aminoglycoside therapy. TDM may also aid in the detection of nonadherence to drug therapy, which represents a frequent and important cause of preventable ADEs. This benefit may even extend to drugs not routinely monitored by traditional blood concentration monitoring.

FUNDAMENTAL PRINCIPLES OF APPLIED PHARMACOKINETICS

Basic Concepts and Definitions

Pharmacology comprises that body of knowledge surrounding chemical agents and their effects on living processes. This is a broad field, and it has traditionally been confined to those drugs that are useful in the prevention, diagnosis, and treatment of disease. Pharmacotherapeutics is that part of pharmacology concerned primarily with the application or administration of drugs to patients for the purpose of prevention and treatment of disease. For this aspect of medical practice to be effective, the pharmacodynamic and pharmacokinetic properties of drugs should be understood. **Toxicology** is the subdiscipline of pharmacology that is concerned with adverse effects of chemicals on living systems. Toxic effects and mechanisms of action may be different from therapeutic effects and mechanisms for the same drug. Similarly, at the high dosage of drugs at which toxic effects may be produced, rate processes are frequently altered compared with those at therapeutic doses. For these reasons, the terms *toxicodynamics* and *toxicokinetics* are now applied to these special situations.

Pharmacodynamics

Pharmacodynamics encompasses the processes of interaction of pharmacologically active substances with target sites, and the biochemical and physiological consequences leading to therapeutic or adverse effects. For many drugs, the ultimate effect or *mechanism of action* at the molecular level is poorly understood, if at all. A pharmacological effect (i.e., the therapeutic or toxic response to a drug) may be elicited either by direct interaction of the drug with the receptor that controls a specific function or by a drug-mediated alteration of the physiological process regulating the function. For most drugs, the intensity and duration of the observed pharmacological effect are proportional to the concentration of the drug at the receptor. In a given tissue, the site at which a drug acts to initiate events leading to a specific biological effect is called the drug's *site of action*.

The *mechanism of action* of a drug is the biochemical or physical process that occurs at the *site of action*. Drug action is usually mediated through a receptor. Cellular enzymes and structural or transport proteins are important examples of drug receptors. Nonprotein macromolecules may also bind drugs, resulting in altered cellular functions controlled by membrane permeability or DNA transcription. Some drugs are chemically similar to important natural endogenous

Fig. 30.1 The dose-effect relationship. The probability of increasing pharmacologic response and risk of toxicity parallels concentration for most drugs. The plateau (maximum effect) is likely due to saturation at the receptor.

substances and may compete for binding sites. In addition, some drugs may block formation, release, uptake, or transport of essential substances. Others may produce an effect by interacting with relatively small molecules to form complexes that actively bind to receptors. These and other examples of receptor binding are more completely discussed in pharmacology texts.

Although the exact molecular interactions that give rise to the mechanism of action for many drugs remain obscure, numerous theoretical models have been developed to explain drug action. One concept postulates that a drug binds to intracellular macromolecular receptors through ionic and hydrogen bonds and van der Waals forces. This theoretical model further postulates that if the drug-receptor complex is sufficiently stable and able to modify the target system, an observable pharmacological response will occur. As Fig. 30.1 illustrates, the response is concentration dependent until a maximal effect is reached. The plateau may be due to saturation at the receptor or overload of a transport process.

The utility of monitoring drug concentration is based on the premise that pharmacologic response correlates with the concentration of the drug at the site of action (receptor). Although attempts have been made to measure the concentration of drugs at the receptor site in a patient, in general, this approach is technically impractical, if not impossible for most drugs. Studies have shown that for many drugs, a strong correlation exists between the serum drug concentration and the observed pharmacological effect. In addition, years of relating blood concentrations to drug effects have demonstrated the clinical utility of drug concentration information. One must nevertheless always keep in mind that a serum drug concentration does not necessarily equal the concentration at the receptor; it merely reflects it.

Pharmacokinetics

Pharmacokinetics describes the processes of uptake of drugs by the body, the distribution of the drugs into tissue, the **bio-transformations** (i.e., metabolism) the drugs undergo, and

Fig. 30.2 Conceptual relationship between pharmacodynamics and pharmacokinetics. Many drug- and patient-specific factors determine both the serum concentration of a therapeutic compound and its metabolites. Serum concentration, in turn, is related to the amount of drug present at the target site, resulting in effects on a variety of molecules (several examples shown) to induce a pharmacologic response. The efficacy and degree of response provide feedback to allow optimization of the dosing regimen for an individual patient.

the elimination of the drugs and their metabolites from the body. Applied pharmacokinetics is the discipline that uses the principles of pharmacokinetics to enhance the safety and effectiveness of a drug in an individual patient. It is this aspect of pharmacology that most strongly influences the interpretation of TDM results and that is dealt with in more detail in this chapter. Fig. 30.2 illustrates the conceptual relationship between pharmacodynamics and pharmacokinetics, and the many factors affecting drug concentration and pharmacological response.

Drugs Constantly Undergo Change in the Body

Many factors are now recognized as having a profound influence on the pharmacokinetics of drugs and consequently on a patient's pharmacological response (Box 30.1). For example, the consideration of the patient's history, with particular emphasis on his or her pathophysiologic state and adjunct drug therapy, is essential at the initiation of drug therapy and TDM because these important factors may affect the absorption, distribution, metabolism, and excretion (ADME) of a drug.

Absorption

Most drugs administered chronically to patients are administered extravascularly. Although intramuscular and subcutaneous routes are used, the oral route accounts for most of the extravascular doses administered. The absorption process depends on the drug dissociating from its dosing form, dissolving in gastrointestinal fluids, and then diffusing across

BOX 30.1 Factors That Affect Drug Distribution in Humans**Demographic Factors**

Age
Weight
Gender
Race
Genetics (e.g., metabolic enzyme polymorphisms)

Health-Related Factors

Liver disease (cirrhosis, hepatitis, cholestasis)
Kidney disease
Thyroid disease (hypothyroidism or hyperthyroidism)
Cardiovascular disease (arrhythmias, congestive heart failure)
Gastrointestinal disease (e.g., sprue or other malabsorption, peptic ulcer disease)
Cancer
Surgery
Burns
Volume status (e.g., dehydration)
Nutritional status (cachectic or anorexic)
Pregnancy or other factors affecting plasma proteins or body composition

Extracorporeal Factors

Hemodialysis
Peritoneal dialysis

Cardiopulmonary bypass
Hypothermia or hyperthermia

Chemical and Environmental Factors Influencing

Absorption of drug
Food or coadministered drug affecting extent or rate of absorption
Immediate- or extended-release formulation
Distribution of drug
Coadministered drugs affecting protein binding to plasma proteins or tissue
Metabolism of drug
Food, herbs, or drugs competing for metabolism
Coadministration of drugs that induce metabolic enzymes (e.g., phenobarbital)
Coadministration of drugs that inhibit metabolic enzymes (e.g., cimetidine)
Excretion of drug
Coadministration of a drug that competes for renal tubular secretory pathways (e.g., probenecid, penicillin)
Coadministration of drugs that enhance renal tubular reabsorption

biological membrane barriers into the bloodstream. The rate and extent of drug absorption may vary considerably depending on the nature of the drug itself (e.g., solubility, pK_a), on the matrix in which it is present, and on the physiological environment (e.g., pH, gastrointestinal motility, vascularity).

The fraction of a drug dose that is absorbed into the systemic circulation is referred to as its **bioavailability**. The bioavailability of a particular drug, if the drug is to be useful, must generally be great enough so that the active component can pass in sufficient amount and in a desirable time from the gut into the systemic circulation. Bioavailability of greater than 70% is most desirable for drugs to be orally useful. An exception would be a case in which the lumen of the gastrointestinal tract is the site of drug action (e.g., antibiotics used to sterilize the gut, such as oral vancomycin). Low bioavailability would then be considered advantageous.

Some drugs that are rapidly and completely absorbed nevertheless have low bioavailability to the systemic circulation. This is true of drugs with a high *hepatic extraction rate*. After oral administration, drugs that are absorbed in the lumen of the small intestine are carried by the portal vein directly to the liver. The liver may extensively metabolize a drug with a high hepatic extraction rate before it reaches the systemic circulation leading to low oral bioavailability. This phenomenon is called the **first-pass effect**.

In addition to the extent of absorption, the rate of absorption is also important. The absorption of a drug is generally considered a first-order process, and the absorption rate constant of a drug is usually much greater than its elimination rate constant. Efforts are now being made in the pharmaceutical industry to decrease the apparent rate of absorption of many

drugs by manipulating their formulations to produce sustained (or extended) release products. Formulations that provide sustained release permit drugs taken orally to be taken at less frequent intervals. Conditions that may influence the extent or rate of drug absorption include abnormal gastrointestinal motility, diseases of the stomach and the small and large intestines, gastrointestinal infections, radiation, food, and interaction with other substances in the gastrointestinal tract.

Distribution

After a drug enters the vascular compartment, it interacts with various blood constituents and is carried by various transport processes to different body organs and tissues. The overall process is referred to as *distribution*. The factors determining the distribution pattern of a drug are binding of the drug to circulating blood components, binding to fixed receptors, passage of the drug through membrane barriers, and the ability to dissolve in structural or storage lipids. Molecular weight, pK_a , lipid solubility, and other physical and chemical properties of the drug are important determinants of distribution.

Once a drug enters the systemic circulation, it distributes and comes to equilibrium with many of the blood components, such as plasma proteins. An equilibrium exists between *free* and *protein-bound* drug fractions. It is generally believed that only the free fraction of the drug is available for distribution and elimination. In addition, only the free drug is available to transit across cellular membranes or to interact with the drug receptor to elicit a biological response. Therefore changes in the protein-binding characteristics of a drug can have a profound influence on the distribution and elimination of a drug, and on the manner in which total plasma or serum steady-state

concentrations are interpreted. Each drug has its own characteristic protein-binding pattern that depends on its physical and chemical properties. As a general rule, however, acidic drugs are bound primarily to albumin, and basic drugs primarily to globulins, particularly α_1 -acid glycoprotein (AAG). Some drugs bind to both albumin and globulins.

Anything that alters the concentration of free drug in the plasma ultimately alters the amount of drug available to enter the tissues and interact with specific receptor systems. Disease states can alter free drug concentrations. For example, in uremia, the composition of plasma is altered by an increase in nonprotein nitrogen compounds, by acid-base and electrolyte imbalances, and often by a decrease in albumin; free drug concentrations are frequently increased. It is important to also recognize that even though the total drug concentration may remain unchanged, displacement of a drug from its plasma protein-binding sites increases free drug concentrations and can result in clinical toxicity. For example, phenytoin is 90% bound and 10% free in healthy subjects. In uremic patients, 20% to 30% of the total plasma concentration of phenytoin may be free. If one considers a healthy patient who has a total plasma phenytoin concentration of 15 $\mu\text{g/mL}$, the free phenytoin concentration is likely to be 1.5 $\mu\text{g/mL}$. If a uremic patient has a total concentration of 15 $\mu\text{g/mL}$, the free drug concentration may be 4.5 $\mu\text{g/mL}$. A free phenytoin concentration of 4.5 $\mu\text{g/mL}$ is sufficient to precipitate severe phenytoin side effects, including lethargy and increased seizure frequency. In uremic patients, it is advisable to quantitate free phenytoin concentrations and adjust the drug dose to maintain free phenytoin concentration at approximately 2.0 $\mu\text{g/mL}$.

Equilibrium dialysis represents the gold-standard method for measuring the free, unbound concentration of a drug. However, this method typically requires 16 to 18 hours of incubation to achieve equilibrium, which severely limits the turnaround time for testing. Ultrafiltration techniques are a useful alternative that can usually be accomplished in a fraction of the time. In ultrafiltration, a sample of serum or plasma is forced through a filter membrane with a low molecular weight cutoff value, typically by centrifugation, to yield a protein-free sample. Provided this process is done rapidly and under appropriate temperature control, ultrafiltration can provide a useful estimate of the free drug concentration in circulating blood.

Metabolism

Biotransformation

The liver is the principal organ responsible for xenobiotic metabolism. One of its major roles is to convert lipophilic nonpolar molecules to more polar water-soluble forms. The drug molecule (a xenobiotic) can be modified by phase I reactions, which alter chemical structure by oxidation, reduction, or hydrolysis; or by phase II reactions, which conjugate the drug (glucuronidation or sulfation) to water-soluble forms. Typically, both phase I and phase II reactions occur. Most drug metabolism takes place in the microsomal fraction of the hepatocytes, where many environmental chemicals and endogenous biochemicals (**xenobiotics**) are also processed and by the same mechanisms.

Enzymes of the hepatic microsomal system can be induced or inhibited. Microsomal **enzyme induction** leads to an increase in the activity of the enzymes present, most commonly through increases in the number of oxidizing enzymes. The many isoenzymes of cytochrome P450 are affected variably by different enzyme-inducing drugs. Phenobarbital and theophylline represent prototypical enzyme inducers with broad induction effects; however, they induce different cytochrome P450 isoforms leading to effects on different drugs. Because the drug-metabolizing enzymes of the liver are also relatively nonspecific and interact with a wide variety of endogenous and exogenous substances, the presence of one drug may inhibit the metabolism of a second drug that is coadministered. When patients are on a drug with a narrow therapeutic index (TI), their dosing regimen would need to be adjusted should a known enzyme-inducing or inhibiting drug be added to or deleted from their therapy.

The role of TDM becomes particularly apparent for drugs that undergo hepatic metabolism. Wide variability in the rate of metabolism of any given drug exists not only in different patients in the general population, but also in the same patient at different times and in different circumstances. This variability is due to factors such as age, weight, gender, genetics, exposure to environmental substances, diet, coadministered drugs, and disease. Furthermore, unlike kidney function, where creatinine provides a useful biomarker of function, there is no acceptable, endogenous, biochemical marker by which hepatic function, and consequently hepatic capability for drug clearance, can be routinely assessed before drug therapy is initiated.

Excretion

Excretion of drugs or chemicals from the body can occur through biliary, intestinal, pulmonary, or renal routes. Although each of these represents a possible mechanism of drug elimination, renal excretion is a major pathway for the elimination of most water-soluble drugs or metabolites and is important in TDM. Alterations in renal function may have a profound effect on the clearance and apparent half-life of the parent compound or its active metabolite(s); decreased renal function causes increased serum drug concentrations and increases the pharmacological response.

Kidney function, in contrast to liver function, is readily and reliably evaluated by estimation of creatinine clearance. Renal clearance of creatinine at 120 mL/min approximates the glomerular filtration rate of 90 to 130 mL/min (see also [Chapter 21](#)). Therefore, measurement of creatinine clearance or estimated glomerular filtration rate (eGFR) on a routine basis provides an effective tool to evaluate kidney function. A strong correlation has been shown to exist between creatinine clearance and the total body clearance or elimination rate constant of those drugs primarily dependent on the kidneys for their elimination. Examples of drugs whose therapeutic use is adjusted to account for changes in creatinine clearance include the aminoglycoside antibiotics gentamicin, tobramycin, and amikacin.

Fig. 30.3 The pharmacodynamics of tacrolimus in renal transplantation. (Reprinted with permission from Venkataramanan, R., Shaw, L. M., Sarkozi, L., Mullins, R., Pirsch, J., MacFarlane, G., Shaked, A. [2001]. Clinical utility of monitoring tacrolimus blood concentrations in liver transplant patients. *Journal of Clinical Pharmacology*, 41[5], 542–551.)

General Considerations for the Clinical Use of Therapeutic Drug Monitoring

There is no universal set of rules that determine whether a drug might benefit from TDM; however, numerous characteristics of a drug contribute to the need for TDM. TDM is most valuable when the drug in question is used chronically, has variable pharmacokinetics, and has a narrow TI. For drugs with a narrow TI, there is little if any window between blood (or serum for those drugs routinely measured in serum) concentrations associated with efficacy and those associated with toxic effects. The immunosuppressive calcineurin inhibitor drug, tacrolimus, provides a good example of a narrow TI drug with a wide variability in pharmacokinetics as shown in Fig. 30.3. The concentrations of tacrolimus that are associated with efficacy (i.e., freedom from graft rejection) and those associated with kidney toxicity overlap considerably. TDM helps navigate this “tightrope.” By itself, however, narrow TI is not necessarily sufficient to warrant TDM. Many narrow TI drugs are routinely used without monitoring such as most cancer chemotherapy drugs. Additional factors therefore contribute to the need for TDM such as the severity of failed drug therapy (e.g., antimicrobials) or toxicity (e.g., ISDs). Difficulty in recognizing efficacy or toxicity with use of these drugs can be life threatening. Many patients, especially those with chronic disease, also require prolonged drug therapy. The problem of compliance is particularly evident with patients who are characteristically free of pain or unusual discomfort as with epilepsy, asthma, hypertension, mild heart disease, and transplantation. Patients may develop a sense that their disease has been cured and they no longer need the drug. The end result of noncompliance is exacerbation of the existing disorder and treatment failure. Drug concentration values therefore provide positive feedback to physicians regarding compliance.

Preanalytical Factors That Affect Therapeutic Drug Monitoring Results

To interpret a TDM result, it is critical that the dose of drug given to the patient is known. Dosage uniformity standards exist for US Food and Drug Administration (FDA)-approved drugs. Although most drug formulations are fairly consistent, the actual dose of a drug in a single tablet, suspension, or vial may vary. United States Pharmacopeia (USP) standards dictate that the mean dose contained in a tablet must be within $\pm 10\%$ of the product labeling and no tested sample may fall outside of 75% and 125% of the mean. As a result, the dose content for a single dose could theoretically vary by as much as 25% and still fall within acceptable USP content uniformity limits. This is further compounded by inaccuracies introduced by manipulation of the dose (e.g., splitting of scored tablets, failure to administer or consume the entire dose or from vomiting). Drugs may also degrade over time, which depends on storage, leading to further dose inaccuracy.

Beyond dose accuracy, pharmacokinetics is inherently time based. Thus, accurate timing of sample collection is often an important factor, especially when timed samples, such as peak or trough samples, are the primary means of monitoring. Vancomycin trough samples provide an example where collection immediately prior to the next dose is recommended due to the relatively short **half-life** of this drug (~6 to 12 hours). Premature sampling may lead to falsely increased concentrations that could alter decision making given the generally narrow therapeutic range for this drug. In contrast, drugs with slow distribution but long half-life, such as digoxin, are optimally sampled in the postdistributive phase of greater than 6 hours following dosing. Sampling during the steady state (generally >4 doses) is also an important assumption made for monitoring of many drugs such as vancomycin.

Variation in collection and handling of samples for TDM can also affect the quality of concentration data. Although serum is the preferred sample for monitoring of many drugs, different collection tubes are available for generating serum that include plain glass or plastic tubes without additive (e.g., red-stoppered BD Vacutainer tubes) and specialized serum separator tubes (e.g., yellow-stoppered BD Vacutainer tubes) that contain a gel that separates serum from the cellular components following centrifugation. The latter tube may affect drug concentration due to adsorption of the drug by the gel following prolonged contact. The adsorptive effects vary across drugs, and have been shown to significantly reduce the concentration of some drugs, such as phenytoin, particularly when the collection tubes are underfilled. The stability of drugs following collection may also vary with some drugs requiring prompt serum generation following by freezing for optimal stability (e.g., busulfan).

The importance of preanalytical factors in the accuracy and precision of TDM results should not be underestimated. TDM laboratories are part of a larger health-care system. It is imperative that laboratories engage and work with the many parts of this system including pharmacists, nurses, and the phlebotomy team. Each individual plays an important role in TDM, and the effective control of the many factors that affect TDM accuracy are key to the success of this complex feedback control system.

POINTS TO REMEMBER

Preanalytic factors affecting TDM results:

- Dose accuracy
- Appropriate sampling time
- Specimen collection and handling
- Physiologic changes in the patient (e.g., serum albumin concentration and phenytoin distribution)

Analytical Factors That Affect Monitoring Results

The laboratory, of course, plays a central role in the TDM process. Beyond the preanalytical factors affecting TDM results, analytical factors are important considerations in the interpretation of drug concentration data. Notable challenges in the analytical field include the availability of standardized reference material and the selectivity of methods for the drug of interest.

Determining whether a method gives accurate results over the long term and across laboratories is often a difficult task. This is generally accomplished by comparing the results of testing against a definitive analytical method or by using a certified reference material. Definitive methods generally employ very time-consuming and expensive techniques (e.g., isotope dilution-mass spectrometry) to establish material purity and quantity that are not practical for general use in most clinical laboratories. The availability of certified reference material (also frequently referred to as standardized reference material) to which methods may be compared is a

critical factor in helping to control systematic error (refer to [Chapter 7](#)). Early studies of method comparability for AEDs demonstrated that concentrations varied greatly across laboratories as well as within laboratories over time. These data led to the development in the early 1980s by the National Institute for Standards and Technology (NIST) of a standard reference material of sufficient purity and accuracy to allow standardization of AED monitoring methods across different laboratories and manufacturers. Unfortunately, this type of standardized reference material is unavailable for the majority of monitored drugs.

The ability of a given method to detect a compound of interest among many potential substances present in a sample (referred to as method selectivity) represents another potential source of systematic error. Selectivity is particularly important for TDM tests because many drugs are structurally related, including to some endogenously produced compounds. Most drugs are also extensively metabolized through several different biotransformation pathways. These metabolites are often similar to the parent compound in structure, but pharmacologic activity is variable. Tacrolimus provides a useful example. Antibodies directed against tacrolimus that are used for immunoassays demonstrate similar reactivity toward tacrolimus along with two of its metabolites, 15-desmethyl-tacrolimus and 31-desmethyl-tacrolimus. Although both metabolites are detected equally, the 15-desmethyl metabolite exhibits little immunosuppressive activity, whereas the 31-desmethyl metabolite exhibits equal immunosuppressive activity when compared to that of tacrolimus. This metabolite interference with target drug detection can lead to inappropriate changes in drug dosing when substantial and not recognized. Beyond metabolites, interference can also occur from unrecognized substances within the sample matrix such as bilirubin. For immunoassay-based testing, heterophile antibodies, such as human-anti-mouse antibody (HAMA), are difficult to detect and can adversely affect testing in unpredictable ways (see [Chapter 15](#)).

Concept of a Therapeutic Range

The relationship between serum drug concentration and clinical outcome is the basis for TDM as depicted in [Fig. 30.1](#). One of the most common interpretative errors encountered regarding TDM is the presumption that a concentration within a reported therapeutic range will ensure treatment success in the absence of toxicity, and concentrations outside that range will not. In reality, the probability of success and toxicity are a continuum across the concentration range. These probabilities are maximized and minimized, respectively, within the therapeutic range. Nevertheless, therapeutic success can certainly occur at concentrations below the therapeutic range. More importantly, success may also be achieved by concentrations above the therapeutic range without associated toxicity in some patients. Experienced users of TDM often recognize these relationships, and weigh the risks and potential benefits of drug concentrations in the context of the clinical situation using the therapeutic range as a guide.

Similar to a reference interval for any laboratory test, therapeutic ranges are based on population data from drug therapy trials, and in some instances, confirmed or established by randomized concentration-controlled trials. The application of these population-based ranges to an individual therefore assumes similarity to the target population. Differences in metabolism, physiology, and/or the underlying disease process can alter these relationships leading to unexpected and undesirable results. Phenytoin used for seizure control illustrates this limitation. A fairly good relationship between serum phenytoin concentration and seizure control exists. However, several factors have been shown to alter the **dose-response relationships** for phenytoin that might impact the utility of defined therapeutic ranges. The presence of concomitant liver disease significantly alters the pharmacokinetics of phenytoin due to its high degree of binding to albumin, a protein that is significantly altered with moderate–severe liver disease. As a result, individuals with liver disease are at significantly higher risk of toxicity at total serum phenytoin concentrations that are otherwise appropriate for individuals without liver disease. The recognition of this problem led to the development of methods for measuring phenytoin that is unbound to albumin in serum (also known as free phenytoin), which also correlates with seizure control. Nevertheless, this example illustrates the need for caution in applying population-based relationships to individual patients who may not be represented by the population used for defining the therapeutic range.

POINTS TO REMEMBER

Analytical factors affecting TDM results:

- Method selectivity for the target drug versus its metabolites
- Method precision relative to the desired therapeutic target range
- Availability of a standardized reference material
- Interfering substances in the sample (e.g., antibodies that react with assay reagents)

THERAPEUTIC DRUG MONITORING OF SPECIFIC DRUGS IN COMMON CLINICAL USE

Antiepileptic Drugs

Phenytoin

Phenytoin (diphenylhydantoin), most commonly available as *Dilantin* but also available in **generic** form, is used in the treatment of primary or secondary generalized tonic-clonic seizures, partial or complex-partial seizures, and status epilepticus. The drug is not effective for absence seizures. Phenytoin likely has many targets, but the most well-described mechanism of action is the modulation of voltage-gated sodium channels through prolonged channel inactivation, which reduces the ability of the neuron to respond at high frequency. The physiological effect of this action is reduction in

central synaptic transmission, which aids in control of abnormal neuronal excitability.

Phenytoin is not readily soluble in aqueous solutions. When administered by intramuscular injection, most of the dose precipitates at the site of injection and is then slowly absorbed. A prodrug called *fosphenytoin* (Cerebyx) was introduced as a therapeutic form of phenytoin to improve phenytoin's pharmacology. Fosphenytoin has increased aqueous solubility for intramuscular injection. After injection, it is rapidly converted to phenytoin. Absorption of oral phenytoin is slow and sometimes incomplete. Variations in the drug preparation have been blamed for low bioavailability. Once absorbed, the drug is tightly bound to protein (90% to 95%). As with all drugs, the pharmacological effect of phenytoin is directly related to the amount present in the free (unbound) state. Only free phenytoin is available to cross biological membranes and interact at biologically important binding sites. The degree of protein binding can be reduced by the presence of other drugs, anemia, and hypoalbuminemia, which can occur in the elderly.

The optimal total phenytoin therapeutic concentration for seizure control without side effects is 10 to 20 $\mu\text{g/mL}$ (40 to 79 $\mu\text{mol/L}$). Free phenytoin concentration in the range of 1 to 2 $\mu\text{g/mL}$ (1 to 8 $\mu\text{mol/L}$) is frequently considered optimal. A side effect of phenytoin not related to plasma concentration is development of gingival hyperplasia.

Phenytoin is metabolized by the liver, and may become saturated within the therapeutic range due to its zero-order pharmacokinetics. Once metabolism is saturated, small dose increments result in large changes in blood concentration (Fig. 30.4); this phenomenon partially explains the wide variation in dosage among patients that is required to accomplish a therapeutic effect. Because of this saturation phenomenon, first-order kinetics do not generally apply to total phenytoin at blood concentrations in excess of 5 $\mu\text{g/mL}$ (20 $\mu\text{mol/L}$).

Fig. 30.4 Nonlinear response to dose changes. Drugs with first-order kinetics (solid black line) display serum steady-state concentrations (C) that vary proportionately with dose (D). In contrast, for drugs with zero-order kinetics (dotted blue line), an increase in dose may result in a disproportionate increase in serum steady-state concentrations.

A number of **drug interactions** result in alteration of the disposition of phenytoin by enhancing metabolism (e.g., alcohol, barbiturates, and carbamazepine), competing with metabolism (e.g., chloramphenicol, cimetidine, disulfiram, isoniazid, and dicumarol), or displacing phenytoin from normal binding to serum protein (e.g., salicylate and valproic acid).

Carbamazepine

Carbamazepine, proprietary name *Tegretol*, is used in the treatment of generalized tonic-clonic, partial, and partial-complex seizures. It is also used for the treatment of pain associated with trigeminal neuralgia and as a mood-stabilizing drug in bipolar disorder. Like phenytoin, carbamazepine modulates the synaptic sodium channel, which prolongs inactivation, reducing the ability of the neuron to respond at high frequency. The physiological effect of this action is reduction in central synaptic transmission, which aids in control of abnormal neuronal excitability. The mechanisms of action in mood stabilization are less clear.

After oral administration, carbamazepine is slowly and erratically absorbed with wide individual variability. The drug is highly protein bound (80%). The elimination half-life early in therapy is approximately 24 hours. With chronic therapy, the enzymes responsible for metabolism are induced, and the elimination half-life is reduced to 15 to 20 hours. Because hepatic metabolism is the principal means by which the drug is eliminated from plasma, any reduction in liver function results in drug accumulation.

The therapeutic concentration range for optimal pharmacological effect of carbamazepine is 4 to 12 $\mu\text{g/mL}$ (17 to 51 $\mu\text{mol/L}$); however, this range is dependent upon concomitant use of other AEDs. Toxicity associated with excessive carbamazepine ingestion occurs at plasma concentrations in excess of 15 $\mu\text{g/mL}$ (63 $\mu\text{mol/L}$) and is characterized by symptoms of blurred vision, paresthesia, nystagmus, ataxia, drowsiness, and diplopia. Side effects unrelated to plasma concentration include development of an urticarial rash, which usually disappears on discontinuation of the drug, and hematologic depression (leukopenia, thrombocytopenia, and aplastic anemia).

The active metabolite of carbamazepine is carbamazepine-10,11-epoxide. This metabolite has been found to accumulate in children to concentrations equivalent to carbamazepine. It may contribute to symptoms of intoxication in children who have a therapeutic plasma concentration of the parent drug. Because carbamazepine is metabolized through the hepatic oxidative enzyme system, drugs that induce this system (phenytoin, phenobarbital) increase the rate of carbamazepine clearance.

Coadministration of phenobarbital, phenytoin, or valproic acid increases the rate of carbamazepine metabolism and reduces the blood concentration. Erythromycin and propoxyphene interfere with metabolism and increase carbamazepine concentrations.

Because of carbamazepine's relatively long half-life, the specimen yielding the most useful information is the one representing the trough concentration, although in the case of suspected mild intoxication, the peak value of the plasma

concentration correlates more closely with toxicity. The peak specimen should be collected 4 to 8 hours after the oral dose in the setting of immediate-release formulations of carbamazepine.

Valproic Acid

Valproic acid, brand name *Depakene* or *Depakote*, is used for treatment of absence seizures. It has also been shown to be useful against tonic-clonic and partial seizures when used in conjunction with other AEDs such as phenobarbital or phenytoin. Beyond its use in the treatment of epilepsy, valproate also has mood-stabilizing effects that make it a useful agent, and alternative, in the treatment of bipolar disorder. The drug inhibits the enzyme gamma-aminobutyric acid (GABA) transaminase, resulting in an increase in the concentration of GABA in the brain. GABA is a potent inhibitor of presynaptic and postsynaptic discharges in the central nervous system.

Valproic acid is rapidly and almost completely absorbed after oral administration. Peak concentrations occur 1 to 4 hours after an oral dose. The principal metabolite, 2-*n*-propyl-3-ketopentanoic acid, has anticonvulsant activity comparable to that of valproic acid, although this metabolite does not accumulate in plasma. The single-dose half-life is 16 hours in healthy adults, but this reduces to 12 hours on chronic therapy and may be as short as 8 hours in children. In neonates and in hepatic disease, when metabolism is reduced, the half-life becomes prolonged. Valproic acid is highly protein bound (93%). In circumstances when competition for protein binding increases, such as in uremia, cirrhosis, or concurrent drug therapy, the percent of free valproic acid increases. The minimum effective therapeutic concentration of valproic acid is 50 $\mu\text{g/mL}$ (346 $\mu\text{mol/L}$). Concentrations in excess of 100 $\mu\text{g/mL}$ (693 $\mu\text{mol/L}$) have been associated with hepatic toxicity and acute toxic encephalopathy.

Ethosuximide

Ethosuximide, proprietary name *Zarontin*, is used for the treatment of absence seizures characterized by brief loss of consciousness. Ethosuximide reduces the flow of calcium through T-type calcium channels in the synapse of thalamic neurons; because thalamic neurons are the main source of 3-Hz spike-wave rhythms in absence seizures, reduction of calcium flow slows the rate of these seizure-inducing pulses.

Ethosuximide is readily absorbed from the gastrointestinal tract. The drug is cleared mainly by metabolism as either the hydroxyethyl compound or the glucuronide ester of the hydroxyethyl metabolite with a half-life of approximately 33 hours, although this may be prolonged in adults. The trough specimen yields the most useful information regarding therapeutic efficacy. The optimal therapeutic concentration of ethosuximide is 40 to 100 $\mu\text{g/mL}$ (283 to 708 $\mu\text{mol/L}$). Toxicity related to an excessive blood concentration of ethosuximide is rare. Symptoms of gastrointestinal distress, lethargy, dizziness, and euphoria may be encountered early in therapy, but patients usually become tolerant to these symptoms.

Topiramate

Topiramate, brand name *Topamax*, is a sulfamate-substituted monosaccharide anticonvulsant that is also approved for use in migraine headache therapy. The mechanisms by which topiramate exerts these effects is not clearly established. It is proposed that several effects may contribute to topiramate's pharmacologic activity including blockage of voltage-dependent sodium channels, augmentation of the neurotransmitter gamma-aminobutyrate action at some of the subtypes of the GABA-A receptor, antagonism of the AMPA/kainite subtype of glutamate receptors, and inhibition of isozymes II and IV of carbonic anhydrase.

Brand name *Topamax* is generally well and rapidly absorbed following oral administration with a usual $T_{\max}$ between 2 and 4 hours and bioavailability of up to 95%. Coingestion of food can delay absorption by approximately 2 hours without effect on $T_{\max}$. Average steady-state serum concentrations can fall by approximately 50% when either phenytoin or carbamazepine is coadministered. The metabolism of topiramate is not well understood or described, but renal clearance of unchanged drug has been reported to account for the majority of clearance in the absence of coadministered inducing drugs like phenytoin or carbamazepine. In the presence of the latter, the contribution of hepatic clearance increases. Thus, upon introduction of one of these inducing drugs into the patient's regimen, or withdrawal, closer monitoring of serum concentrations of topiramate is warranted. In the presence of significant renal disease, lowering the dosage and judicious use of TDM is recommended. Topiramate is only weakly bound to plasma proteins, and therefore circumstances that alter drug binding in serum do not affect topiramate clearance or steady-state concentrations. Based on retrospective studies and a concentration-controlled study, the usual range of concentrations is 5 to 20 $\mu\text{g/mL}$ (15 to 59 $\mu\text{mol/L}$).

Lamotrigine

Lamotrigine, proprietary name *Lamictal*, is not a GABA analog, but binds to the GABA receptor; it is therefore considered a GABA receptor agonist. Lamotrigine acts like phenytoin and carbamazepine, and blocks repetitive nerve firings induced by depolarization of spinal cord neurons. Lamotrigine was approved by the FDA in 1994 for adjunctive therapy of partial seizures in adults. It has yet to be approved for use in children. Studies also suggest lamotrigine is effective against absence seizures.

Lamotrigine is well tolerated and completely absorbed from the gastrointestinal tract after oral administration. It is 60% bound to plasma proteins. Optimal response appears to occur with blood concentrations in the range of 2.5 to 15 $\mu\text{g/mL}$ (~10 to 60 $\mu\text{mol/L}$). However, dizziness, ataxia, diplopia, blurred vision, nausea, and vomiting are signs of toxicity that may occur when the blood concentration exceeds 10 $\mu\text{g/mL}$ (40 $\mu\text{mol/L}$). Half-life ranges from 15 to 35 hours with monotherapy. Elimination occurs through hepatic metabolism; the primary metabolite is the glucuronide ester. Coadministration with cytochrome P₄₅₀-inducing drugs such as phenobarbital,

phenytoin, or carbamazepine results in reduced lamotrigine concentrations; dosage increases of approximately 30% are required to maintain optimal blood concentrations.

Levetiracetam

Levetiracetam, marketed under the trade name *Keppra*, is an anticonvulsant drug approved in the United States for adjunctive therapy in patients with partial seizures. Levetiracetam belongs to the lactam class of molecules that share a 5-member pyrrolidone ring, which include piracetam and ethosuximide. The mechanism of action for levetiracetam, although not fully understood, appears to be via binding to the synaptic vesicle protein, SV2A, leading to a reduction in the rate of synaptic vesicle release.

Levetiracetam, available in both oral and intravenous formulations, is mostly absorbed (>95%) within the gastrointestinal tract. Food intake causes a modest delay in absorption with reduced peak serum concentrations; however, overall bioavailability is unaffected. Levetiracetam is metabolized to the inactive acetamide form by hydrolysis (~27% to 34%) with the majority of the drug excreted by the kidneys unchanged into urine. Clearance of the drug is therefore affected by kidney disease. An increase in levetiracetam clearance has been observed during the third trimester of pregnancy; however, this change in clearance is variable. Because there is no significant hepatic metabolism of levetiracetam, liver function does not affect the pharmacokinetics of this drug.

Serum concentrations of levetiracetam appear to correlate linearly with dose within the typical dosing range. Although the optimal target range for serum concentration has not been fully defined, retrospective analysis of data from clinical trials of levetiracetam suggests that concentrations within the range of 12 to 46 $\mu\text{g/mL}$ (70 to 270 $\mu\text{mol/L}$) are associated with efficacy.

Felbamate

Felbamate, proprietary name *Felbatol*, was approved by the FDA in 1993 for primary or adjunctive therapy of partial seizures. Its use is limited to those patients who fail other drug treatments because felbamate carries with it a substantial risk of aplastic anemia and liver failure that is not related to blood concentration. Biweekly monitoring of complete blood count, serum aminotransferases, and bilirubin is recommended to detect early onset of these side effects. Felbamate is particularly effective in control of Lennox-Gastaut syndrome.

Felbamate is completely absorbed from the gastrointestinal tract. The drug is 30% bound to plasma proteins, and optimal blood concentrations for felbamate, although poorly defined, has been suggested to range from 30 to 60 $\mu\text{g/mL}$ (126 to 252 $\mu\text{mol/L}$). It is eliminated by hepatic metabolism, with its half-life ranging from 14 to 21 hours. Felbamate saturates metabolism when the concentration exceeds 120 $\mu\text{g/mL}$ (504 $\mu\text{mol/L}$); at that concentration, metabolism converts from first order to zero order. There are currently no commercially available immunoassays for felbamate. High-performance liquid chromatography (HPLC) and capillary electrophoresis have been reported for felbamate analysis.

TABLE 30.1 Pharmacokinetic Parameters of Antiepileptic Drugs

Drug	RECOMMENDED THERAPEUTIC RANGE		Mean Time to Steady State (days)	Observed Range of Half-Life in Adults (h)	Mean Oral Bioavailability (%)	Protein Binding (%)	Important Metabolizing Enzymes
	µg/mL	µmol/L					
Carbamazepine	4–12	17–51	2–4	8–12	70	75	CYP3A4
Clonazepam	0.015–0.060	0.048–0.190	3–10	17–56	>90	85	CYP3A4
Ethosuximide	40–100	283–708	7–10	30–60	>90	0	CYP3A4
Felbamate	30–60	126–252	3–4	14–21	>90	25	CYP3A4
Gabapentin	2–12	12–70	1–2	5–9	Variable	0	NA
Lamotrigine	2.5–15	10–59	3–6	20–30	>90	55	NA
Levetiracetam	12–46	70–270	1–2	6–8	>90	0	NA
Phenobarbital	10–40	43–172	12–24	70–140	>90	50	CYP2C19
Phenytoin	10–20 (free: 1.0–2.0)	40–79	5–17	30–100	80	90	CYP2C9, 2C19
Primidone	5–10	23–46	2–4	3–22	>90	20	CYP2C9, 2C19
Topiramate	5–20	15–59	4–5	20–30	80	15	NA
Valproic acid	50–100	346–693	2–4	11–20	>90	90	CYP2C9, 2C19, 2B6, 2E1, 2A6
Zonisamide	10–40	47–188	9–12	50–70	65	50	CYP2C9, 3A4

Phenobarbital

Phenobarbital is used in the treatment of all seizures except absence seizures, and is known by a wide variety of proprietary names and found in combination with many other drugs. It is particularly useful for treatment of generalized tonic-clonic, partial, focal motor, temporal lobe, and febrile seizures.

Absorption of oral phenobarbital is slow but complete. The time at which peak plasma concentrations are reached is widely variable and ranges from 4 to 10 hours after the dose. Phenobarbital is 40% to 60% bound to plasma proteins. The elimination half-life is from 70 to 100 hours and is age dependent (children average 70 hours, geriatric patients 100 hours). Because hepatic metabolism is one of the prime routes of elimination, reduced liver function results in prolonged half-life.

The optimally effective therapeutic concentration of phenobarbital is between 15 and 40 µg/mL (66 to 177 µmol/L). The predominant side effect observed in adults at blood concentrations greater than 40 µg/mL (177 µmol/L) is sedation, although tolerance to this effect develops with chronic therapy.

Phenobarbital is metabolized in the liver to *p*-hydroxyphenobarbital, which is largely excreted as the glucuronide or sulfate ester. When renal and hepatic functions are decreased, patients experience decreased clearance of the drug. Elimination of phenobarbital may be decreased in the presence of valproic acid and salicylate if reduction in urinary pH occurs. During chronic administration of valproate or salicylate, the concentration of phenobarbital may increase 10% to 20%, and a dose adjustment may be necessary to avoid intoxication. Phenobarbital induces mixed-function oxidative enzymes, resulting in increased metabolism of other xenobiotics after approximately 1 to 2 weeks of therapy.

Because of the long elimination half-life of phenobarbital, the blood concentration does not change rapidly. Therefore, a serum specimen collected late in the dose interval (trough) is representative of the overall effect. Results from specimens collected 2 to 4 hours after the dose can be misleading, because they may be construed to be the peak concentration when in actuality they precede the peak. Table 30.1 summarizes pharmacokinetic data of anticonvulsant drugs.

Primidone

Primidone, proprietary name *Mysoline*, is effective in the treatment of tonic-clonic and partial seizures. The mechanism of action of this drug is similar to that described for phenobarbital, and the therapeutic effect is due partially to the accumulation of its major metabolite, phenobarbital. A second metabolite of primidone, phenylethylmalonamide, also has some antiepileptic activity.

Primidone is rapidly and completely absorbed after oral administration. Once absorbed, it is not highly protein bound and it has a half-life of approximately 10 hours. Disposition of the drug is not known to be significantly altered by other disease states or other drugs.

The optimal therapeutic concentration of primidone in adults has been established as 5 to 12 µg/mL (23 to 55 µmol/L). Because phenobarbital is an active metabolite of primidone, concurrent analysis of phenobarbital is required for complete result interpretation. The previously defined therapeutic range for phenobarbital applies to adequate primidone therapy. The phenobarbital concentrations rise gradually over a period of 1 to 2 weeks after therapy is initiated. Toxicity due to accumulation of primidone occurs at serum concentrations in excess of 15 µg/mL (69 µmol/L) and is usually associated with symptoms of sedation, nausea, vomiting, diplopia, dizziness,

TABLE 30.2 Pharmacokinetic Parameters of Commonly Monitored Antibiotics

Drug	Therapeutic Targets ^a (μg/mL [μmol/L])	Half-Life (h)	Oral Bioavailability (%)	Protein Binding (%)
Aminoglycosides				
Amikacin	C _{max} : 25–35 (43–60) C _{min} : 1–8 (1.7–13.7)	2 ^b	NA	<11
Gentamicin	C _{max} : 5–12 (10.5–25) C _{min} : <1 (<2)	2 ^b	NA	<30
Tobramycin	C _{max} : 5–12 (11–25.7) C _{min} : <1 (<2)	2 ^b	NA	<15
Glycopeptides				
Vancomycin	C _{min} : >10–15 (>6.9–10.4)	6–12 ^c	<1 ^d	10–50
Other				
Chloramphenicol	C _{max} : 10–25 (31–77) C _{min} : 1–8 (3–25)	Adults: 1.5–4.1 Newborn: ≥24 ^f	70–80 ^e	60

^aTarget blood concentrations depend upon the infection (e.g., tissue compartment), organism and its sensitivity to the antibiotic (i.e., minimal inhibitory concentration).

^bClearance of aminoglycoside antibiotics is dependent upon kidney function. The half-life shown is the average elimination phase half-life in healthy individuals; however, the half-life may be significantly prolonged in individuals with renal disease.

^cVancomycin best conforms to a multicompartment (2 or 3 compartment) pharmacokinetic model. The half-life shown represents the terminal, elimination half-life.

^dAbsorption of vancomycin from the gastrointestinal tract leading to toxic concentrations has been observed in individuals with pseudomembranous colitis.

^eBioavailability of chloramphenicol depends upon the chemical form (succinate or palmitate).

^fChloramphenicol clearance is reduced in neonates due to limited glucuronide conjugating activity of the liver. Half-life is generally >24 h immediately after birth and decreases to ~10 h by 2 weeks of age.

ataxia, and a phenobarbital concentration greater than 40 μg/mL (177 μmol/L). Specimen collection is dictated by the same rules that apply for phenobarbital; the trough concentration is most useful.

Coadministration of acetazolamide with primidone results in decreased gastrointestinal absorption of primidone and subsequent diminished plasma concentrations. Primidone administered in association with phenytoin produces a modest increase in the phenobarbital/primidone ratio because phenytoin competes with the hepatic hydroxylating enzymes associated with phenobarbital's metabolism. Coadministration of valproic acid, for the same reasons outlined for phenobarbital, causes a modest increase in both primidone and phenobarbital serum concentrations.

Zonisamide

Zonisamide is the generic name used in the United States for a widely used seizure medication whose common brand name is Zonegran. The FDA approved zonisamide for use in 2000 with the suggestion that it be used together with other anticonvulsants in the treatment of partial seizures in adults.

Orally administered zonisamide is generally well absorbed with little to no effect of concomitant food consumption, and this drug is only weakly bound to plasma proteins. Zonisamide is extensively metabolized by oxidative, acetylation, and other pathways and has essentially linear pharmacokinetics resulting in linearity for doses ranging from 10 to 15 mg/kg per day. Concomitantly administered inducing drugs such as phenytoin or carbamazepine cause increased metabolism-based clearance and therefore a need for dose adjustment that can

be aided by TDM of zonisamide. When concomitant therapy with an inducing drug is being withdrawn, adjustment of zonisamide dosing using TDM is warranted.

A target TDM range of 10 to 40 μg/mL (47 to 188 μmol/L) has been recommended, based largely on retrospective studies and, as with all other anticonvulsants, there is significant overlap of serum zonisamide concentrations between seizure-free patients and patients who do not respond to therapy with this drug, and between patients who encounter side effects and those who do not. Thus finding an optimal therapeutic concentration within the individual patient is an essential need, not simply titrating the patient to be within the target therapeutic range.

Antibiotics

Antibiotics that require TDM include aminoglycosides, chloramphenicol, sulfonamides, vancomycin, trimethoprim, β-lactams, and tetracyclines. Pharmacokinetic details of these antibiotics are summarized in Table 30.2.

Aminoglycosides

Aminoglycosides are polycationic agents that kill aerobic gram-negative bacteria. They act by binding to the 30S ribosomal subunit of bacterial mRNA, thereby inhibiting protein synthesis. They are inactive under anaerobic conditions because an oxygen-dependent active transport mechanism is involved in the transfer of aminoglycosides across the bacterial cell wall. The aminoglycoside class of drugs includes amikacin, gentamicin, kanamycin, neomycin, netilmicin, sisomicin, streptomycin, and tobramycin.

The aminoglycosides are a very polar group of compounds and are thus poorly absorbed from the intestinal tract. They are routinely administered intravenously or intramuscularly to achieve a high degree of bioavailability. When administered directly into the blood, they rapidly distribute to the extracellular fluid but do not cross cell membranes or bind to plasma proteins; this behavior is consistent with their unusually low volume of distribution. Most tissues and nonrenal or hepatic secretions contain very small concentrations of aminoglycosides, with the exception of the renal cortex, where the drug is concentrated, and bile, because of active hepatic secretion. The drugs are mainly excreted by glomerular filtration. Elimination half-lives are short, ranging from 2 to 3 hours. Because clearance is highly dependent on renal function, any impairment of glomerular filtration causes accumulation of these drugs.

Therapy with antibiotic agents like the aminoglycosides differs from the approach used for most other drugs discussed in this chapter. The goal is to achieve a concentration in plasma such that the bacteria are killed but the host remains undamaged. Because the organisms treated are variable and can become resistant to certain drugs, treatment with specific aminoglycoside agents should always be directed by susceptibility testing. Table 30.2 identifies target maximum peak and trough serum concentrations.

Dose corrections must be made in patients with compromised renal function because these patients have prolonged half-life and slower elimination. This should then be followed up by quantification of the blood concentration and dose adjustment following the method outlined by Gilbert.

Toxicity associated with aminoglycosides manifests as delayed-onset vestibular and cochlear sensory cell destruction and acute renal tubular necrosis. The degree and severity of cell damage are variable among the different drugs, but they all cause cell damage if the concentrations are high. Unfortunately, the therapeutic concentration guidelines identified in Table 30.2 do not guarantee the avoidance of toxicity; a small number of patients experience toxic effects regardless of the concentration. Fortunately, most patients reverse the toxic effects without direct intervention if the toxicity is associated with reasonable blood concentrations. Irreparable loss of vestibular, cochlear, or renal function usually correlates with administration of one of the aminoglycosides at increased blood concentrations for periods longer than 2 weeks.

Chloramphenicol

Chloramphenicol, proprietary name *Chloromycetin* and others, is used as a bactericidal agent. It acts by binding to the 50S ribosomal subunit of bacteria mRNA, and inhibits protein synthesis in prokaryotic organisms. Use of this drug depends on its relative toxicity against the microorganism versus the host. The drug is used against gram-negative bacteria such as *Hemophilus influenzae*, *Neisseria meningitidis*, *Neisseria gonorrhoeae*, *Salmonella typhi*, all *Brucella* species, *Bordetella pertussis*, *Vibrio cholerae*, and *Shigella*. These organisms are all susceptible to a concentration of 6 µg/mL (19 µmol/L).

Organisms that require higher concentrations of 12 µg/mL (37 µmol/L) are *Escherichia coli*, *Klebsiella pneumoniae*, *Pseudomonas pseudomallei*, *Chlamydia*, and *Mycoplasma*.

Chloramphenicol is rapidly absorbed in the gastrointestinal tract. Peak serum concentrations occur 1 to 2 hours after the oral dose. In plasma, chloramphenicol is approximately 50% protein bound and is cleared with a half-life of 2 to 3 hours. Peak serum concentrations of chloramphenicol palmitate or succinate occur 4 to 6 hours after administration. Chloramphenicol distributes to all tissues, and it concentrates in the cerebrospinal fluid. The drug is actively metabolized by the liver by *N*-acetylation and glucuronidation. Thus, chloramphenicol accumulates in cases of hepatic disease. Renal disease does not dramatically reduce clearance.

Host toxicity displayed after chloramphenicol therapy includes hematologic toxicity and cardiovascular collapse; both show a modest relationship to blood concentration. The blood concentration-related hematologic toxicities include anemia, characterized by maturation arrest in the marrow; cytoplasmic vacuolation of early erythroid and myeloid cells; reticulocytopenia; and increases in both serum iron and serum iron-binding capacity. These symptoms all are associated with serum concentrations in excess of 25 µg/mL (77 µmol/L). Development of idiosyncratic aplastic anemia has also been observed, but this complication appears unrelated to dose or blood concentration. Cardiovascular collapse, which occurs primarily in newborns, has been related to a total serum chloramphenicol concentration in excess of 40 µg/mL (155 µmol/L). An oral dose of 50 mg/kg per day results in an optimal peak serum concentration of 10 to 25 µg/mL (31 to 77 µmol/L) in a healthy adult.

Procedures for the determination of chloramphenicol concentrations in blood serum include HPLC and immunoassay. Methods for chloramphenicol determination must be able to differentiate between the prodrug forms, chloramphenicol palmitate or succinate, and their active metabolite, chloramphenicol.

Vancomycin

Vancomycin is a glycopeptide that is bactericidal against gram-positive bacteria and some gram-negative cocci. Vancomycin is used because of its activity against methicillin-resistant staphylococci and corynebacteria. It has thus become popular for treatment of endocarditis and sepsis caused by these organisms.

Although the drug is generally poorly absorbed when given orally, absorption leading to toxicity has been observed in patients with pseudomembranous colitis. A 1-g dose given intravenously every 12 hours usually results in a peak blood concentration of 20 to 40 µg/mL (14 to 28 µmol/L) and a trough concentration of 5 to 10 µg/mL (4 to 7 µmol/L). It has an average elimination half-life of 5 to 6 hours. Blood concentration-related toxicity involves the auditory nerve. Concentrations less than 30 µg/mL (21 µmol/L) are rarely associated with this development. Toxicities not related to dose or blood concentrations include fever, phlebitis, and pain at the infusion site. Erythema or flushing of the face, neck,

and upper torso occurring within approximately 5 to 10 minutes following vancomycin infusion (sometimes referred to as “red man syndrome” or “red neck syndrome”) has also been observed. This syndrome is due to acute, non-IgE-mediated mast cell degranulation, and is generally controlled by slow infusion and administration of antihistamines. In patients with impaired renal function, the serum concentration may increase to toxic concentrations because of reduced clearance.

Antifungal Antibiotics

Over the past decade, increasing evidence has accumulated to support the use of TDM to enhance the therapeutic safety and efficacy of antifungal medicines. The azole class of antifungals has the most data supporting concentration monitoring. There is also limited data supporting the monitoring of flucytosine. Studies of TDM for other classes of antifungal medicines including the echinocandins (i.e., caspofungin) and the polyenes (e.g., Amphotericin B) have generated data showing no or limited value to monitoring these drugs.

HPLC and liquid chromatography–tandem mass spectrometry (LC-MS) methods for detection of multiple azoles have been described, and represent the predominant methods used for clinical testing by reference laboratories. Although these methods are generally highly specific, it should not be assumed that results are transferrable across laboratories. A recent review of proficiency testing data that evaluated 5 years of data from 57 different laboratories around the world demonstrated that a wide variation in results, especially at low concentrations, is common leading to results that can deviate by more than 20%. New immunoassays for voriconazole and posaconazole have been described, but experience with these is limited. The availability of reliable immunoassays for these antifungals could foster more widespread experience in the effectiveness of their monitoring. Metabolism of the drugs can also affect interpretation of concentration data as discussed in more detail later.

Antineoplastic Agents

Methotrexate

Methotrexate has proved useful in (1) the management of acute lymphoblastic leukemia in children; (2) choriocarcinoma and related trophoblastic tumors in women; (3) carcinomas of the breast, tongue, pharynx, and testes; (4) maintenance of remission in leukemia; and (5) treatment of severe, debilitating psoriasis. High-dose methotrexate administration followed by leucovorin rescue is effective in treatment of carcinoma of the lung and osteogenic sarcoma. Intrathecal administration is effective in treating meningeal leukemia or lymphoma.

Methotrexate inhibits DNA synthesis by decreasing availability of pyrimidine nucleotides. Methotrexate competitively inhibits the enzyme dihydrofolate reductase, thus decreasing the concentrations of the tetrahydrofolate essential to the methylation of the pyrimidine nucleotides and consequently the rate of pyrimidine nucleotide synthesis. Leucovorin, a folate analog, is used to rescue host cells from methotrexate inhibition; as a synthetic substrate for dihydrofolate reductase,

leucovorin administration allows resumption of tetrahydrofolate-dependent synthesis of pyrimidines and reinitiation of DNA synthesis. Methotrexate is a nonspecific cytotoxin, and prolongation of blood concentrations appropriate to killing tumor cells may lead to severe, unwanted cytotoxic effects such as myelosuppression, gastrointestinal mucositis, and hepatic cirrhosis.

Serum concentrations of methotrexate are commonly monitored during high-dose therapy (>50 mg/m²) to identify the time at which active intervention by leucovorin rescue should be initiated. Criteria for blood concentrations indicative of a potential for toxicity after single-bolus high-dose therapy are as follows:

1. Methotrexate concentration greater than 10 μ mol/L 24 hours after dose
2. Methotrexate concentration greater than 1 μ mol/L 48 hours after dose
3. Methotrexate concentration greater than 0.1 μ mol/L 72 hours after dose

Characteristically, blood concentrations are monitored at 24, 48, and 72 hours after the single dose, and leucovorin is administered when methotrexate concentrations are inappropriately high for a postdose phase. The route of elimination for methotrexate is primarily renal excretion. During the period of high blood concentrations, particular attention must be paid to maintaining output of a large volume of alkaline urine. The pK_a of methotrexate is 5.5; thus small decreases in urine pH result in significant reduction in its solubility. Keeping urinary pH alkaline diminishes the risks of intratubular precipitation of the drug and obstructive nephropathy during the treatment period. Monitoring blood concentrations therefore provides the basis for decisions for timing of initiation and continuance of leucovorin treatment and for managing urinary pH.

Methotrexate has been measured in biological specimens using a wide variety of techniques. Radioimmunoassay (RIA) and the folate reductase inhibition techniques have been used, but nonisotopic immunoassays are now the method of choice. Liquid chromatographic procedures have also been developed to allow for coanalysis of the drug and its metabolites.

Busulfan

Busulfan is a DNA alkylating agent available in both oral and intravenous formulations. High-dose busulfan is often used as part of the myeloablative preparative regimen for hematopoietic stem cell transplantation (HSCT). Clinical use of busulfan is complicated by significant interpatient variability in pharmacokinetic behavior with reported coefficients of variation of 23% and 25% for the oral and intravenous (IV) formulations, respectively. Age, obesity, underlying disease, and organ dysfunction also exert a significant influence on observed clearance for busulfan. Children younger than 6 typically display more than twice the average clearance of 2.5 mL/min per kilogram reported for adults. The observed variability in the pharmacokinetic behavior of busulfan is relevant because several studies have identified a pharmacodynamic relationship

between exposure to busulfan and both its toxicity and efficacy. Exposure to busulfan is typically estimated by measurement of several plasma concentrations over a 6-hour dose interval. This exposure is generally expressed as either the area under the concentration-time curve (referred to as the AUC) or the mean steady-state concentration ($\bar{C}_{SS}$). Dosing of busulfan is usually every 6 hours or once daily over 4 days for a total of 16 or 4 doses, respectively. As a result, a study is typically performed following the first dose, and the results are promptly reported to effect a dose adjustment as early as possible in the course of the treatment regimen; however, the completion and reporting of a busulfan pharmacokinetic study is not a simple task. A variety of chromatographic methods are used for measurement of busulfan in plasma with gas chromatography-mass spectrometry (GC-MS) and LC-MS/MS generally the preferred methods. Given the complexity of the analytical methodology, onsite testing is not always available. Sample extraction and analysis also usually require several hours to complete for a single patient. Nevertheless, using the above TDM approach with dose adjustment, exposures that are within less than 10% of the target exposure are possible, and toxicity can be avoided without a compromise in efficacy.

Immunosuppressive Drugs

Tacrolimus

Tacrolimus, proprietary name *Prograf* and formerly called FK506, is a macrolide antibiotic isolated from a strain of *Streptomyces tsukubaensis* that has significant **immunosuppressant** properties. Tacrolimus mediates its immunosuppressive action by entering the lymphocyte, and binding to a receptor known as FK506-binding protein (FKBP). Once bound to FKBP, this drug-receptor complex interacts with, and blocks, the calcium-dependent phosphatase, calcineurin, which is critical for the translocation of the nuclear factor of activated T cells (NFAT) to the nucleus, where the latter regulates the transcription of cytokines and other genes important for T cell activation, proliferation, and function. Calcineurin inhibition therefore leads to marked suppression of T cell-mediated immune responses such as those involved in solid organ transplant rejection and graft-versus-host disease following bone marrow transplantation. NFAT plays a role in other cell types, likely contributing to the toxic effects of tacrolimus.

Tacrolimus is administered predominantly orally in capsule form (*Prograf*) containing 0.5 mg, 1 mg or 5 mg of the drug. A sterile solution containing the equivalent of 1 mg/mL of tacrolimus for intravenous administration and an ointment containing 0.1% or 0.03% for topical use on skin are also available. Rapid but incomplete absorption are characteristic of standard oral tacrolimus formulations, with an average time to peak concentration of 1.6 to 2.3 hours and average oral bioavailability of 17% to 22%. Recently, several prolonged release formulations of tacrolimus have been developed with the first, *Advagraf*, now available commercially. Extended release formulations afford delayed maximal concentrations with improved bioavailability leading to a slight reduction in dose to achieve equivalent AUC.

There is a fairly good correlation between tacrolimus trough concentration, graft rejection, and toxicity. The target range for tacrolimus blood concentrations depends upon the concomitant use of other ISDs, the transplant type, and the time following transplantation. An example of the immunosuppressive regimens used at the authors' institution with the associated tacrolimus target ranges are shown in [Table 30.3](#).

The steady-state trough concentration of tacrolimus per unit of dose varies widely within and between patients. The between-subject variability of dose-normalized tacrolimus has been estimated to be fivefold. Factors known to contribute to this variability are many and include hematocrit; plasma albumin concentration; patient age; genotypes of metabolizing enzyme CYP3A5; drug-drug, herb-drug, and food-drug interactions; and disease. The influence of one or more of these factors in transplant patients explains the wide within- and between-subject variability of tacrolimus concentrations. This, taken together with the narrow TI and the requirement of contemporary practice to lower the tacrolimus dosing and target trough concentration during the first transplant year and beyond to limit nephrotoxicity, is the basis for the need for close concentration monitoring of this drug.

Due to the high binding of tacrolimus to FK506 binding proteins within cells including erythrocytes, the plasma concentration of tacrolimus is typically 1.5% to 8% of whole blood. Methods for quantitative analysis of this drug therefore generally begin with cell lysis and protein precipitation of whole blood to liberate cell-bound tacrolimus to allow measurement of the total drug present within whole blood. The lysis step is most commonly performed as a manual step using a water-miscible solvent (e.g., methanol) solution containing ZnSO_4 followed by centrifugation. Performance of this initial step is one of the critical points in tacrolimus analysis, and it represents an important source of potential error if not performed correctly or consistently.

Interferences in the measurement of tacrolimus include metabolites of the drug and other substances present in human blood such as antibodies that react with components of the assay (for additional discussion on interference in immunoassay, refer to [Chapter 15](#)). The former represents the more frequent and challenging interfering substance as discussed previously in the section on Analytic Factors affecting testing results.

Cyclosporine

Cyclosporine, proprietary names *Sandimmune* (Cyclosporine A, or CsA) and *Neoral*, is a cyclic peptide composed of 11 amino acids, some of novel structure, isolated from the fungus *Trichoderma polysporum*. The compound has been shown to be effective in suppressing solid organ allograft rejection and graft-versus-host disease following bone marrow transplantation. CsA is approved for use in renal, cardiac, hepatic, pancreatic, and bone marrow transplants.

CsA acts by a mechanism that is very similar to tacrolimus. Following entry into the cell, CsA forms a complex with cytoplasmic receptors termed cyclophilins that are molecularly distinct from FKBP. These cyclosporine-cyclophilin

TABLE 30.3 Immunosuppressive Regimens and Associated Tacrolimus Target Ranges Used at the Author's Institution

Organ	Immunosuppressive Regimen	Time Posttransplant	TACROLIMUS THERAPEUTIC RANGE	
			µg/L	nmol/L
Kidney	Tacrolimus + MMF	0–1 months	8–12	10.4–15.6
		2–3 months	7–10	9.1–13
		4–6 months	6–8	7.8–10.4
		7–12 months	5–7 (6–8 for higher risk)	6.5–9.1 (7.8–10.4 for higher risk)
		>12 months	4–6 (5–7 for higher risk)	5.2–7.8 (6.5–9.1 for higher risk)
Heart	Tacrolimus + MMF	0–3 months	10–12	13–15.6
		4–6 months	10	13
		6–12 months	8–10	10.4–13
		>12 months	5–8	6.5–10.4
Liver	Tacrolimus + steroids +/- Azathioprine or MMF	0–3 weeks	8–12 (6–8 with renal insufficiency)	10.4–15.6 (7.8–10.4 with renal insufficiency)
		4–6 weeks	6–10 (6–8 with renal insufficiency)	7.8–13 (7.8–10.4 with renal insufficiency)
		7 weeks–9 months	6–10 (6–8 with renal insufficiency)	7.8–13 (7.8–10.4 with renal insufficiency)
		10 months–2 years	5–8	6.5–10.4
		>3 years	4–6 (6 for AIH; 3–4 with renal insufficiency if also on an anti-proliferative agent)	5.2–7.8 (7.8 for AIH; 3.9–5.2 with renal insufficiency if also on an anti-proliferative agent)
			3–4 (6 for AIH)	3.9–5.2 (7.8 for AIH)
Lung	Tacrolimus + MMF + Steroids	0–12 months	8–12	10.4–15.6
		>12 months	6–8	7.8–10.4
Bone marrow	Tacrolimus		5–15	6.5–19.5

MMF, Mycophenolate mofetil.

molecular complexes interact with and inhibit the calcineurin phosphatase preventing NFAT activation that is critical for lymphocyte proliferation and function.

Absorption of CsA in the form of *Sandimmune* is highly variable, ranging from 5% to 40%. There is a poor relationship between dose and blood concentration; however, the whole-blood concentration of CsA correlates with the degree of immunosuppression and toxicity. A microemulsion form of CsA, *Neoral*, has more reproducible absorption, averaging 40%, and exhibits better correlation among dose, blood concentration, and clinical response.

Immunosuppression requires trough whole-blood concentrations of at least 100 ng/mL (83 nmol/L). Kahan and colleagues found that trough whole-blood concentrations exceeding 600 ng/mL (499 nmol/L) were associated with hepatic, renal, neurological, and infective complications. Shaw and colleagues have discussed strategies for reducing the toxicity of CsA and other ISDs.

Therapeutic trough blood concentrations of CsA for renal transplants are 100 to 300 ng/mL (83 to 250 nmol/L), whereas 200 to 350 ng/mL (166 to 291 nmol/L) is used as the target concentration for cardiac, hepatic, and pancreatic transplants; however, concomitant immunosuppression used in combination therapy, similar to combined drug therapy in other situations such as AED therapy in epilepsy, significantly affects the range of concentrations that are effective.

Simultaneous immunosuppression with low-dose prednisone and either azathioprine (AZA) or mycophenolate mofetil (MMF) allows the patient to enjoy a good response to CsA at lower concentrations—some renal transplant patients obtain a satisfactory response with trough CsA concentrations of 70 ng/mL (58 nmol/L).

CsA is slowly absorbed, and peak concentrations are reached in 4 to 6 hours. Like tacrolimus, CsA is also highly (~90%) protein bound and concentrated in erythrocytes. The degree of concentration in erythrocytes is temperature dependent in vitro; thus measurement of plasma concentration requires strict attention to specimen temperature if reproducible results are to be obtained. Because of this effect, the best specimen for analysis is whole blood. CsA is also heavily metabolized, and immunoassays are generally subject to metabolite interference similar to the effects described for tacrolimus.

Several drugs alter the disposition of CsA. Ketoconazole, erythromycin, melphalan, amphotericin B, and aminoglycoside antibiotics all prolong metabolism of CsA sufficiently to increase the risk of nephrotoxicity. Coadministration of phenytoin, phenobarbital, carbamazepine, and rifampin results in induction of cytochrome P₄₅₀ enzymes, which increase the rate at which CsA is metabolized. Intravenous administration of sulfadimidine and trimethoprim decreases CsA concentrations.

Currently, nonisotopic immunoassays performed on whole blood are the most commonly employed methods for

measurement of CsA; however, many laboratories use HPLC and LC-MS/MS methods, which are more specific and less subject to metabolite interference. It is therefore important to ensure consistency with TDM by following individuals with the same method over time and to interpret results within the context of the method used.

Sirolimus

Sirolimus, also known as rapamycin, is a macrocyclic antibiotic that is a fermentation product of the actinomycete *Streptomyces hygroscopicus* that was isolated from soil samples collected on Rapa Nui (Easter Island) following a search for novel antifungal agents. Structurally, sirolimus is a lipophilic macrocyclic lactone comprised of a 31-member macrolide ring. It demonstrates antifungal, antitumor, and immunosuppressive activity in animal model studies, and is approved in the United States for the prophylaxis of acute rejection in renal transplant patients.

The complex of sirolimus and the intracellular **immunophilin**, FKBP12, modulates the immune response by combining with the specific cell-cycle regulatory protein called mTOR (the mammalian target of rapamycin) and inhibiting its activation. This inhibition results in suppression of cytokine-driven T-lymphocyte proliferation, inhibiting the progression from the G₁ to the S phase of the cell cycle.

The metabolism of sirolimus by the human body is driven by oxidative metabolism via CYP3A in the gastrointestinal tract and liver. There are at least seven metabolites characterized as 41-O- and 7-O-demethyl, several hydroxy, hydroxy-demethylated, and didemethylated sirolimus. Total sirolimus metabolites accounted for 48% to 70%, and no single metabolite accounted for more than 10% of sirolimus in trough whole blood from stable renal transplant patients; however, the immunosuppressive activity of individual metabolites is reported to be lower than the parent drug.

Sirolimus is available as both an oral solution and tablet. Sirolimus is rapidly absorbed from the gastrointestinal tract with the average time to reach maximal concentration in whole blood of about 2 hours. The average bioavailability of sirolimus is low, at 15%, and attributable to extensive intestinal and hepatic metabolism by CYP3A and to counter-transport by the multidrug efflux pump P-glycoprotein in the gastrointestinal tract. This absorption barrier varies considerably within a single patient and from patient to patient. It is also the site of clinically important drug-drug and drug-food interactions.

Sirolimus distributes extensively into blood cells as reflected by the average blood-to-plasma ratio of 36:1 in renal transplant patients. Approximately 95% distributes into red blood cells, 3% in plasma, and 1% each in lymphocytes and granulocytes. The extensive and avid binding of sirolimus to the ubiquitously distributed intracellular FKBP12 accounts for the high blood-to-plasma sirolimus concentration ratio. Approximately 2.5% of the sirolimus within the plasma fraction is unbound with the remainder bound to plasma proteins.

The relationship between sirolimus whole-blood trough concentrations and efficacy and toxicity has been investigated

in renal transplant patients who received concomitant full-dose CsA and corticosteroid therapy. According to these analyses, the minimum effective sirolimus concentration below which there is a significant increase in risk for acute rejection is 4 to 5 µg/L (4.4 to 5.5 nmol/L). The threshold concentration of 13 to 15 µg/L (14 to 16 nmol/L) was identified, above which the risks increase for the concentration-related side effects, thrombocytopenia (<100,000 platelets/mm³), leukopenia (<4000 leukocytes/mm³), and hypertriglyceridemia (>300 mg/dL or 3.4 mmol/L serum triglycerides). More studies are needed to define these relationships for other transplant populations and for different concomitant immunosuppressants.

Several chromatographic (i.e., LC-MS, LC-MS/MS, HPLC) detection methods have been validated and are in use in laboratories worldwide. A commercial, automated immunoassay has also been developed. This latter assay, while showing high precision, exhibits modest bias due to metabolite interference (~25%) when results are compared to chromatographic methods.

Everolimus

In April 2010, everolimus, a more water-soluble analog of sirolimus, was approved for use in CsA-sparing regimens including the requirement for adjusting everolimus doses using target trough blood concentrations in renal transplant patients. The target ranges were established from earlier retrospective studies and used prospectively to demonstrate equivalent acute rejection rates compared to the combination of standard dose CsA and empiric dose MMF. More recently, the use of everolimus has expanded with approval in liver transplantation in combination with low-dose tacrolimus.

The mechanism of action and pharmacodynamic effects of everolimus are comparable to those for sirolimus. Similar to the other immunosuppressive drugs, wide pharmacokinetic variability of everolimus has been observed. This variability is driven by the variable metabolism via CYP3A4/5 and p-glycoprotein along with frequent drug-drug interactions that are comparable to those observed for sirolimus. Everolimus trough concentrations show a significant, linear correlation with overall drug exposure as assessed by AUC with a coefficient (r^2) of 0.79. Similar degrees of correlation between everolimus trough concentration and thrombocytopenia, leucopenia, hypertriglyceridemia, or hypercholesterolemia have been observed in an investigation of 54 stable renal transplant patients (18 to 68 years). Based upon the robust correlation between trough concentration and both efficacy and toxicity, a trough concentration of 3 to 8 ng/mL (3.1 to 8.3 nmol/L) has been suggested as the optimal target range.

The bioanalytical method used for measurement of everolimus concentration in the pharmacokinetic assessments and prospective TDM protocols of many clinical investigations is a validated LC-MS/MS method. Use of this bioanalytical methodology provides sensitive and selective measurement of everolimus, which is important for reliable measurement of blood concentrations at the low end of the recommended target concentration range (3 ng/mL [3.1 nmol/L]) in currently utilized immunosuppression protocols. In the future, we can

anticipate the availability of immunoassays for everolimus, and it will be essential to understand the comparison between these methods and the current chromatographic methods.

Mycophenolic Acid

Mycophenolic acid (MPA) is a product of the *Penicillium* species that exhibits antitumor, antiviral, antifungal, antibacterial, and immunosuppressive activity. MPA is administered as its morpholinoethyl ester, MMF. MMF, also known as RS-61433, is considered a prodrug because its immunosuppressive activity is expressed only after its hydrolysis to MPA in the body. MPA inhibits inosine monophosphate dehydrogenase, an important enzyme in the purine metabolic pathway. T lymphocytes rely on this pathway for purine synthesis, whereas other cells use the hypoxanthine-guanosine ribosyl transferase salvage pathway for purine biosynthesis. Thus MPA selectively inhibits purine synthesis, and thus transcription, in T lymphocytes. MPA is of interest clinically because it has immunosuppressive activity similar to the thiopurine, AZA, but without many of its side effects.

MMF is completely absorbed and rapidly and completely metabolized to MPA, the active metabolite. The latter is metabolized in the liver by phase II enzymes to form the major metabolite, mycophenolic acid glucuronide (MPAG). The elimination half-life of MPA averages 18 hours, the volume of distribution averages 4 L/kg, and typical serum concentrations range from a peak of 12 µg/mL (37.4 µmol/L) to a trough value of 2 µg/mL (6.24 µmol/L). Based on the available studies, the optimal immunosuppression for MPA appears to be achieved with target AUCs in the 30 to 60 mmol*min/mL range. Although poorly correlated, this is approximated by trough serum concentrations in the range of 2 to 4 µg/mL (6.24 to 12.5 µmol/L).

Other Drugs

Digoxin

Digoxin, proprietary name *Lanoxin*, is one of a group of cardiac glycosides obtained from digitalis plants (e.g., *Digitalis lanata*). Although used substantially less frequently than in the past due to newer drugs, digoxin is still used for treatment of supraventricular arrhythmias such as atrial fibrillation due to its activity on atrioventricular nodal conduction. Digoxin also acts as an inotropic agent that restores the force of cardiac contraction in congestive heart failure. However, its use has decreased substantially. The drug binds to the extracytoplasmic side of the α -subunit of membrane-bound Na, K-ATPase, inhibiting both cellular Na⁺ efflux, and K⁺ influx in myocardial cells. This reduces the sodium/potassium gradient in the Purkinje fibers of the atrial, junctional, and ventricular myocardium, resulting in a decreased transmembrane potential. Inhibition of Na, K-ATPase is postulated to enhance movement of calcium ions in the cell, increasing calcium ion availability and improving cardiac contractility. In addition to direct effects on the excitable tissues within the heart through the Na, K-ATPase, digoxin has also been shown to alter autonomic activity within the heart to promote

parasympathetic activity, which may further contribute to its mechanism of action.

At low concentrations, digoxin causes the atrium to be less electrically excitable. Moderate concentrations of digoxin are required to reduce the rate of depolarization in the spontaneously depolarizing conductive fibers (Purkinje fibers), and toxic concentrations of digoxin are necessary to diminish depolarization of the ventricular myocardium. Disagreement over the clinical value of digoxin measurements and the failure of the digoxin concentration to correlate with clinical toxicity are usually related to aberrations in serum and tissue concentrations of sodium, potassium, magnesium, and calcium. Increased sensitivity to digoxin can be noted in states of hypokalemia, hypomagnesemia, and hypercalcemia, which make establishment of the true therapeutic concentration of digoxin difficult because all parameters are interactive.

Absorption of digoxin is variable and dependent on the drug formulation. Digoxin is concentrated in tissues, and at steady state, the concentration of digoxin in cardiac tissue is 15 to 30 times that of plasma. Accumulation of digoxin in tissue lags behind the plasma concentration—that is, although the peak plasma concentration is reached 2 to 3 hours after the oral dose, the peak tissue concentration occurs 6 to 10 hours after an oral dose. Although pharmacological effects and toxicity correlate with tissue concentration rather than plasma concentration, the safe therapeutic plasma concentration of digoxin has been reported to range from 0.8 to 2.0 ng/mL (1 to 2.6 nmol/L). This range is not determined at the peak plasma concentration but rather at the time of peak tissue concentration. Thus, to ensure a correlation between plasma concentration and tissue concentration, the appropriate time to collect the specimen is 8 hours or more after the dose, at which time serum digoxin has reached distributional equilibrium with the drug in tissues. Results from specimens collected earlier than 8 hours after the dose are misleading because high concentrations may be misinterpreted as toxic concentrations, whereas they are more likely due to incomplete distribution.

Digoxin toxicity is characterized by nonspecific symptoms of nausea, vomiting, anorexia, and predominance of green/yellow visual distortion. Cardiac symptoms of intoxication include multiform premature ventricular contractions, ventricular bigeminy, ventricular tachycardia, and ventricular fibrillation. Children can tolerate higher concentrations and do not usually exhibit toxicity until the digoxin concentration exceeds 4 ng/mL (5.2 nmol/L).

Elimination of digoxin follows first-order kinetics; 50% to 70% is excreted unchanged or in the form of digoxigenin monosaccharides or disaccharides in the urine. A small amount is metabolized to dihydrodigoxin and also excreted by the kidneys. The remainder is found in the stool as digoxigenin and its saccharides.

Currently, immunoassays remain the most widely used method for measurement of digoxin in serum and biological fluids. Use of Digibind or DigiFab digoxin-specific Fab fragments, which neutralize the drug and are used in the setting of acute toxicity, can complicate digoxin measurement

by many immunoassays. Results of digoxin monitoring following administration of Digibind should therefore be interpreted with caution.

Lithium

Lithium, whose proprietary names include *Eskalith*, *Lithane*, *Lithonate*, and others, is administered as lithium carbonate and used for the treatment of the manic phase of affective disorders, mania, and manic-depressive illness. The mechanism of action for lithium is not entirely clear. Early research suggested that it acts by enhancing re-uptake of catecholamines, thereby reducing their concentration in the neuronal junction and producing a sedating effect on the central nervous system. More recently, lithium and other mood-affecting drugs such as valproic acid, carbamazepine, and the tricyclic antidepressants, have been shown to inhibit GSK3- β , a protein central to the Wnt/ β -catenin signaling pathway that affects gene expression involved in many aspects of cellular behavior, neuronal polarity, plasticity and survival, and brain development. GSK3- β appears critical in the action of dopamine and serotonin on the brain affecting behavior. At least two mechanisms account for lithium's effects on GSK3- β . Lithium directly competes with magnesium, which is an important cation for GSK3- β activity. It also indirectly affects GSK3- β by inhibiting a critical phosphatase normally required for its activation. Although other mechanisms of action cannot be excluded, the mechanisms described above are likely to account for many of lithium's effects on mood.

Absorption of lithium from the gastrointestinal tract is complete, with peak plasma concentration reached 2 to 4 hours after an oral dose. This cation does not bind to protein. Lithium elimination is biphasic; during the first phase, 30% to 40% of the dose of lithium is cleared, with an apparent half-life of 24 hours. During the second phase, the remainder of lithium incorporated into the cellular ion pool is cleared, exhibiting a half-life of 48 to 72 hours. Clearance is predominantly a function of the kidneys, where active reabsorption occurs. Reduced renal function causes prolonged clearance times.

The optimal therapeutic response to lithium has not been related to a specific serum concentration; however, toxicity is related to serum concentration. Serum lithium concentrations are monitored to ensure patient compliance and to avoid intoxication. It is recommended that a standardized 12-hour postdose serum lithium concentration be used to assess adequate therapy. The interval of 0.5 to 1.2 mmol/L was identified as the optimal trough therapeutic concentration. Concentrations of 1.2 to 1.5 mmol/L signify a warning range, and a concentration in excess of 1.5 mmol/L *in a specimen drawn 12 hours after the dose* indicates a significant risk of intoxication. Early symptoms of intoxication include apathy, sluggishness, drowsiness, lethargy, speech difficulties, irregular tremors, myoclonic twitching, muscle weakness, and ataxia. These symptoms, although not life threatening, are uncomfortable for patients and indicate that the onset of life-threatening seizures is imminent.

Lithium excretion parallels that of sodium. It readily passes the glomerular membrane and is reabsorbed in the proximal

convoluted tubules. In situations in which patients are vulnerable to dehydration (fever, watery stools, vomiting, loss of appetite, hot weather), the potential for lithium intoxication is increased. In dehydration, the proximal tubular response to reabsorption of sodium (and lithium) is reduction of clearance. Increased reabsorption of lithium leads to increased blood concentration of lithium. Severe intoxication, characterized by muscle rigidity, hyperactive deep tendon reflexes, and epileptic seizures, is usually associated with lithium concentrations in excess of 2.5 mmol/L.

The concentration of lithium in serum, plasma, urine, or other body fluids can be determined by several methods including flame emission photometry, atomic absorption spectrometry, ion-selective electrode or inductively coupled plasma-mass spectrometry (ICP-MS) or inductively coupled plasma-optical emission spectrometry (ICP-OES). In contemporary clinical practice, automated methods are primarily used for routine measurement of lithium in serum using a chromophore (e.g., a substituted porphyrin) that forms a colored product readily detected spectrophotometrically upon binding to lithium. The availability from NIST of a standard reference material (NIST SRM 3129a) provides manufacturers with the opportunity to prepare traceable calibrators and improve standardization of assays.

Theophylline

Theophylline, available under many proprietary names, relaxes bronchial smooth muscles to relieve or prevent asthma. The therapeutic effect of theophylline is likely due to antagonism of adenosine receptors in smooth muscle, whereas the toxic effects are due to inhibition of cyclic nucleotide phosphodiesterase. With increased use of β -adrenergic agonists, and because of the considerable toxicity associated with it, theophylline is now considered a second-level approach used only in treatment of persistent asthma.

Theophylline is readily absorbed after oral, rectal, or parenteral administration. If the drug is taken orally without food, the blood concentration peaks within 2 hours. If it is administered with food or as a slow-release formula, peak concentrations occur 3 to 5 hours after the dose. Once absorbed, it is 50% protein bound. The drug is rapidly cleared in adolescents and in adults who smoke due to its higher rate of metabolism due to increased levels of CYP1A2. In these individuals, the half-life ranges from 3 to 4 hours. Nonsmoking adults in good health have an elimination half-life of about 9 hours. The half-life in neonates and in adults with congestive heart failure can be prolonged to 20 to 30 hours, depending on the degree of liver immaturity or loss of liver function. Coadministration of cimetidine, ciprofloxacin, and ticlopidine leads to reduced clearance of theophylline.

There is a proportional relationship between forced expiratory volume and theophylline concentration, with the optimum therapeutic effect occurring at concentrations ranging from 8 to 20 $\mu\text{g/mL}$ (44 to 111 $\mu\text{mol/L}$). Suppression of exercise-induced bronchospasm in asthmatic patients occurs at concentrations exceeding 10 $\mu\text{g/mL}$ (56 $\mu\text{mol/L}$) and is optimal at 15 $\mu\text{g/mL}$ (83 $\mu\text{mol/L}$). Neonatal apnea treated with theophylline

responds to slightly lower concentrations, ranging from 5 to 10 $\mu\text{g/mL}$ (28 to 56 $\mu\text{mol/L}$). Relaxation of bronchial smooth muscle is directly proportional to blood concentration and continues at concentrations greater than 20 $\mu\text{g/mL}$ (111 $\mu\text{mol/L}$). When the blood level exceeds 20 $\mu\text{g/mL}$ (111 $\mu\text{mol/L}$), the secondary side effects become significant.

Theophylline typically exhibits first-order kinetics of elimination when used in most patients with serum concentrations in the range of 5 to 15 $\mu\text{g/mL}$ (28 to 83 $\mu\text{mol/L}$); however, at serum concentrations greater than 20 $\mu\text{g/mL}$ (111 $\mu\text{mol/L}$), theophylline exhibits zero-order pharmacokinetics with small dose increases leading to disproportionately large increases in serum concentration and intoxication. Symptoms of theophylline toxicity include nausea, vomiting, headache, diarrhea, irritability, and insomnia. Transient central nervous system stimulation occurring at initial administration is not directly related to blood concentration. This effect diminishes with chronic use. Serious toxicity

characterized by cardiac arrhythmias and seizures is usually associated with serum concentrations in excess of 30 $\mu\text{g/mL}$ (167 $\mu\text{mol/L}$). Once seizure activity begins, the final prognosis is very poor. Morbidity is reported in nearly all patients, and mortality can be as high as 50%.

Caffeine

A minor metabolite of theophylline in adults, caffeine has been shown to accumulate to significant concentrations in neonates. Caffeine itself is an effective inhibitor of apnea, which may explain the lower therapeutic concentration required for control of neonatal apnea. Therapy with caffeine alone has also been demonstrated as effective in the treatment of neonatal apnea; it is gaining popularity because of caffeine's long half-life in neonates (>30 hours). The optimal therapeutic concentration of caffeine in this situation ranges from 8 to 14 $\mu\text{g/mL}$ (41 to 72 $\mu\text{mol/L}$). Caffeine can be measured by HPLC or immunoassay.

REVIEW QUESTIONS

1. Pharmacokinetics refers to the branch of pharmacology that deals with:
 - a. the time-dependent processes of absorption, distribution, metabolism, and the excretion of drugs and their metabolites from the body.
 - b. the relationship between a drug's concentration and its effects on its target receptor.
 - c. the toxic effects of a drug.
 - d. the distribution of drugs to patients.
 - e. the study of time-dependent effects of a drug on the body.
2. Which of the following statements are true regarding phenytoin?
 - a. Phenytoin exhibits zero-order kinetics with saturation of metabolism at conventional doses.
 - b. Phenytoin binds tightly to red blood cells and requires whole blood testing.
 - c. Phenytoin steady-state concentration is linearly proportion to the dose in most patients.
 - d. Phenytoin is excreted mostly unchanged in the urine.
 - e. Phenytoin concentration monitoring is best performed using collection of blood in a serum separator tube.
3. Which of the following best describes drug therapy with aminoglycosides?
 - a. The risk for ototoxicity with gentamicin is best correlated with serum trough concentration.
 - b. The risk of nephrotoxicity induced by amikacin is best correlated with peak drug concentration.
 - c. Aminoglycoside dosing should be adjusted for patients with renal insufficiency.
 - d. Aminoglycoside dosing should be adjusted for patients with liver dysfunction.
 - e. Once daily (extended interval) dosing of aminoglycoside antibiotics is frequently used in patients with end-stage renal failure.
4. Which of the following statements regarding therapeutic range are TRUE?
 - a. A therapeutic range is the range of drug concentrations in which patients will respond to therapy.
 - b. A therapeutic range is the range of drug concentrations in which the probability of efficacy is maximized and the probability of toxicity is minimized.
 - c. The concentration of a drug should not exceed its therapeutic range because patients will develop toxicity.
 - d. Therapeutic ranges are always validated in randomized prospective trials of therapeutic drug monitoring.
 - e. The therapeutic range of a drug is unaffected by other drugs used in combination and can therefore be applied to all situations in which a drug is used.
5. Which of the following best describes digoxin use and monitoring?
 - a. The time of blood collection for digoxin does not affect interpretation of digoxin concentration.
 - b. Digoxin is a mainstay of heart failure treatment due to its calcium channel-blocking effects.
 - c. Digoxin absorption is very consistent across different formulations.
 - d. Digoxin is frequently used to treat atrioventricular (AV) nodal dysfunction due to its enhancing effects on sympathetic nervous system activity within the heart.
 - e. The measurement of digoxin concentrations can be affected by prior administration of Digibind (Digoxin Immune Fab).

Clinical Toxicology

Loralie Langman, Laura K. Bechtel, Christopher P. Holstege*

OBJECTIVES

1. Define the following terms:
 - Anion gap
 - Confirmatory test
 - Osmol gap (OSMg)
 - Screening test
 - Spot test
 - Sympathomimetic
 - Toxicology
 - Toxidrome
2. State and explain the formulas for calculating anion gap (AG) and OSMg; given appropriate information, calculate and interpret the results of these formulas, and list possible interferences with these calculated measurements.
3. For each of the following cellular hypoxia causative agents, describe the agent, the toxic effects, the treatment, and the method(s) of analysis, including specimen requirements and laboratory results, for each:
 - Carbon monoxide (CO)
 - Cyanide
 - Methemoglobin-forming agents
4. For each of the following alcohols, describe the pharmacologic action, the metabolites, the antidote, and the method(s) of analysis, including specimen requirements and laboratory results, for each:
 - Ethanol
 - Ethylene glycol
 - Isopropanol
 - Methanol
5. For each of the following analgesics, describe the toxic effects of overdose, the dose and time of symptom onset, the metabolizing enzyme and metabolite, the antidote, and the method(s) of analysis, including specimen requirements and laboratory results, for each:
 - Acetaminophen
 - Salicylate
6. For the following cholinergic/anticholinergic toxidrome agents, describe the clinical uses (if any), the mechanism of action, the metabolites, the methods of analysis, and the laboratory results for each:
 - Antihistamines
 - Antimuscarinics
 - Antipsychotics
 - Organophosphates/carbamates
 - Tricyclic antidepressants (TCAs)
7. For the following drugs, describe the manifestations of intoxication, the metabolizing enzyme and metabolite, the pharmacologic response, clinical uses if any, the antidote, and the screening tests and confirmatory methods for each:
 - Amphetamines/methamphetamines
 - Barbiturates
 - Benzodiazepines (BZs)
 - Cannabinoid
 - Cocaine
 - Marijuana
 - Opioids
 - Phencyclidine (PCP)
 - Synthetic opioids
8. List and describe five drugs used in drug-facilitated sexual assault (DFSA), including drug classification, pharmacologic effects, and methods of analysis.
9. For the following specimen types, state the advantages and disadvantages of each when used for drug analysis, and list a method of analysis for each:
 - Hair
 - Meconium
 - Saliva (oral fluid)
 - Sweat
10. Discuss the strengths and weaknesses, as well as the uses, of screening assays compared with confirmatory assays.

KEY WORDS AND DEFINITIONS

Amphetamine A sympathomimetic amine that has a stimulating effect on the central and peripheral nervous systems

Analgesics Agents that relieve pain without causing loss of consciousness

Analyte Substance or chemical constituent that is of interest in an analytical procedure

Anticholinergic toxidrome The signs and symptoms characteristic of poisoning caused by an anticholinergic agent (a substance that blocks the neurotransmitter acetylcholine in the central and peripheral nervous systems)

*A more extensive review of the subject and additional references are found in: Langman L.J., Bechtel L., Meier B.M., & Holstege C.P. (2018). Clinical toxicology. In N. Rifai, A.R. Horvath, C.T. Wittwer (Eds.), *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics* (pp. 832–887). St Louis, Elsevier.

Antihistamines Antagonists of the H₁ or H₂ histamine receptors that are used to treat allergic reactions or gastric hyperacidity

Barbiturate Any of a class of sedative-hypnotic agents derived from barbituric acid or thiobarbituric acid and classified into long-, intermediate-, short-, and ultrashort-acting classes

Benzodiazepines Any of a group of minor tranquilizers that have a common molecular structure and similar pharmacologic activity, including antianxiety, sedative, hypnotic, amnestic, anticonvulsant, and muscle-relaxing effects

Cholinergic toxidrome A toxidrome that represents the acute phase of cholinesterase inhibitor poisoning

Clinical toxicology A subdivision of toxicology that involves the analysis of drugs, heavy metals, and other chemical agents in body fluids and tissues for the purpose of patient care

Confirmatory testing As used in programs that test for drugs of abuse, confirmatory tests are used to confirm a positive or sometimes negative result that had been presumptively classified as positive for a specific drug. Examples of techniques used for confirmatory testing include gas chromatography-mass spectrometry (GC-MS) and high-performance liquid chromatography (HPLC)-tandem mass spectrometry (LC-MS/MS)

Drug of abuse A drug that is repeatedly and deliberately used in a way other than prescribed or socially sanctioned (i.e., a drug that is taken for nonmedicinal reasons)

Enantiomer A molecule that exhibits stereoisomerism through the presence of one or more chiral centers (i.e., stereoisomers that are nonsuperimposable mirror images)

Ethylene glycol An ethylene compound with two hydroxy groups located on adjacent carbons. It is a common ingredient in antifreeze and is highly toxic if ingested

Gamma-hydroxybutyrate (GHB) A potent sedative, hypnotic, euphoric agent that is illicitly ingested for its pleasurable effects

Half-life ($t_{1/2}$) The length of time it takes for one-half of an administered drug to decrease due to biologic processes

Intoxication A state of impaired mental or physical functioning resulting from ingestion of alcohol or drug

Levorotary or (–) rotation A counterclockwise rotation of plane polarized light by a stereoisomer (e.g., L- or [l(–)]-methamphetamine)

Lysergic acid diethylamide (LSD) A derivative of an alkaloid found in certain fungi that has hallucinogenic properties

Marijuana A crude preparation of the leaves and flowering tops of (male or female plants) *Cannabis sativa*, usually used in cigarettes and inhaled as smoke for its euphoric properties

Medication half-life The time required for the plasma concentration of a drug to reach half of its original concentration

Miosis Constriction of the pupil of the eye, resulting from a normal response to an increase in light or caused by certain drugs or pathologic conditions

Mnemonics A mnemonic or mnemonic device is any learning technique that aids information retention, for example, an invented combination of letters (acronym) with each letter acting as a cue to an idea you need to remember (a free, nonprofit, online searchable database of medical mnemonics to help you remember the important details is available: <http://www.medicalmnemonics.com/>)

Opiate/opioid Opiate refers to any of a group of naturally occurring (poppy plant) or semisynthetic narcotic alkaloids with pharmacologic actions and chemical structure similar to morphine. Opioid is a general term that is applied to all substances with morphine-like properties, regardless of origin or chemical structure

Poison Any substance that, when relatively small amounts are ingested, inhaled, or absorbed, or when it is applied to, injected into, or developed within the body, has chemical action that may cause damage to structure or disturbance of function, producing symptoms, illness, or death

Screening test An initial test, such as that used to “screen” specimens to eliminate “negative” ones from further consideration and to identify presumptively positive specimens that then require confirmatory testing

Sedative-hypnotic drug A sedative that depresses activity of the central nervous system (CNS) and reduces anxiety and induces sleep

Toxidrome A syndrome caused by a dangerous concentration of toxins in the body

Toxin A poisonous substance that is produced by living cells or organisms and is capable of causing disease when introduced into the body tissues and is often capable of inducing neutralizing antibodies or antitoxins

Toxicology is a broad, multidisciplinary science whose goal is to determine the effects of chemical agents on living systems. Innumerable potential **toxins** inflict harm, including pharmaceuticals, herbals, household products, environmental agents, occupational chemicals, drugs of abuse, drugs

used in sexual attacks, and drugs used by athletes for their performance-enhancing effects. Each year, millions of human exposure cases are reported to the American Association of Poison Control Centers. The Centers for Disease Control and Prevention has reported that **poisoning** is one

of the top 10 causes of injury-related death in the United States in all adult age groups.

This chapter provides a general overview of **clinical toxicology** and the laboratory services necessary to support the care of poisoned patients. Because a comprehensive discussion of all aspects of toxicology is beyond the scope of this chapter, the clinical significance and toxicity of only a select number of common drugs, drugs of abuse, and other chemicals are discussed.

Basic Information

In practice, it is neither possible nor necessary to test for the thousands of clinically significant toxins that may be encountered. In reality, up to 24 drugs or agents account for 80% or more of cases of **intoxication** treated in most emergency departments. The scope of clinical toxicology testing provided by the laboratory depends on the pattern of local drug use and on the available resources of the institution.

The value of drug and/or substance testing (screening) is well established (1) in the workplace, (2) for some athletic competitions, (3) to identify drug use, (4) to evaluate drug exposure and/or withdrawal in newborns, (5) to monitor patients in pain management and drug abuse treatment programs, and (6) to aid in the prompt diagnosis of toxicity for which a specific antidote or treatment modality is required (Table 31.1). In many other instances of drug toxicity, the value of drug screening, especially on an emergency basis, is controversial.

Clinical Considerations

To operate effectively, the laboratory should be closely associated with the health care team that is directly managing the patient. Through close and collaborative work, clinical information provided helps to guide appropriate ordering of tests and to ensure that interpretation of results is complete and accurate. For example, the team caring for the patient should provide the following information with the laboratory request:

1. The time and date of the suspected exposure, along with the time and date of sample collection.
2. History obtained from the patient or from witnesses that might aid in identification of the toxin
3. Assessment of the physical state of the patient at the time of presentation.

Such information is useful for guiding test selection and interpretation of results.

Analytical Considerations

Because of the wide variety of drugs, no single analytical technique is adequate for broad-spectrum drug detection. Therefore, several analytical approaches in combination are generally required. Other critical issues include speed of analysis, turnaround time, and availability of services. A drug analysis that requires several hours to complete or that is not available during all hours may be of little value in a clinical emergency. Alternatively, a rapid test that may provide false information could result in erroneous diagnostic and therapeutic decisions.

TABLE 31.1 Antidote or Specific Treatment for Intoxication

Toxin	Potential Antidote/Treatment
Acetaminophen	N-Acetylcysteine
Aluminum	Deferoxamine
Anticholinergics	Physostigmine
Arsenic	DMSA, BAL
Barbiturates	Multiple-dose oral activated charcoal, sodium bicarbonate
Benzodiazepines	Flumazenil
β-Adrenergic blockers	Calcium, glucagon, high-dose insulin
Calcium channel blockers	Calcium, glucagon, high-dose insulin
Carbamates	Atropine
Carbamazepine	Multiple-dose oral activated charcoal, extracorporeal techniques
Cardiac glycosides	Antidigoxin Fab fragments
Carbon monoxide	Oxygen (normobaric or hyperbaric)
Copper	d-Penicillamine
Cyanide	Hydroxocobalamin, nitrites, thiosulfate
Ethylene glycol	Fomepizole (4-methylpyrazole), ethanol, hemodialysis
Heparin	Protamine sulfate
Iron	Desferoxamine
Isoniazid	Pyridoxine
Lead	EDTA, BAL, DMSA, d-penicillamine
Mercury	BAL, DMSA, d-penicillamine
Methanol	Fomepizole (4-methylpyrazole) or ethanol, hemodialysis
Methemoglobin	Methylene blue, vitamin C
Methotrexate	Leucovorin
Opioids	Naloxone
Organophosphates	Atropine, pralidoxime
Sulfonylureas	Glucose, octreotide
Salicylates	Sodium bicarbonate, hemodialysis
tricyclic antidepressants	Sodium bicarbonate
Theophylline	Multiple-dose oral activated charcoal, extracorporeal techniques
tPA, streptokinase, urokinase	Aminocaproic acid
Warfarin	Phylloquinone (vitamin K1), plasma

BAL, Dimercaprol; DMSA, 2,3-dimercaptosuccinic acid.

Clinical Evaluation

When a health care team initially evaluates a patient who presents with a potentially toxicologically induced problem, the final diagnosis is often determined by reviewing the history, performing a directed physical examination, using ancillary tests (e.g., electrocardiogram [ECG], radiology), and applying a rational approach to laboratory testing.

Toxic Syndromes

Toxic syndromes (**toxidromes**) are clinical syndromes that are essential for the successful recognition of poisoning patterns and are a constellation of clinical signs and symptoms that suggests a specific class of poisoning. The most

TABLE 31.2 Symptoms of the Important Toxidromes

Toxidrome	Symptom
Anticholinergic	Agitation
	Blurred vision
	Decreased bowel sounds
	Dry skin
	Flushing
	Hallucinations
	Hyperthermia
	Ileus
	Lethargy/coma
	Mumbling speech
	Mydriasis
	Psychosis
	Tachycardia
	Urinary retention
Cholinergic	Diarrhea
	Diaphoresis
	Urination
	Miosis
	Bradycardia
	Bronchorrhea
	Emesis
	Lacrimation
	Salivation
	Bradycardia
Opioid	Decreased bowel sounds
	Hypotension
	Hypothermia
	Lethargy/coma
	Miosis
	Shallow respirations
	Slow respiratory rate
	Ataxia
Sedative-hypnotic	Blurred vision
	Confusion
	Diplopia
	Dyesthesias
	Hypotension
	Lethargy/coma
	Nystagmus
	Respiratory depression
	Slurred speech
	Agitation
Sympathomimetic	Diaphoresis
	Excessive motor activity
	Excessive speech
	Hallucinations
	Hypertension
	Hyperthermia
	Insomnia
	Restlessness
	Tachycardia
	Tremor

commonly encountered toxidromes include anticholinergic, cholinergic, opioid, sedative-hypnotic, and sympathomimetic (Table 31.2). Many toxidromes have overlapping features. For example, anticholinergic findings are highly similar to

sympathomimetic findings, with an exception being effects on sweat glands. In this exception, anticholinergic agents produce warm, flushed dry skin, but sympathomimetic agents produce diaphoresis. Toxidrome findings may also be affected by individual variability, comorbid conditions, and coingestants. For example, tachycardia associated with sympathomimetic or anticholinergic toxidromes may be absent in a patient who is concurrently taking β -antagonist medications. In addition, although toxidromes may be applied to classes of drugs, one or more toxidrome findings may be absent for some individual agents within these classes. For instance, meperidine is an opioid **analgesic**, but it does not induce **miosis**, which helps to define the “classic” opioid toxidrome. When accurately identified, the toxidrome may provide invaluable information for diagnosis and subsequent treatment.

SCREENING PROCEDURES FOR DETECTION OF DRUGS

Screening procedures are designed for the relatively rapid and generally qualitative detection of drugs or other toxic substances. Screening procedures may be designed to detect a particular drug or drug class. In general, **screening tests** have adequate clinical sensitivity but lack specificity. Thus a negative result may rule out with reasonable certainty the presence of clinically significant concentrations of a particular drug but not necessarily all drugs within a class. Because of possible interferences, a positive result should be considered “presumptive positive” and should be confirmed by an alternate procedure of greater specificity. Screening tests frequently include simple visual color tests (spot tests) and immunoassays.

Spot Tests

Spot tests are less frequently used currently because some have been largely replaced by rapid immunoassays that may be performed at the point of care (POC) or in the central laboratory. For a more comprehensive description, refer to previous editions of this textbook.

Electrocardiogram

Because numerous drugs cause changes in the ECG, interpretation of the ECG in the poisoned patient has been known to significantly facilitate appropriate laboratory testing, diagnosis, and management of care.

Anion Gap

A basic metabolic panel is recommended and is an important initial screening test for all poisoned patients. When low serum bicarbonate is discovered on a metabolic panel, the clinician should determine whether an elevated anion gap (AG) exists. The formula most commonly used for the AG calculation is as follows:

$$AG = [Na^+] - [Cl^- + HCO_3^-]$$

The reference interval for this AG is accepted to be 8 to 16 mmol/L, but it has been suggested that because of changes in

the technique used to measure chloride, these limits could be lowered to 6 to 14 mmol/L.

An increase in the AG, accompanied by a metabolic acidosis, represents an increase in unmeasured endogenous (e.g., lactate) or exogenous (e.g., salicylates) anions. Clinically useful **mnemonics** for causes of high AG metabolic acidosis are the classic MUDPILES (representing Methanol, Uremia, Diabetes, Paraldehyde, Iron, Isoniazid, Inhalants, Lactate, Ethylene glycol, and Salicylate) and the more recently proposed GOLD MARK (Glycols [ethylene and propylene], Oxoproline, L-lactate, D-lactate, Methanol, Aspirin, Renal failure, and Ketoacidosis).

It is imperative that clinicians who admit poisoned patients initially presenting with an increased AG metabolic acidosis investigate the cause of that acidosis. Many symptomatic poisoned patients may have an initial mild metabolic acidosis upon presentation caused by processes resulting in elevated serum lactate (e.g., transient hypoxia or hypovolemia). However, with adequate supportive care (e.g., oxygenation and hydration), the AG acidosis should steadily improve. If, despite adequate supportive care, an AG metabolic acidosis worsens in a poisoned patient, the clinician should consider continued absorption of exogenous acids (e.g., salicylate), formation of acidic metabolites (e.g., ethylene glycol, methanol, toluene metabolites), and cellular ischemia with worsening lactic acidosis (e.g., cyanide) as potential causes.

Osmolal Gap

The main osmotically active constituents of serum are Na^+ , Cl^- , HCO_3^- , glucose, and urea. Several empirical formulas based on measurement of these substances have been used to estimate serum osmolality. In practice, one has not shown itself to be superior to the others, yet each equation demonstrates significant differences in the osmolal gap reference interval. Therefore reference intervals must be validated on appropriate patient populations. Two commonly used formulas (in conventional and SI units) are presented here:

$$\text{OSMc (mOsm/kg)} = 2 \text{ Na (mmol/L)} \\ + \text{glucose (mg/dL)} / 18 \\ + \text{urea (mg/dL)} / 2.8$$

$$\text{OSMc (mOsm/kg)} = 2 \text{ Na (mmol/L)} \\ + \text{glucose (mmol/L)} \\ + \text{urea (mmol/L)}$$

or

$$\text{OSMc (mOsm/kg)} = 1.86 \text{ Na (mmol/L)} \\ + \text{glucose (mg/dL)} / 18 \\ + \text{urea (mg/dL)} / 2.8 + 9$$

$$\text{OSMc (mOsm/kg)} = 1.86 \text{ Na (mmol/L)} \\ + \text{glucose (mmol/L)} \\ + \text{urea (mmol/L)} + 9$$

The difference between the actual osmolality (OSMm), measured by freezing-point depression, and the calculated

TABLE 31.3 Laboratory Findings Characteristic of Ingestion of Alcohols

Alcohol	Serum Osmolal Gap	Metabolic Acidosis With Anion Gap	Serum Acetone	Urine Oxalate
Ethanol	+	–	–	–
Methanol	+	+	–	–
Isopropanol	+	–	+	–
Ethylene glycol	+	+	–	+

osmolality (OSMc) is referred to as delta-osmolality, or the osmol gap (OSMg).

$$\text{OSMg} = \text{OSMm} - \text{OSMc}$$

Elevated OSMg implies the presence of unmeasured osmotically active substances. Compounds that increase serum osmolality when present in significant concentrations include volatile alcohols such as ethanol, methanol, isopropanol, acetone, and ethylene glycol. The calculation of OSMg is commonly used as a screen. However, it is important to remember that volatile alcohols are not detected when osmolality is measured with a vapor pressure osmometer. Therefore, for the purpose of determining the OSMg, only osmolality measurements based on freezing-point depression are acceptable.

What constitutes a normal osmolal gap is widely debated. Large variability is seen in the normal population. It would be expected that each 100 mg/dL (21.7 mmol/L) of ethanol (molecular weight = 46.068 g/mol) in serum results in an approximate increase of 21.7 mOsm/kg. However, this is not found to be the case. Applying a correction factor of 0.83 to the ethanol value will more closely approximate the contribution of ethanol to the OSMg. However, it has been observed that ethanol does not follow a completely predictable relationship with OSMg. In severe ethanol intoxication, OSMg is increased with increasing concentration, implying that something is present besides the alcohol.

A significant residual osmolal gap (>10 mOsm/kg) after correction for ethanol suggests the possible presence of one of the other volatile alcohols. This information, in conjunction with the presence or absence of metabolic acidosis or serum acetone, is helpful to the clinician when specific measurements of alcohols other than ethanol are not available on an emergency basis (Table 31.3). It must be realized that ketones and substances administered to patients such as polyethylene glycol, mannitol (osmotic diuretic), and propylene glycol (solvent for diazepam and phenytoin) may increase serum osmolality.

Immunoassay

Different types of immunoassays are useful in screening specimens for drugs. In some cases, these assays are relatively specific for a single drug (**lysergic acid diethylamide [LSD]**) but in others can detect several drugs within a class are detected (e.g., opiates). The detection limit for various

members of a class of drugs or the degree of cross-reactivity for similar drugs varies, and each manufacturer of immunoassay reagents should be consulted for specific information. These assays are easy to perform; many are available for use on automated instrumentation and may be able to provide “semiquantitative” results. For the vast majority of drugs of abuse, immunoassays are the methods of choice for initial screening. However, for more comprehensive drug screening, chromatographic procedures complement immunoassays.

Point of Care

Numerous POC drug test devices for urine (and oral fluid) are designed for easy, rugged, and portable use by nontechnical personnel. Although these devices are relatively simple to use, proper training of nonlaboratory users is important for optimal performance. These non-instrument-based immunoassay test devices are designed for use at the site of collection; results are available within minutes and are variously configured to detect only one drug or many drugs simultaneously. A more detailed description of these methods is found in the package insert for each specific test kit.

Gas Chromatography

Gas chromatography (GC) is relatively rapid, capable of resolving a broad spectrum of drugs, and widely used for qualitative and quantitative drug analysis. Common detectors for drug detection by GC are flame ionization and alkali flame ionization (nitrogen phosphorus [NP]) detectors. GC coupled to a mass spectrometer (GC-MS) provides an analytical system with the greatest accuracy of identification. Numerous methods for general drug screening by GC-MS spectrometry have been published.

High-Performance Liquid Chromatography

The resolving power of high-performance liquid chromatography (HPLC) in separating widely divergent chemical constituents has been applied to the complex challenge of comprehensive drug screening in biologic fluids. Advantages of HPLC over GC include its usefulness in analyzing polar compounds without derivatization (e.g., morphine, benzoylcegonine [BE]) and thermally labile drugs (e.g., chlordiazepoxide). The advent of diode array detectors that provide a spectral scan of compounds as they elute from the column has greatly increased the discriminatory power of this technique. Analytical systems based on coupling of liquid chromatography (LC) with mass spectrometry (MS) (LC-MS or LC-MS/MS) significantly improve resolution of drugs from complex matrices.

PHARMACOLOGY AND ANALYSIS OF SPECIFIC DRUGS AND TOXIC AGENTS

The toxic consequences of several drugs and toxins are individually discussed in this section. They have been grouped into the following categories: agents that cause cellular hypoxia, alcohols, analgesics (nonprescription), agents related to anticholinergic toxidrome, drugs of abuse, and drug-facilitated crimes (DFCs).

AGENTS THAT CAUSE CELLULAR HYPOXIA

Carbon monoxide (CO) and methemoglobin-forming agents interfere with oxygen transport, resulting in cellular hypoxia. Cyanide interferes with oxygen use and therefore causes an apparent cellular hypoxia.

Carbon Monoxide

CO is a colorless, odorless, tasteless gas that is a product of incomplete combustion of carbonaceous material. Small amounts of CO are produced endogenously in the metabolic conversion of heme to biliverdin.

When inhaled, CO combines tightly with the heme iron (Fe^{2+}) of hemoglobin to form carboxyhemoglobin. The binding affinity of hemoglobin for CO is approximately 250 times greater than that for oxygen. Moreover, the binding of CO to a hemoglobin subunit increases the oxygen affinity for the remaining subunits in the hemoglobin tetramer. Thus, at a given tissue PO_2 value, less oxygen dissociates from hemoglobin when CO is also bound, shifting the hemoglobin-oxygen dissociation curve to the left. Consequently, CO not only decreases the oxygen content of blood, it also decreases oxygen availability to tissue. This produces a greater degree of tissue hypoxia than would result from an equivalent reduction in oxyhemoglobin due to hypoxia alone. CO may also bind to other heme proteins, such as myoglobin and mitochondrial cytochrome oxidase a_3 ; this may limit oxygen use when tissue PO_2 is very low.

Treatment for CO poisoning involves removal of the individual from the contaminated area and administration of oxygen. The **half-life** ($t_{1/2}$) of carboxyhemoglobin in the body is variable. Low carboxyhemoglobin concentrations relative to the severity of poisoning may be observed if the patient was removed from the CO-contaminated environment several hours before blood sampling. Hyperbaric oxygen therapy for CO is highly debated, and current position papers have reported no evidence to support its use.

Analytical Methods

Carbon monoxide may be released from hemoglobin and then measured by GC, or it may be determined indirectly as carboxyhemoglobin by spectrophotometry. GC methods are accurate and precise even for very low concentrations of CO. Spectrophotometric methods are rapid, convenient, accurate, and precise, except at very low concentrations of carboxyhemoglobin (<3%).

GC methods measure the CO content of blood and are considered to be reference procedures. When blood is treated with potassium ferricyanide, carboxyhemoglobin is converted to methemoglobin and CO released into the gas phase. Measurement of the released CO may be performed by GC, using various methods and detectors. In clinical practice, CO binding capacity is determined after an aliquot of the blood specimen is treated with CO to saturate the hemoglobin. The results are then expressed as percentage of carboxyhemoglobin:

$$\% \text{ HbCO} = \frac{\text{CO}_{\text{content}}}{\text{CO}_{\text{capacity}}} \times 100$$

TABLE 31.4 Examples of Acquired Causes of Methemoglobinemia

Local anesthetics	Analgesics	Miscellaneous
Benzocaine	Phenazopyridine	Aminophenol
Lidocaine	Phenacetin	Aniline, <i>p</i> -chloroaniline
Prilocaine	Nitrites and nitrates	Bromates
Antimicrobials	Ammonium nitrate	Chlorates
Chloroquine	Amyl nitrite	4-Dimethyl- amino-phenolate (4-DMAP)
Dapsone	Butyl nitrite	Metoclopramide
Primaquine	Isobutyl nitrite	Nitrobenzene
Sulfonamides	Potassium nitrate	Nitroethane
Trimethoprim	Sodium nitrate	Nitroglycerin
	Nitrogen oxides	Phenazopyridine
	Nitric oxide	Potassium permanganate
	Nitrogen dioxide	Propanil

Spectrophotometric methods rely on the characteristic spectral absorption properties of carboxyhemoglobin. The most common are based on automated, multiwavelength measurements of several hemoglobin species, and they are rapid and convenient. Spectrophotometric methods generally compare favorably with GC procedures at carboxyhemoglobin concentrations greater than 2% to 3%, but their precision is poor below these concentrations. Therefore they are sufficiently accurate and precise for measurement of CO after exogenous exposure, but they are too insensitive to detect the increased endogenous production of CO that occurs in hemolytic anemia.

Fetal hemoglobin and adult hemoglobin differ slightly in their spectral properties. Consequently, falsely high carboxyhemoglobin values of 4% to 7% may occur when blood from neonates is measured by some spectrophotometric methods by using fewer wavelengths. Moreover, erroneous results may occur with lipemic and icteric specimens and in the presence of methylene blue (see later section, "Methemoglobin-Forming Agents").

Methemoglobin-Forming Agents

The heme iron in hemoglobin is normally present in the ferrous state (Fe^{2+}). When oxidized to the ferric state (Fe^{3+}), methemoglobin is formed, and this form of hemoglobin cannot bind oxygen. Congenital methemoglobinemia may result from a deficiency of NADH-methemoglobin reductase or, more rarely, from hemoglobin variants (hemoglobin M) in which heme iron is both more susceptible to oxidation and more resistant to reduction by the methemoglobin reductase system.

An acquired (toxic) methemoglobinemia may be caused by various drugs and chemicals (Table 31.4). The normal percentage of methemoglobin is less than 1.5% of total hemoglobin. All symptoms associated with methemoglobinemia are consequences of hypoxia associated both with diminished

O_2 content of blood and with decreased O_2 dissociation from hemoglobin species. The PO_2 is normal in these patients and therefore so is the calculated hemoglobin oxygen saturation. Thus a normal PO_2 in a cyanotic patient is a significant indication of the possible presence of methemoglobinemia; therefore measurement of methemoglobin is important in these cases. Specific therapy for toxic methemoglobinemia involves the administration of methylene blue. Methylene blue and sulfhemoglobin cause spectral interference in the measurement of methemoglobin with some CO-oximeters but not with the Malloy-Evelyn method.

Analytical Methods

Methemoglobin may be measured using the manual spectrophotometric method of Evelyn and Malloy or by performing automated multiwavelength measurements with a CO-oximeter. Methemoglobin interferes with the noninvasive pulse oximetry method, measuring the absorbance of light at 660 nm (oxyhemoglobin) and 940 nm (deoxyhemoglobin). Because methemoglobin is not stable at room temperature, specimens should be kept on ice or refrigerated but not frozen. The stability of methemoglobin at 4°C has not been well studied. Some sources report significant decreases in methemoglobin concentration after 4 to 8 hours, whereas others describe little or no change after 24 hours. Freezing results in an increase in methemoglobin concentration.

Cyanide

Cyanide consists of one atom of carbon triple-bonded to one atom of nitrogen ($\text{C}\equiv\text{N}$). Inorganic cyanides (also known as cyanide salts) contain cyanide in anion form (CN^-) and are used in numerous industries. Organic compounds that have a cyano group bonded to an alkyl residue are called nitriles. Iatrogenic cyanide poisoning may occur during use of nitroprusside.

Cyanide in serum readily crosses all biologic membranes and avidly binds to heme iron (Fe^{3+}) in the cytochrome oxidase-a3 complex within mitochondria. When bound to cytochrome oxidase-a3, cyanide is a competitive inhibitor that causes decoupling of oxidative phosphorylation. Patients exposed to toxic concentrations of cyanide exhibit a wide variety of clinical effects depending on the poisoning severity. Hydroxycobalamin or the cyanide antidote kit should be administered as soon as cyanide poisoning is suspected.

Analytical Methods

After microdiffusion, whole blood CN^- is measured by spectrophotometry or by headspace GC.

ALCOHOLS OF TOXICOLOGIC INTEREST

Several alcohols are toxic and medically important; they include ethanol, methanol, isopropanol, acetone (also a metabolite of isopropanol), and ethylene glycol.

Ethanol

Ethanol is widely available and often abused chemical substance. Consequently, measurement of ethanol is one of the

TABLE 31.5 Stages of Acute Alcoholic Influence/Intoxication

Blood Alcohol Concentration (g/dL)	Influence	Clinical Signs/Symptoms
0.01–0.05	Subclinical	Influence/effects not apparent or obvious Behavior appears normal Impairment detectable by special tests
0.03–0.12	Euphoria	Mild euphoria increased sociability, talkativeness, self-confidence decreased inhibitions mild sensorimotor impairment Slowed information processing Loss of efficiency in finer performance tests Impairment of perception and memory
0.09–0.25	Excitement	Emotional instability; loss of critical judgment comprehension Decreased sensory response; increased reaction time Reduced visual acuity, peripheral vision, and glare recovery Sensorimotor incoordination; impaired balance Drowsiness
0.18–0.30	Confusion	Disorientation, mental confusion; dizziness Exaggerated emotional states (fear, rage, grief, etc.) Disturbances of vision (diplopia, etc.) and of perception of color, form, motion, dimensions Increased pain threshold
0.25–0.40	Stupor	Ataxia; dysarthria, apathy, lethargy General inertia; approaching loss of motor functions Markedly decreased response to stimuli Marked muscular incoordination; inability to stand or walk Vomiting; incontinence of urine and feces Impaired consciousness; sleep or stupor
0.35–0.50	Coma	Unconsciousness; coma; anesthesia Depressed or absent reflexes Subnormal temperature Impairment of circulation and respiration Possible death
0.45+	Death	Possible death from respiratory arrest

Modified from Dubowski, K. M. (1980). Alcohol determination in the clinical laboratory. *American Journal of Clinical Pathology*, 74, 747–504.

more frequently performed tests in the toxicology laboratory. The principal pharmacologic action of ethanol involves central nervous system (CNS) depression, and effects vary depending on the blood ethanol concentration (Table 31.5) and an individual's tolerance. A blood alcohol concentration of 80 mg/dL (0.08%) has been established as the per se limit for operation of a motor vehicle in many countries.

When consumed with other CNS depressant drugs, ethanol exerts a potentiation or synergistic depressant effect. This occurs at relatively low alcohol concentrations, and numerous deaths have resulted from combined ethanol and drug ingestion. Ethanol is also a teratogen, and alcohol consumption during pregnancy can result in a newborn with fetal alcohol spectrum disorder (FASD). FASD is an umbrella term that describes the variety of effects that can occur in an individual whose mother drank alcohol during pregnancy (<http://www.nofas.org>). These effects may include physical, mental, behavioral, and/or learning disabilities with possible lifelong implications and are 100% preventable when a woman completely abstains from alcohol during her pregnancy.

Ethanol is metabolized principally by liver alcohol dehydrogenase (ADH) to acetaldehyde, which is subsequently

**Fig. 31.1** Metabolism of ethanol.

oxidized to acetic acid by aldehyde dehydrogenase (Fig. 31.1). The rate of elimination of ethanol from blood approximates a zero-order process. This rate varies among individuals, averaging approximately 15 mg/dL per hour for males and 18 mg/dL per hour for females. At both low (<20 mg/dL) and high (>300 mg/dL) ethanol concentrations, elimination becomes more nearly first order; it is accelerated at high

concentrations. The elimination rate is also influenced by drinking practices (e.g., alcoholics have increased elimination rates caused by enzyme induction).

Methanol

Methanol is used as a solvent in several commercial products, as a constituent in windshield wiper fluid, copy machine fluids, fuel additives (octane boosters), paint remover or thinner, **antifreeze**, canned heating sources, deicing fluid, **shellacs**, and **varnishes**.

Methanol is oxidized by liver ADH (at approximately one-tenth the rate of ethanol) to formaldehyde. Formaldehyde in turn is rapidly oxidized by aldehyde dehydrogenase to formic acid, which may cause serious acidosis and optic neuropathy, resulting in blindness or death. The mainstay of therapy for methanol toxicity includes the administration of fomepizole or ethanol as a competitive ADH inhibitor, plus either folate or folinic acid, and hemodialysis when required.

Isopropanol and Acetone

Isopropanol is readily available to the general population as a 70% aqueous solution for use as rubbing alcohol but can also be found in cleaners, disinfectants, antifreezes, cosmetics, solvents, and inks. Isopropanol is rapidly metabolized by ADH to acetone, which is eliminated much more slowly. Therefore concentrations of acetone in serum often exceed those of isopropanol during the elimination phase after isopropanol ingestion. Acetone has CNS depressant activity similar to that of ethanol, and because of its longer half-life, it may prolong the apparent CNS effects of isopropanol. Supportive care is the mainstay of treatment, with dialysis only in severe intoxication.

Ethylene Glycol

Ethylene glycol is present in antifreeze products, deicing products, detergents, paints, and cosmetics. Ethylene glycol itself is relatively nontoxic; however, metabolism of ethylene glycol by ADH results in the formation of numerous acid metabolites, including oxalic acid and glycolic acid, which are responsible for much of the toxicity of ethylene glycol. It is difficult to define a serum ethylene glycol concentration associated with a high probability of death, and the determination of ethylene glycol and glycolic acid may provide useful information in cases of ethylene glycol ingestion. The mainstay of therapy for ethylene glycol toxicity includes administration of ethanol or fomepizole as a competitive ADH inhibitor and dialysis.

Analysis of Ethanol

Serum/Plasma and Blood Ethanol

Serum, plasma, and whole blood are suitable specimens for the determination of ethanol. Alcohol distributes into the aqueous compartments of blood; because the water content of serum is greater than that of whole blood, higher alcohol concentrations are obtained with serum as compared with whole blood. Experimentally, the serum-to-whole blood ethanol

ratio is 1.18 (1.10 to 1.35) and varies slightly with hematocrit. Therefore laboratories that perform alcohol determinations should make clear the choice of specimen.

Because of the volatile nature of alcohols, specimens should be kept capped to avoid evaporative loss. Blood may be stored, when properly sealed, for 14 days at room temperature or at 4°C, with or without preservative. For longer storage or for nonsterile postmortem specimens, sodium fluoride should be used as a preservative to minimize changes in ethanol concentration.

To measure ethanol in serum/plasma, enzymatic analysis is the method of choice for many laboratories. In this method, ethanol is measured by oxidation to acetaldehyde with NAD, a reaction catalyzed by ADH. With this reaction, the formation of NADH, measured at 340 nm, is proportional to the amount of ethanol in the specimen:

Under most assay conditions, ADH is reasonably specific for ethanol, with interferences by isopropanol, acetone, methanol, and ethylene glycol of typically less than 1%. As a precaution, the venipuncture site is recommended to be cleansed with an alcohol-free disinfectant, such as aqueous benzalkonium chloride.

Spuriously increased results for ethanol have been described in the presence of both high concentrations of lactate dehydrogenase (LDH) and lactate. However, not all ethanol assays are known to have this interference. It is recognized that the lactate and LDH must hit some critical concentration for the interference to occur with those affected assays. Theoretically, other dehydrogenases and substrates may cause similar interference.

Breath Ethanol

Statutory laws for driving under the influence of alcohol were originally based on the concentration of ethanol in venous whole blood. Because collection of blood is invasive and requires the participation of medical personnel, determination of alcohol in expired air (breath) has long been the mainstay of evidential alcohol measurements. The fundamental principle for the use of breath analysis is that alcohol in capillary alveolar blood rapidly equilibrates with alveolar air in a ratio of approximately 2100:1 (blood/breath). To alleviate confusion and uncertainty surrounding conversion from breath to blood alcohol concentration, the traffic laws in many countries specify per se limits for blood and/or breath.

Urine Ethanol

Urine has been used as an alternative, less invasive specimen for determination of alcohol use. During the postabsorptive phase that follows alcohol ingestion, the concentration of alcohol in urine is approximately 1.3 times that in blood. However, the use of urine alcohol measurements to estimate blood concentrations is discouraged because the ratio is highly variable and, perhaps more important, because the urine alcohol concentration may better reflect an average of the blood alcohol concentration during the period in which urine is collected in the bladder.

Analysis of Volatile Alcohols

Flame ionization GC remains the most common method of detection and quantitation of volatile alcohols in biologic samples. Not only does it distinguish between ethanol, methanol, isopropanol, and acetone, it has the capability to measure concentrations as low as 10 mg/dL (0.01%).

Ethyl Glucuronide and Ethylsulfate

Ethyl glucuronide (EtG), ethyl sulfate (EtS), and phosphatidylethanol (PEth) are biomarkers of ethanol consumption. EtG and EtS are phase II metabolites of ethanol. EtG is a phase II metabolite of ethanol formed through the UDP-glucuronosyltransferase catalyzed conjugation of ethanol with glucuronic acid. EtS is formed also directly by the conjugation of ethanol with sulfate group. Because EtG has a long urinary elimination time (≤ 80 hours), its specificity for ethanol exposure, and the low detection limits, EtG is used as a marker of recent ethanol intake in a variety of clinical and legal settings, including medical monitoring for relapse, emergency department patient evaluation, postmortem assessment, and transportation accident investigation. Monitoring both EtG and EtS in urine improves sensitivity when using ethanol biomarkers for monitoring recent drinking. EtG, but not EtS, can be produced post specimen collection in diabetics due to glucose fermentation. Although upper respiratory infections, as well as β -glucuronidase hydrolysis, may lower levels of EtG, they but do not seem to affect EtS. However, challenges associated with factors such as establishing appropriate cutoff concentrations capable of distinguishing between drinking and incidental exposure such as nonbeverage sources of ethanol exposure (i.e., hand sanitizers, mouthwash), nonuniform laboratory reporting limits, sample stability, and microbial activity may complicate interpretation of results.

ANALGESICS (NONPRESCRIPTION)

Acetaminophen

Acetaminophen has analgesic and antipyretic actions. In normal doses, acetaminophen is safe and effective but may cause severe hepatic toxicity when consumed in overdose quantities. Initial clinical findings in acetaminophen toxicity are relatively mild and nonspecific and include nausea, vomiting, and abdominal discomfort. These conditions are not predictive of impending hepatic necrosis. The measurement of serum acetaminophen concentration becomes paramount for proper assessment of the severity of overdose and for appropriate decision making for antidotal therapy with *N*-acetylcysteine (NAC) using the Rumack-Matthew nomogram (Fig. 31.2).

Acetaminophen is normally metabolized in the liver to glucuronide (50% to 60%) and sulfate ($\approx 30\%$) conjugates. A smaller amount ($\approx 10\%$) is metabolized by a cytochrome P450 mixed-function oxidase pathway that is thought to involve formation of a highly reactive intermediate *N*-acetylbenzoquinoneimine (NAPQI). This intermediate normally undergoes conjugation with glutathione and then subsequent transformation to cysteine and mercapturic acid

Fig. 31.2 Rumack-Matthew nomogram. (From Rumack, B. H., & Matthew, H. [1975]. Acetaminophen poisoning and toxicity. *Pediatrics*, 55, 871–876. Reproduced by permission of *Pediatrics*.)

conjugates of acetaminophen. With acetaminophen overdose, the sulfation pathway becomes saturated; consequently, a greater portion is metabolized by the P450 mixed-function oxidase pathway. When the tissue stores of glutathione become depleted, arylation of cellular molecules by the benzoquinoneimine intermediate leads to hepatic necrosis. Specific therapy for acetaminophen overdose is administration of NAC, which acts as a glutathione substitute. Antidotal therapy with NAC is most effective when administered before hepatic injury occurs, as signified by elevation of activities of aspartate transaminase (AST) and alanine transaminase (ALT).

Many spectrophotometric methods are available for determination of acetaminophen. In general, these methods are simple and relatively easy to perform but are subject to various interferences such as bilirubin or bilirubin byproducts absorbing at similar wavelengths. Some methods also measure the nontoxic metabolites and the potentially toxic parent acetaminophen, and thus may produce misleading results. Therefore only methods specific for parent acetaminophen should be used. Immunoassays are widely used for this purpose because they are rapid, easily performed, and accurate. A qualitative, one-step lateral flow immunoassay (cutoff of 25 µg/mL) may be suitable for point-of-care application, yet it has a low positive predictive value. Most chromatographic methods are very accurate and are considered reference procedures.

Salicylate

Acetylsalicylic acid (aspirin) has analgesic, antipyretic, and anti-inflammatory properties. Salicylates directly stimulate the central respiratory center and thereby cause hyperventilation and respiratory alkalosis. In addition, salicylates cause uncoupling

Fig. 31.3 Structure of tricyclic antidepressants (TCA) and related drugs.

of oxidative phosphorylation. As a result, heat production (hyperthermia), oxygen consumption, and metabolic rate may be increased. Salicylates also enhance anaerobic glycolysis but inhibit the Krebs cycle and transaminase enzymes, which leads to accumulation of organic acids and thus to metabolic acidosis.

Following acute salicylate overdose, patients initially may be asymptomatic, especially if that product is enteric coated. Patients may develop nausea, vomiting, abdominal pain, tinnitus, tachypnea, oliguria, and altered mental status ranging from agitation to lethargy to coma. Individuals with chronic intoxication present in a similar fashion as those with acute exposures, yet such exposures typically are more insidious and therefore are often misdiagnosed.

Use of salicylate concentrations to guide management must be done cautiously and only in conjunction with careful evaluation of a patient's clinical status. The absorptive phase of salicylates is often unpredictable (delayed or erratic) as a result of bezoar formation, enteric-coated product, gastric outlet obstruction, or pylorospasm. Therefore a specimen drawn soon after the original ingestion may not be reflective of the potential peak concentration; therefore monitoring of serial concentrations can be very useful. Because products containing salicylates are readily available, the clinical effects of salicylate toxicity are nonspecific, and lack of metabolic acidosis does not rule out the potential for salicylate toxicity,

clinicians should have a low threshold for obtaining serum salicylate concentrations.

Classic methods for measurement of salicylate in serum are based on the method of Trinder. Despite the limitations of these methods, they continue to be used to assess salicylate overdose. The Trinder method results agree very closely with those of a reference HPLC procedure. A qualitative, one-step lateral flow immunoassay (cutoff of 100 µg/mL) is commercially available for point-of-care application but has a low positive predictive value (0.47). GC and LC methods are the most specific methods for salicylate, but their general availability, especially for emergency use, is limited and probably is not necessary.

AGENTS RELATED TO ANTICHOLINERGIC TOXIDROME

Numerous agents can induce an anticholinergic toxidrome include (e.g., tricyclic antidepressants [TCAs], antihistamines). These agents have divergent therapeutic applications but in overdose often share similar anticholinergic toxidrome.

Tricyclic Antidepressants and Related Drugs

TCAs are so named because of their three-ring structure (Fig. 31.3). They represent a class of drugs frequently prescribed for the treatment of depression. The *N*-demethylated

TABLE 31.6 Examples of Classical and Atypical Antipsychotics

Antipsychotics	Examples
Classical Antipsychotics	
Phenothiazines	Chlorpromazine Promethazine Perphenazine Fluphenazine Thioridazine Mesoridazine Trifluoperazine
Thioxanthenes	Flupentixol Zuclopentixol
Dibenzoxazepine	Loxapine
Dihydroindoles	Molindone
Butyrophenones	Droperidol Haloperidol
Diphenylbutylpiperidines	Pimozide
Benzamides	Sulpiride
Atypical Antipsychotics	
Dibenzodiazepine derivatives	Clozapine Olanzapine
Dibenzothiazepine derivatives	Quetiapine
Benzisoxazole derivatives	Risperidone
Benzisothiazol piperazine derivative	Ziprasidone
Phenylindole derivatives	Sertindole

metabolites of several TCAs are pharmacologically active and contribute variably to overall pharmacodynamic activity.

The therapeutic mechanism of TCAs is the blockade of neuronal reuptake of serotonin and/or norepinephrine. However, TCAs have many other pharmacologic actions that contribute to adverse effects at both therapeutic and toxic doses, including: anticholinergic; antihistaminic; α_1 -receptor blocker actions; inhibition of the GABA channel; and of cardiac potassium efflux and fast sodium channels.

Analytical Methods

TCAs are measured by chromatographic methods or by immunoassay. Immunoassays are rapid and relatively easy to perform but may be subject to interference by other drugs and they cannot necessarily be used to identify which TCA is being quantitated. In cases of overdose, qualitative identification (serum or urine) is sufficient because the severity of intoxication is more reliably indicated by an increase in the QRS interval on an ECG than by the serum concentration.

Antipsychotic Drugs

Antipsychotic drugs are generally used for numerous psychiatric disorders. In addition to their psychotherapeutic effects, certain members of this group are used for other indications. Antipsychotic compounds are traditionally divided and subdivided according to their chemical structure (Table 31.6).

The principal manifestations of phenothiazine toxicity involve the CNS and the cardiovascular system. The presentation for most of these drugs is related to their mechanisms of action, which include dopamine blockade (CNS depression), α_1 -blockade (hypotension and miosis), anticholinergic, and K-efflux blockade (QT prolongation). Toxicity is strongly correlated with peak serum concentrations.

Neuroleptics are measured by chromatographic methods and by immunoassay. Chromatographically, GC methods with NP, electron capture (EC), and MS detectors are used, along with HPLC, LC-MS, and LC-MS/MS methods.

ANTIHISTAMINES

Antihistamines are medications that are popular among the general public for treatment of allergic reactions and as common sleep aids. Histamine is released from mast cells and plays an important physiological role in immediate hypersensitivity and allergic responses. Histamine functions as a neurotransmitter in the CNS and stimulates gastric acid secretion. Currently available antihistamine drugs clinically antagonize H_1 and H_2 histamine receptors. The principal H_2 receptor response is stimulation of gastric acid secretion, whereas other actions of histamine such as smooth muscle contraction, vasodilation, increased capillary permeability, pain, and itching are primarily mediated by H_1 receptors.

First-generation lipophilic antihistamines (e.g., diphenhydramine) bind H_1 receptors, exhibit peripheral and CNS effects, and bind to muscarinic receptors, resulting in anticholinergic activity. Second-generation antihistamines (e.g., fexofenadine) are highly specific for peripheral H_1 receptors and do not penetrate the CNS. Therefore second-generation H_1 receptor antagonists display minimal sedative and anticholinergic effects. Individuals overdosed with first-generation H_1 antihistamines present clinically with CNS depression or stimulation and peripheral anticholinergic effects.

Commonly available antihistamines are detected using GC-MS/MS and LC-MS/MS. However, the clinical necessity of quantitative serum antihistamine concentrations is questionable because poor correlation has been noted among patient's age, dose, blood concentration, clinical effects, and death. Antihistamines are detected by forensic laboratories as agents potentially used in facilitating sexual assault (see later section, "Drug-Facilitated Crimes").

Although detection of antihistamines is not typically clinically relevant for the acutely toxic patient, it is important to note that very high concentrations of first-generation antihistamines, such as promethazine and diphenhydramine, have been documented to cross-react with urine drugs of abuse immunomethods used for screening purposes. Therefore physicians and medical review officers (MROs) should be aware of potential false-positive results from on-site drug testing devices, as well as immunoscreening.

Antimuscarinic Agents

Besides numerous pharmaceutical agents, several plant and mushroom species contain antimuscarinic compounds (e.g.,

atropine, scopolamine) that cause anticholinergic symptoms when ingested. Testing for atropine and scopolamine is performed by LC-MS methods.

AGENTS RELATED TO CHOLINERGIC TOXIDROME

Agents inducing **cholinergic toxidrome** are diverse and act by either inactivation of cholinesterase enzymes or direct stimulation of acetylcholine receptors. Acetylcholine is an essential neurotransmitter that affects parasympathetic synapses (autonomic and CNSs), sympathetic preganglionic synapses, and the neuromuscular junction (see also prior section, “Toxic Syndromes”). The duration of acetylcholine action is controlled by acetylcholinesterase (AChE) and butyrylcholinesterase/pseudocholinesterase. AChE is found in red blood cells, nervous tissue, and skeletal muscle. Butyrylcholinesterase is found in plasma, liver, heart, pancreas, and brain.

Organophosphate and Carbamate Compounds

Organophosphate insecticides are toxic because they inactivate AChEs that are required for hydrolyzing acetylcholine at nerve junctions. This inhibition is a consequence of phosphorylation of the serine hydroxyl group at the active site of the cholinesterase catalytic triad (Ser-Glu-His). Subsequent hydrolysis results in irreversible dealkylation of AChE.

Carbamates are structurally different from organophosphates; carbamates exert their toxicity at the active site of AChE but inhibit enzyme activity through carbamylation rather than phosphorylation of the serine hydroxyl group. Most carbamates exhibit poor CNS penetration and have a shorter duration of action than organophosphates.

Excess synaptic acetylcholine stimulates muscarinic receptors (peripheral and CNSs) and stimulates but then depresses or paralyzes nicotinic receptors. Activation of peripheral muscarinic receptors causes signs and symptoms described by the mnemonics SLUDGE (Salivation, Lacrimation, Urination, Defecation, gastrointestinal [GI] distress, Emesis) or DUMBBELS (Diarrhea, Urination, Miosis, Bradycardia, and Bronchorrhea-bronchoconstriction, Emesis, Lacrimation, Sweating-salivation). Stimulation or paralysis of nicotinic receptors at the neuromuscular junction causes muscle fasciculations, cramping, weakness, and respiratory muscle paralysis. Stimulation of nicotinic receptors at sympathetic ganglia results in hypertension, tachycardia, pallor, and mydriasis. Thus the actual signs and symptoms observed with these toxins depend on the balance of muscarinic and nicotinic receptor activation.

Specific therapy for organophosphate and carbamate insecticide poisoning includes administration of atropine, to block the muscarinic (but not the nicotinic) actions of acetylcholine, and pralidoxime, to reactivate cholinesterase in organophosphate poisoning. Treatment requires immediate attention and should not rely on **confirmatory testing**. Cholinesterase activity is often monitored by clinicians in occupational settings, following acute intentional and accidental exposure, to determine response to therapy.

AChE and butyrylcholinesterase enzyme activities are typically monitored using spectrophotometric analyses. AChE activity present at nerve junctions is similar to that present in red blood cells and is an appropriate index of neurotoxicity and therefore correlates more closely with the degree of neurotoxicity. This assay is more sensitive than serum cholinesterase activity and often is used to confirm exposure and to predict enzyme reactivation during treatment.

Butyrylcholinesterase (pseudocholinesterase), also present in serum, is inhibited by these insecticides. The activity of butyrylcholinesterase declines then returns to normal more rapidly than is observed for the red cell enzyme. Serum butyrylcholinesterase is readily measured on hemolyzed samples and in clinical laboratories without isolation of red blood cells. However, interindividual variability is high; making interpretation of test results more difficult. Because butyrylcholinesterases are synthesized in the liver, this assay is particularly sensitive to interferences associated with pregnancy and liver disease.

In acute poisoning, symptoms generally begin when cholinesterase activity is inhibited by approximately 50% of the lower limits of the reference interval, and this degree of inhibition is of diagnostic value. However, the degree of cholinesterase inhibition generally does not correlate well with the clinical severity of poisoning. Interpretation of test results is made more difficult by considerable individual variability of reference activities.

DRUGS OF ABUSE

Many definitions exist for the term *drugs of abuse*. For this chapter, this term is defined as “a drug that is repeatedly and deliberately used in a way other than prescribed or socially sanctioned (i.e., a drug that is taken for nonmedicinal reasons).”

Drug use and abuse are widespread in society, and public awareness has been heightened as to their impact on public safety and on lost productivity in industry. To resolve these issues, governmental, industrial, educational, and sports agencies are increasingly requiring drug testing of prospective and existing employees, students, and participants in professional and amateur athletics. Moreover, drug abuse during pregnancy is a matter of concern, both medically and socially. Testing for drugs of abuse may be a medical requirement for organ transplantation candidates, pain management clinics, drug abuse treatment programs, and psychiatric programs. Drug testing for these purposes represents a significant activity for toxicology laboratories.

Testing for drugs of abuse usually involves testing a single urine specimen for various drugs. However, it should be noted that testing of a single random urine drug specimen detects only fairly recent drug use and it does not differentiate casual use from chronic drug abuse. The latter requires sequential drug testing and clinical evaluation. Moreover, urine drug testing (UDT) alone cannot determine the degree of impairment, the dose of drug taken, or the exact time of use. Because of these and other limitations of testing for drugs in urine, integrating the use of alternate biologic specimens for drug testing is a matter of growing interest.

Fig. 31.4 Select amphetamine-type stimulants.

Initial screening tests for the previously listed drugs are typically immunoassays. These assays are calibrated at established cutoff concentrations. Specimens yielding responses greater than the cutoff (threshold) value are considered presumptively positive, whereas values less than the cutoff are considered negative. Immunoassays may demonstrate limited and variable specificity within certain drug classes. Similar drugs may result in a positive test; for example, pseudoephedrine, present in cold medications, may produce a positive response in immunoassays designed to detect amphetamine and methamphetamine. Therefore it is imperative that positive screening tests be confirmed by an alternate, more definitive test. The most widely accepted method for confirmatory testing is GC-MS; however, LC-MS/MS is also used and accepted.

In the following sections, the pharmacologic and analytical aspects of commonly measured drugs will be discussed.

Amphetamine Type Stimulants

Several stimulants and hallucinogens chemically related to phenylethylamine are referred to collectively as amphetamine-type stimulants (ATSS). They are considered to be sympathomimetic drugs because they mimic or enhance endogenous transmitters in the sympathetic nervous system.

Amphetamine and methamphetamine (Fig. 31.4) are CNS stimulant drugs that have limited legitimate pharmacologic use, including narcolepsy, obesity, and attention-deficit/hyperactivity disorders (ADHDs). They produce an initial euphoria and have a high abuse potential. These drugs have a stimulating effect on both the central and peripheral nervous systems. In the brain, a primary action is to increase the concentrations of extracellular monoamine neurotransmitters (dopamine, serotonin, norepinephrine).

Amphetamine and methamphetamine increase blood pressure, heart rate, body temperature, and motor activity, relax bronchial muscle, and depress the appetite. Abuse of these drugs may lead to strong psychological dependence,

marked tolerance, and mild physical dependence associated with tachycardia, increased blood pressure, restlessness, irritability, insomnia, personality changes, and a severe form of chronic intoxication psychosis similar to schizophrenia. These unpleasant responses reinforce repetitive use of the drugs to maintain the “high.” Tolerance and psychological dependence develop with repeated use of amphetamines. Long-term effects may include depression and impaired memory and motor skills, probably caused by a decrease in dopamine transporters and by damage to dopaminergic and serotonergic neurons. Methamphetamine has greater CNS efficacy, most likely because of its greater ability to penetrate the CNS.

The main metabolic pathways of amphetamine and methamphetamine include aromatic hydroxylation, aliphatic hydroxylation, *N*-demethylation, oxidative deamination, *N*-oxidation, and conjugation of nitrogen. Pharmacogenetics is thought to play a role in differences seen in the metabolism/elimination of these drugs. CYP2D6 is responsible for 4-hydroxylation of amphetamine and methamphetamine and *N*-demethylation of methamphetamine.

In addition to hepatic metabolism, amphetamine is eliminated as an unchanged drug in urine. Elimination is dependent on urine pH. Therefore elimination half-life (renal excretion and hepatic metabolism) varies with urine pH from 7 to 14 hours at acid pH to 18 to 34 hours at alkaline pH. These effects of urine pH on the elimination of unchanged amphetamines are a consequence of tubular reabsorption of nonionized amphetamine (pK_a , 9.9). Similarly methamphetamine is eliminated in urine in a pH-dependent manner, similar to that used for amphetamine.

Designer Amphetamines

The terms “designer drugs” and “club drugs” originated in the 1980s. These drugs include phenylethylamine, benzylpiperazine, phenylpiperazine, pyrrolidinophenone, and cathinone and derivatives (Table 31.7) and have gained popularity and notoriety among people who participate in all-night dance parties (raves) and who visit nightclubs. Most designer drugs produce feelings of euphoria and energy and a desire to socialize; they also promote social and physical interactions. They are used at these events to enhance energy for prolonged partying and/or dancing and to distort or enhance visual and auditory sensations. The moniker “club drug” does not imply that recreational use is restricted to this social environment. In this context, designer drugs mistakenly have the reputation of being safe; several experimental studies in rats and humans and epidemiologic studies have revealed risks to humans such as life-threatening serotonin syndrome, hepatotoxicity, neurotoxicity, psychopathology, and the abuse potential of such drugs.

Ephedrine and Pseudoephedrine

These amines are diastereoisomers that possess two asymmetrical carbon atoms and exist as isomers designated as 1*R*,2*S*- and 1*S*,2*R*-ephedrine and 1*R*,2*R*- and 1*S*,2*S*-pseudoephedrine.

The 1R,2S-ephedrine (ephedrine) and 1S,2S-pseudoephedrine (pseudoephedrine) isomers occur naturally in various plants of the *Ephedra* genus.

Ephedrine is both an α -adrenergic and a β -adrenergic receptor agonist. In addition, it enhances the release of nor-epinephrine from sympathetic neurons and is considered a mixed-acting sympathomimetic drug. Adverse effects such as hypertension, tremors, myocardial infarction, seizures, and stroke have resulted in fatalities. Because of this, the US Food and Drug Administration (FDA) banned the sale of dietary supplements containing ephedra in 2004.

Pseudoephedrine is used primarily as a decongestant because of its vasoconstrictive properties (α -adrenergic action). Pseudoephedrine can be used as a precursor for the illicit synthesis of methamphetamine. Because of this, the quantity per purchase of products containing these drugs is now restricted in many places.

Methylphenidate (Ritalin)

Methylphenidate (MPH) is a psychostimulant with pharmacologic properties similar to those of S(+) amphetamine. It is commonly used to treat ADHD and narcolepsy. It also exists

TABLE 31.8 Prescription Drugs That Either Are, or Are Metabolized to, Amphetamine or Methamphetamine

Drug		Drugs Detected ¹³
Adderall	amphetamine	amphetamine

Vyvanse	lisdexamfetamine	D-amphetamine
Didrex	benzphetamine	D-methamphetamine D-amphetamine

as an isomer, as (*R,R*)-MPH (d-MPH), and as (*S,S*)-MPH (l-MPH). The pharmacologic actions of MPH are almost solely performed by the d-isomer. Diversion and abuse of MPH have been increasing among children and adults because of its stimulant and purported aphrodisiac properties. In overdose, the clinical effects of MPH are similar to those of amphetamines.

Analytical Methods

The initial screening test for amphetamines and related drugs is typically immunoassay. For confirmatory testing of a presumptive positive test, a quantitative drug measurement is performed using GC-MS or LC-MS/MS.

Most amphetamine immunoassays have been designed to detect amphetamine/methamphetamine; others have been designed to detect MDMA and MDA; and others to more broadly capture the ATS group, all with varying cross-reactivity. Few amphetamine immunoassays were suitable for detection of the designer amphetamine or MPH, although some other chemically related compounds, such as pseudoephedrine, have been shown to produce positive results. In addition, many psychotropic medications have been reported to interfere with immunoassays. Regarding MPH, it should be noted that its detection by urine drug immunoassay is problematic because it does not cross-react well with amphetamine antibodies and is present in low concentration.

All positive immunoassay results should be confirmed by a second independent method. However, if the other designer amphetamines are suspected, due to the poor cross-reactivity, a negative amphetamine immunoassay screen cannot rule out the presence of these drugs. Fortunately, numerous GC- and LC-based methods for identification and quantitation of these drugs in biologic samples have been described.

Most published methods for analysis of members of the amphetamine class use liquid-liquid extraction (LLE) or solid-phase extraction (SPE). ATSs are considered volatile and are lost during a dry-down or evaporation step during extraction. In addition, because of their extreme volatility at the high temperatures encountered in GC-MS, and of lack of specificity of the mass spectrum, derivatization before analysis is frequently used. LC-MS and LC-MS/MS have been gaining in popularity.¹ Other prescription drugs that are metabolized to amphetamine or methamphetamine are listed in Table 31.8. Care must be taken in interpreting the results of drug screens.

TABLE 31.9 Half-life and Significant Active Metabolites of Select Barbiturates

Drug	Half-Life	Active Metabolite
Ultrashort Acting		
thiopental	6–46 h	pentobarbital
methohexital	1.2–2.1 h	
thiamylal	0.6–0.8 h initial 12–34 h terminal	
Short Acting and Intermediate Acting		
pentobarbital	15–48 h	
secobarbital	22–29 h	
butalbital	35–88 h	
aprobarbital	14–34 h	
amobarbital	15–40 h (dose dependent)	
butabarbital	34–42 h	
Long Acting		
phenobarbital	2–6 day	
mephobarbital	48–52 h	phenobarbital

Barbiturates

The success of barbital in 1903 and phenobarbital in 1912 led to the synthesis and testing of more than 2500 barbiturate derivatives, of which approximately 50 were distributed commercially. However, because of their low therapeutic index and high potential for abuse, they have been largely replaced by the safer **benzodiazepines** (BZs). Nevertheless, **barbiturates** continue to be available. The classification of barbiturates as ultrashort acting, short acting, intermediate acting, and long acting refers to the duration of effect, not to the elimination half-life (Table 31.9).

The barbiturates produce varying degrees of CNS depression, ranging from mild sedation to general anesthesia, and exert their effects by activate inhibitory GABA_A receptors and inhibit excitatory AMPA receptors explain their CNS-depressant effects.

Analytical Methods

Numerous commercial immunoassays for barbiturates are available, and although the degree of cross-reactivity of other barbiturates varies with each assay, most have sufficient cross-reactivity to detect the major therapeutically used barbiturates.

Numerous confirmatory methods for barbiturates have been described. These include GC with flame ionization detection, nitrogen phosphorous detection, and MS, capillary electrophoresis-ultraviolet (UV), LC using ultraviolet (LC-UV) detection, and LC-MS.

Benzodiazepines

The prototype BZs are diazepam and nordiazepam (*N*-desmethyl diazepam). More than 30 members of this group are presently used worldwide. As a class of drugs, BZs are among the most commonly prescribed drugs in the Western hemisphere because of their efficacy, safety, low addiction potential, and minimal side effects and because of

TABLE 31.10 Half-Life of Select Benzodiazepines

Drug	Half-Life (h)	Significant Phase I Metabolites
Short Acting

^aActive metabolite.^bNot available in the United States.^cConverted to nordiazepam by gastric HCl.

the high public demand for sedative and anxiolytic agents. The BZs given by themselves or in combination with other drugs, particularly narcotic analgesics (opioids), are among the most widely abused drugs.

Virtually all results of the pharmacologic effects of BZs are caused by their actions on the CNS. The most prominent of these effects are sedation, hypnosis, decreased anxiety, muscle relaxation, anterograde amnesia, and anticonvulsant activity. Benzodiazepines are believed to exert most of their effects by interacting with inhibitory neurotransmitter receptors directly activated by GABA. Benzodiazepines act at GABA_A but not GABA_B receptors by binding directly to a specific site that is distinct from that of GABA binding. Ethanol increases both the rate of absorption of BZs and the associated CNS depression, and there are significant additive effects with other sedative or hypnotic drug.

Benzodiazepines may be divided into three categories based on their onset time and elimination half-lives: short-acting agents, intermediate-acting agents, and long-acting agents (Table 31.10). These pharmacokinetic properties in part determine the primary clinical applications for some

BZs. Benzodiazepines undergo hepatic oxidation (phase I) and conjugation (phase II), often forming metabolites with pharmacologic activity (see Table 31.10).

Treatment of BZ toxicity is primarily supportive. Flumazenil may be used in select cases as a competitive inhibitor of the BZ site on the GABA complex.

Analytical Methods

Benzodiazepines are measured through a variety of techniques. However, their structural diversity and wide variation in potency provide a challenge for laboratories seeking to detect all relevant members in one analytical scheme.

Several commercial immunoassay systems are available for detection and screening. Cross-reactivity in screening immunoassays of the various BZs and their metabolites varies considerably from manufacturer to manufacturer, and screening assays cannot be used to distinguish between the individual BZs. Most assays are calibrated to a common metabolite such as oxazepam, temazepam, or nordiazepam. However, the large number of different functional groups that may be present on the BZ nucleus makes it difficult to detect all drugs in this class, and some compounds may not be detected by many assays. Other factors, such as low doses and short half-lives, make the detection of some BZs especially challenging. In the absence of sufficiently sensitive or specific immunoassays, direct analysis by a confirmatory method is warranted in suspected cases.

New-generation **sedative-hypnotic drugs** such as zolpidem (Ambien), eszopiclone (Lunesta), and zaleplon (Sonata) modulate the GABA_A receptor, much like the BZs, yet they are structurally different, thus not detectable.

Analysts need to be aware that the specimen type will dictate the target substance. Blood analyses invariably will target the parent BZ and perhaps the major active metabolite (e.g., nordiazepam for diazepam and other analogues metabolized to nordiazepam), whereas in urine, a metabolite is often the required target species.

Benzodiazepines and their metabolites have been extracted from biologic specimens by LLE or SPE. A hydrolysis step may be necessary to cleave the glucuronide conjugates.

Many BZs are analyzed without derivatization by GC; these include diazepam, nordiazepam, flurazepam, and alprazolam. Drugs that are more polar, including those with hydroxyl groups (such as oxazepam, temazepam, and lorazepam) or a nitro group (clonazepam, nitrazepam), display poor chromatographic characteristics and require derivatization. Chlordiazepoxide is thermally unstable and may degrade at high temperatures in the GC. Some consider GC-MS as the definitive confirmatory method; however, LC with UV detection (240 nm) and LC-MS/MS are used to detect BZs and metabolites without derivatization.

Cannabinoids

Cannabinoids are a group of compounds found in the plant *Cannabis sativa* and has been used for centuries as a medicinal and a psychotropic agent. The main psychotropic effects are euphoria, distorted perceptions, relaxation, and a feeling of well-being.

Delta-9-tetrahydrocannabinol (THC) is the primary psychoactive component of the *C. sativa* plant. It binds to the endogenous cannabinoid receptors, CB1 (neuronal) and CB2 (immune cells). These transmembrane receptors are G-protein-coupled receptors that mediate signal transduction through inhibition of adenylate cyclase and calcium ions and through activation of potassium ion channels. The distribution pattern of CB1 receptors in the CNS accounts for most of the clinical effects of THC, such as those affecting mood, memory, cognition, pain, and appetite. CB2 may regulate immune and inflammatory processes.

When **marijuana** is smoked, THC diffuses into the plasma in seconds and is distributed into multiple phases. First, it distributes to highly vascularized tissues in minutes because of its lipophilic nature. THC then is redistributed back into the bloodstream, undergoes hepatic metabolism, and slowly accumulates into less vascularized and fatty tissues. After cessation of marijuana smoking, THC and its metabolites are slowly released from fat stores.

The main psychotropic effects after inhalation of marijuana occur within minutes and can persist for several hours. The peak plasma concentration of THC is dependent on the dose and occurs during the early acute phase (6 to 10 minutes). Numerous factors contribute to the variability in dose, such as method of consumption, depth of inhalation, exposure frequency, and cannabis potency. Onset of clinical symptoms and peak plasma concentrations after oral ingestion of THC is slower (2 to 6 hours) than after inhalation. The intensity of clinical effects described for smoked cannabis occurs during multiple phases. These phases are categorized as acute (0 to 60 minutes), postacute (60 to 150 minutes), and residual (>150 minutes). The ratio of THC to 11-nor-delta-9-tetrahydrocannabinol-9-carboxylic acid (THC-COOH) metabolite has been used to estimate the time of exposure to marijuana. This approach may be useful in naive users but is unreliable in chronic abusers of marijuana.

THC is metabolized by CYP2D6 liver enzymes to greater than 100 metabolites. The main active metabolite, 11-hydroxy-THC, is further oxidized to the most abundant inactive THC-COOH.

Cannabinoids have some medicinal use. For example, dronabinol (Marinol) contains synthetic THC and is used to treat anorexia and nausea in patients with acquired immunodeficiency syndrome (AIDS), nausea and vomiting associated with chemotherapy, or asthma and glaucoma.

Legitimate concern has been raised concerning positive results from “passive inhalation” of nearby users, or for use or consumption of hemp. Since 1998 the US Federal Government has prohibited the importation of *C. sativa* seeds and oil containing greater than 0.3% THC to reduce human exposure to THC. These measures were successful in reducing potential positive cannabinoid drug screen results from dietary sources.

Analytical Methods

An immunoassay method is typically used to screen for potential cannabinoids. Immunoassay screens have been

designed to detect cannabis use in urine samples using antibody reagents developed against the inactive THC-COOH metabolite; these reagents cross-react with numerous other THC metabolites. A positive screening result for THC obtained by immunoassay is frequently confirmed by detection of THC-COOH by GC-MS/MS or LC-MS/MS analysis of the urine specimens.

A positive result from a urine cannabinoid screen or a positive result found by confirmatory testing does not indicate intoxication or degree of exposure. The window of detection for the urine concentration of THC-COOH varies among casual (2 to 7 days) and chronic abusers (up to 73 days) of marijuana and is dose dependent. Variables affecting the duration of detection include dose, frequency of exposure, route of exposure, body composition, fluid excretion, and method of detection. In practice, monitoring of abstinence is particularly challenging because dilution of urine due to normal biologic fluctuations (hydration) or ingested adulterants has caused a negative result one day and a positive on the next. To correct for hydration fluctuations, urine concentrations of THC-COOH are normalized per milligram creatinine in monitoring individuals who are resuming cannabis use. With the use of these normalized THC-COOH/creatinine concentrations, a ratio is calculated by comparing any normalized urine specimen (U2) with a previously collected normalized urine specimen (U1). “New use” is defined as a U2/U1 ratio greater than or equal to 0.5 to 1.5 in urine specimens taken more than 24 hours apart and containing THC-COOH concentrations greater than 15 ng/mL. Using the 1.5 cutoff rate results in decreased false-positive but increased false-negative decisions.

Cocaine

Cocaine is an alkaloid found in *Erythroxylon coca*. In clinical medicine, it is used for local anesthesia and vasoconstriction in nasal surgery and to dilate pupils in ophthalmology. Cocaine abuse has a long history, and cocaine is still one of the most common illicit drugs of abuse.

Cocaine is sold on the street in two forms: a hydrochloride salt (powder) and a free-base product known as “crack.” The hydrochloride salt form of cocaine is administered by nasal insufflation (“snorting”) or intravenously. Crack comes as a rock crystal that is heated and its vapors inhaled. It should be noted that “crack” cocaine is not to be confused with “free-basing,” which is a process in which the user purifies cocaine HCl by mixing an aqueous solution of cocaine with baking soda or ammonia and adding diethyl ether, thereby extracting the free form of the drug into the organic solvent. However, because of the extremely flammable nature of diethyl ether, and therefore the risk of igniting any remaining ether, free-basing is no longer a common practice.

Chemically, cocaine is methylbenzoyllecognine (COC). Its metabolism is complex (Fig. 31.5) and occurs via both non-enzymatic hydrolysis and enzymatic transformation in the plasma and liver, producing both active and inactive metabolites. COC is rapidly metabolized to BE and ecgonine methyl ester, both of which are inactive. It should be noted that

Fig. 31.5 Metabolism of cocaine.

cocaethylene, produced when cocaine and ethyl alcohol are used simultaneously, has the same CNS stimulatory activity as cocaine in experimental animals. Norcocaine (NC) is of clinical interest because of its conversion to potentially hepatotoxic metabolites: hydroxyl-NC and then NC-nitroxide.

BE has a **half-life** longer than that of COC. It is the most commonly monitored **analyte** in urine for determination of COC use. BE is further metabolized to minor metabolites such as m-hydroxybenzoyl ecgonine (m-HOBE), which has been shown to be an important metabolite in the meconium of cocaine-exposed babies. Anhydroecgonine methyl ester (AEME; methyl ecgonidine) has been identified as a unique COC metabolite after smoked COC ("crack") administration. Anhydroecgonine ethyl ester (AEEE; ethyl ecgonidine) has been identified in COC smokers who also use ethyl alcohol.

Cocaine is a potent CNS stimulant that elicits a state of increased alertness and euphoria with actions similar to those of amphetamine but of shorter duration. These CNS effects are thought to be largely associated with the ability of cocaine to block dopamine reuptake at nerve synapses, thereby prolonging the action of dopamine in the CNS. It is this response that leads to recreational abuse of cocaine. Cocaine also blocks the reuptake of norepinephrine at presynaptic nerve terminals; this produces a sympathomimetic response.

The CNS and cardiovascular effects of cocaine exhibit acute tolerance; its effects are more pronounced when the concentration of cocaine in blood is increasing than when it is at a similar but decreasing concentration (*clockwise hysteresis*). Thus it is difficult to correlate isolated blood concentration values with psychomotor effects.

COC is frequently used with other drugs, most commonly ethanol. This combination produces greater euphoria and an enhanced perception of well-being relative to COC. CE appears to be equipotent to COC with regard to dopamine transporter affinity but is less potent than cocaine pharmacologically. It has been suggested that simultaneous COC and ethanol use carries an 18- to 25-fold increase in risk of toxicity than that associated with COC alone.

Analytical methods. The half-life of COC is 0.5 to 1.5 hours, whereas the half-life of BE is 4 to 7 hours. Thus BE is the analyte of choice in screening for cocaine use. The initial screening test for cocaine use is the immunoassay detection directed against the primary metabolite BE.

Most confirmatory assays offer quantification of both parent drug and metabolite. Numerous methods have been described for measurement of COC and various metabolites. GC techniques for analysis of COC and its metabolites require derivatization, especially of polar metabolites. GC-MS is the method of choice for many laboratories. In addition,

LC methods measure simultaneously many of the more polar potentially significant secondary metabolites such as CE, NC, AEME, and AEEE. For these reasons, LC-MS/MS methods are gaining in popularity.

Lysergic Acid Diethylamide

LSD is an extremely potent psychedelic ergot alkaloid derived from the fungus *Claviceps purpurea*, which grows on wheat and other grains. LSD shares structural features with serotonin (5-hydroxytryptamine), a major CNS neurotransmitter and neuromodulator. The drug LSD binds to serotonin receptors in the CNS and acts as a serotonin agonist. The principal psychological effects of LSD are perceptual distortions of color, sound, distance, and shape (synesthesia); depersonalization and loss of body image; and rapidly changing emotions from ecstasy to depression or paranoia. The most common adverse effects of LSD are panic attacks. In addition, unpredictable recurrence of hallucinations (flashbacks) may occur weeks or months after last drug use, and LSD may elicit psychotic reactions (thought disorders, hallucinations, depression, and depersonalization).

The drug is rapidly absorbed from the gastrointestinal tract, and its effects begin within 40 to 60 minutes, peak at approximately 2 to 4 hours, and subside by 6 to 8 hours. The elimination half-life is approximately 3 hours. LSD is extensively metabolized in humans and the metabolite 2-oxo-3-hydroxy-LSD is present in urine at concentrations 10- to 43-fold greater than those of LSD.

Analytical Methods

Because of the very high potency of LSD and its subsequent rapid and extensive metabolism, only approximately 1% to 2% of the drug is excreted unchanged in urine. Thus detection of LSD presents an especially difficult analytical challenge. Even with sensitive assays, the detection window for LSD is generally only 12 to 24 hours. The detection window may be extended, perhaps twofold to threefold, by including 2-oxo-3-hydroxy-LSD in the confirmatory test, while using sensitive techniques such as GC-MS-MS, LC-MS-MS, or LC-MS. To avoid degradation of LSD and 2-oxo-3-hydroxy-LSD or epimerization of LSD to iso-LSD, urine specimens should be protected from sunlight, bright fluorescent light, and elevated temperature at alkaline pH.

Opiates and Opioids

The term **opioid** describes compounds that encompass the natural and semisynthetic **opiates** that include variations on the structure of morphine and fully synthetic opioids with minimal structural homology to the natural alkaloids (Fig. 31.6). The defining characteristic of this class of drugs is their morphine-like activity stemming from interaction with opioid receptors. Other compounds that are referred to as “opioids” include receptor antagonists and mixed agonist/antagonists, as well as other opium-derived alkaloids such as papaverine.

Opioids interact with the family of opioid receptors that are variably distributed throughout the body. The classical

opioid receptors are divided into the mu, delta, and kappa (μ , δ , and κ or MOR, DOR, and KOR, respectively) subfamilies. Opioid receptor agonists typically produce analgesia, and antagonists block this response. Most opioids have both substantial addictive capacity and potentially life-threatening side effects. Thus the benefits of their use in non-end-stage patients must be carefully weighed against the chance of serious consequences. The development of tolerance and the risk of prescription diversion complicate even further the process of monitoring long-term opioid therapy for compliance and efficacy.

One of the more important CYP enzymes, CYP2D6, is particularly notable for its role in variable clinical response to opioids; it will be discussed in greater detail in a later section. Many additional CYP enzymes, including CYP3A and CYP2C and others, are involved in opioid metabolism. It is important to note that several of these enzymes are subject to substrate inhibition and/or induction. Substrate-dependent changes in metabolic activity are affected by other drugs, herbal supplements, and endogenous compounds that are substrates of the same enzyme. For example, methadone concentrations may be lower than expected in a patient taking St. John's Wort—a noted CYP3A4 inducer—but higher in a patient ingesting a CYP3A4 inhibitor such as grapefruit juice.

Types of Opiates

Natural opium alkaloids. Opium is obtained from the unripe seed capsules of the poppy plant, *Papaver somniferum*. The milky juice is dried and powdered to make powdered opium, which contains several alkaloids. These alkaloids are divided into two distinct chemical classes: *phenanthrenes* and *benzylisoquinolines*. The principal phenanthrenes are morphine, codeine, and thebaine. The principal benzylisoquinolines are papaverine, which is a smooth muscle relaxant, and noscapine.

Poppy seeds from the poppy plant *P. somniferum* contain morphine and, to less extent, codeine. Ingestion of bakery products containing poppy seeds leads to excretion of morphine (and codeine) in urine. In practice, caution is required when the results of a positive urine test for morphine and codeine are interpreted.

Morphine. The archetypical opiate, morphine is used as the basis of comparison for relative characterizations of the opioid class. Morphine interacts primarily with MOR to mediate its effects. Its major metabolites are glucuronide conjugates, including inactive morphine-3-glucuronide (M3G; $\approx 60\%$), active morphine-6-glucuronide (M6G; $\approx 10\%$), and a small amount of morphine-3,6-diglucuronide. With long-term administration, and when morphine concentrations are high, a minor fraction is converted to hydromorphone (up to 2.5% of the urine morphine concentration).

The detection time for morphine in urine is usually 48 to 72 hours, but this varies with individual differences in metabolism excretion and route and frequency of use.

Codeine. Because of its use as an antitussive and analgesic, codeine is frequently prescribed and is commonly combined with nonopiate analgesic agents such as aspirin and

Natural opium alkaloids

Semi-synthetic opiates

Fully synthetic opiates

Opioid antagonists and agonist/antagonists

Fig. 31.6 Structure of common opioids.

acetaminophen. Codeine has only approximately one-tenth the analgesic potency of morphine and is generally considered a prodrug. The small fraction of codeine converted to morphine by CYP2D6 is considered to be responsible for the analgesic effect. During the early phase of excretion, codeine and conjugates predominate, but after this time, morphine conjugates are the major product. Approximately 3 days after codeine use, morphine and its conjugates are the only metabolites detected.

Genetic variation may play a significant role in the metabolism of codeine and several other opioids. More

than 60 alleles have been described for CYP2D6, with resultant enzymatic activity ranging from essentially zero, in the case of null alleles, to many times higher than normal, in the case of amplified alleles (<http://www.cypalleles.ki.se/cyp2d6.htm/>). Thus, at the same codeine dose, patients with minimal CYP2D6 activity (poor metabolizers) would likely receive inadequate analgesia because of lack of conversion to morphine; however, patients with very high CYP2D6 activity (ultrarapid metabolizers) would be at risk for adverse responses to excessive morphine. Without knowledge of the CYP2D6 genotype, these clinical presentations

TABLE 31.11 Examples of Semisynthetic Opiates Include Heroin, Hydrocodone, Hydromorphone, Oxycodone, and Oxymorphone and Their Metabolites

Parent Drug	Primary Metabolite Active(s)	Minor Metabolite(s)
Natural and Semisynthetic Opiates		
morphine		hydromorphone (<3%)
codeine	morphine	hydrocodone (<11%)
heroin	6-acetylmorphine, morphine	
hydromorphone		
hydrocodone	hydromorphone, norhydrocodone	dihydrocodeine
oxycodone	oxymorphone, noroxycodone	
oxymorphone	noroxymorphone	
Fully Synthetic Opioids		
fentanyl	nor-fentanyl	
meperidine	normeperidine	
methadone	EDDP (2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine)	
tramadol	N-desmethyiltramadol, O-desmethyiltramadol	
Opioid Antagonists and Mixed Agonists/Antagonists		
Buprenorphine		
naloxone	noroxymorphone	
naltrexone		

are confusing. Therefore the possibility of pharmacogenetic effects is important to consider when appropriate dosing, patient compliance, and potential diversion or illicit uses are assessed. Like morphine with long-term administration, and when codeine concentrations are high, a minor fraction is converted to hydromorphone (up to 11% of the urine codeine concentration).

Semisynthetic opiates, fully synthetic and opioid antagonists, and mixed agonists/antagonists. Examples of semisynthetic opiates include heroin, hydrocodone, hydromorphone, oxycodone, and oxymorphone and their metabolites (outlined in Table 31.11).

Analytical Methods

Many different immunoassay methods are used to screen for opiates. Given their relatively rapid turnaround time and ability to detect several opiates, immunoassays are the methods of choice to screen urine samples for their opiate content. Antibodies in opiate abuse screens commonly target morphine, and there is significant variability in cross-reactivity such that many opiates and opioids with high abuse potential such as oxycodone are often poorly detected.

The cutoff concentrations used for drugs in federally regulated tests, in particular, opioids (2000 ng/mL), are too high to be of value in monitoring compliance of pain management patients or other clinical settings. For these circumstances, a cutoff of 300 ng/mL morphine (or morphine equivalents) is commonly used to distinguish negative from positive urine specimens. Monitoring compliance for oxycodone in pain management programs should use oxycodone-specific immunoassays because of the low cross-reactivity of oxycodone in most opiate immunoassays.

It is important for drug testing laboratories to communicate relevant aspects of the metabolic interconversion of opiates to physicians responsible for these programs.

GC-MS and LC-MS/MS are techniques of choice for confirmatory testing after a positive screening result or when looking for opiates that are not well detected by immunoassay. GC-MS has historically been considered the method of choice. However, despite the long-standing role of GC in opiate analysis, LC methods are common and are often analytically advantageous. One notable example is that LC provides the ability to analyze glucuronide-conjugated metabolites, as well as parent compounds. In addition, LC methods can be used to measure polar metabolites without prior derivatization, and on-column extraction is possible with some LC systems. One trend in method development is the ability to quantitate/identify combinations of morphine, other opiates, and opioids and their metabolites.

Phencyclidine and Ketamine

Phencyclidine (PCP) and ketamine are potent analgesics and general anesthetics. They are classified as dissociative anesthetics because they produce rapid-acting dissociation of perception, consciousness, movement, and memory. PCP and ketamine share similar structural features and pharmacologic actions. The effects are dose dependent and vary between individuals. PCP is listed as a Schedule II drug in the US Federal Controlled Substance Act and is not approved for human use. Ketamine is a Schedule III drug that is commonly used as an anesthetic. Both drugs have been used illicitly as a **drug of abuse**, as well as in cases of drug-facilitated sexual assault (DFSA). At anesthetic doses, it produces profound analgesia, but the individual is awake yet incapacitated, with

limited voluntary limb movement. They bind and antagonize the excitatory glutamergic system by binding to NMDA receptors. They also decrease GABA transmission, disrupt cortical activity, and increase dopamine and norepinephrine synaptic reuptake.

Analytical Methods

Whether or not PCP and ketamine are included in a general urine drug screen depends on applicable regulations and on the prevalence of use in the local community. In some locations, the prevalence of PCP or ketamine use may be too low to warrant routine screening. Initial screening is typically done by immunoassay. Immunoassays for PCP are generally reliable; however, false-positives have been reported because of high concentrations of dextromethorphan (DXM), diphenhydramine, and thioridazine. Immunoassay-positive specimens should be confirmed using GC-MS or LC-MS techniques. Note, these techniques will also detect norketamine and dehydronorketamine, the active metabolites of ketamine.

Specimen Validity Testing

Several techniques are used by persons attempting to mask or adulterate drugs to avoid detection. These tactics may include the exchange of urine from a drug-free individual or dilution of the urine specimen by excessive consumption of water, use of a diuretic or simple addition of water to the specimen to reduce drug concentrations to less than cutoff limits. In addition, readily available adulterants, such as detergent, bleach, salt, alkali, ammonia, tetrahydrozoline, or acid, may be added to the specimen after collection in an attempt to interfere with immunoassay screening procedures. Other more sophisticated adulterants specifically marketed to avoid drug detection include glutaraldehyde (Urine Aid; Clear Choice), nitrite (Klear; Whizzies), chromate (Urine Luck; Sweet Pee's Spoiler), and a combination of peroxide and peroxidase (Stealth). These adulterants also interfere with immunoassays to variable degrees, and the oxidizing agents (nitrite, chromate, and peroxide/peroxidase) may result in destruction of morphine, codeine, and the principal metabolite resulting from marijuana use, thus interfering with their GC-MS confirmation and with immunoassays. Direct observation of urine collection is the most stringent means to guard against specimen exchange or adulteration. However, an individual's right to privacy and dignity must be weighed against the need for the highest degree of certainty of specimen integrity. Alternative measures to prevent specimen adulteration include limitations on clothing or other personal belongings allowed in the specimen collection area, addition of coloring agent to toilet water, and inactivation of the hot water tap.

DRUG-FACILITATED CRIMES

DFCs are defined as voluntary or surreptitious use of alcohol, drugs, and/or chemical agents to incapacitate an individual and facilitate a criminal act. This includes DDFSAs. In addition to alcohol, the drugs that have been implicated in DFCs

include chloral hydrate, BZs, non-BZ sedative-hypnotics, **gamma-hydroxybutyric acid (GHB)**, dextromethorphan, ketamine, PCP, and nonprescription medications such as antihistamines and anticholinergics. The Society of Forensic Toxicologists Drug-Facilitated Crimes Committee has recommended analytical cutoff for testing of commonly encountered compounds (http://soft-tox.org/files/SOFT_DFC_Rec_De_t_Limits_1-2014.pdf). They include impaired judgment, confusion, reduced inhibitions, sedation, hypnosis, loss of muscle coordination, and sometimes anterograde amnesia. Because of the amnesic properties of these drugs, victims often may not report their sexual assault for several days. Therefore sensitive analytical techniques are necessary to detect these drugs and their metabolites in urine or hair samples after a single dose.

Choral Hydrate

Chloral hydrate is classified as a sedative and as a hypnotic. The CNS depressant effects of chloral hydrate are believed to be due to its active metabolite trichloroethanol (TCE). The clinical diagnosis of chloral hydrate intoxication is difficult to differentiate from alcohol or sedative-hypnotics because it shares similar clinical effects. The exact mechanism of action of chloral hydrate has not been determined. The elimination half-life of chloral hydrate is very short (4 minutes), but the half-life of its metabolite TCE is 6 to 10 hours. If coingested with alcohol, the metabolism of chloral hydrate is impaired. Because both ethanol and chloral hydrate are metabolized by CYP2E1 and ADH, coingestion not only exacerbates the clinical effects but also prolongs the duration of action.

Analytical Methods

Chloral hydrate is not detected on routine drug screens. Chloral hydrate and its metabolite TCE are detected with the use of LC-MS and capillary GC with electron-capture detection (GC-ECD), or GC flame ion detection (GC-FID).

Benzodiazepines

Benzodiazepines that have been reported in sexual assault victims are diazepam, triazolam, temazepam, and clonazepam (see the Benzodiazepines section earlier for more details). Flunitrazepam has achieved significant public awareness. It is a fast-acting sedative-hypnotic categorized as a Schedule I drug in the United States, but sexual predators are able to acquire this drug through illegal trafficking. Sexual assault predators use flunitrazepam because it is easily dissolved into a beverage, it is relatively tasteless and odorless, it quickly incapacitates their victims, and routine drug screens do not detect its presence.

Analytical Methods

Detection of flunitrazepam is especially challenging because of the low doses and the low degree of cross-reactivity of most immunoassays with the principal urinary metabolite, 7-aminoflunitrazepam (see BZ analytical methods earlier), although specific immunoassays have been developed. Direct analysis or confirmatory testing of 7-aminoflunitrazepam by GC-MS or LC-MS/MS is indicated in suspected cases.

Non-benzodiazepine hypnotics:

Zolpidem (Ambien)

Eszopiclone (Lunesta)

Zaleplon (Sonata)

Benzodiazepines:

Diazepam

Fig. 31.7 Chemical structures of diazepam (typical benzodiazepine) and the nonbenzodiazepine sedative-hypnotics (zolpidem, eszopiclone, zaleplon).

Nonbenzodiazepine Sedative-Hypnotics

A new generation of sedative-hypnotics is available that are structurally different from BZs (Fig. 31.7). They include zopiclone, eszopiclone, zolpidem, and zaleplon and are prescribed as sleep aids through a prescription for a Schedule IV drug. However, they are readily prescribed, easily shared, and sold illegally. The rapid onset and amnesic properties of this class of drugs result in disinhibition, passivity, and retrograde amnesia, which are favorable characteristics for use in DFCs. The pharmacologic effects of these agents result from their interaction with a specific subtype of GABA_A receptor complex. These drugs modulate the GABA_A receptor chloride channel by binding to the BZ receptors in the brain without binding to peripheral BZ receptors.

Analytical Methods

Although these drugs do not cross-react with most BZ immunoassays, specific reagent systems (ELISA) directed against the non-BZ hypnotics are available. However, most screening and confirmatory testing are performed by GC-MS or LC-MS/MS.

Gamma-Hydroxybutyrate, 1,4-Butanediol, and Gamma-Butyrolactone

GHB and its synthetic precursor compounds, 1,4-butanediol (1,4-BD) and gamma-butyrolactone (GBL), are Schedule I agents in the United States, and availability is restricted in

numerous other countries. GHB is an odorless and colorless liquid, or it can be obtained as an off-white powder that easily dissolves in liquids. When ingested, it has CNS depressant effects, resulting in sedation and hypnosis.

GHB is a naturally occurring substance that is produced in the brain. It is metabolized to GABA by multiple endogenous enzymes. Consumption of GHB, or the synthetic GHB precursor compound 1,4-BD or GBL, will promote GABA activity. In addition to increased metabolism to GABA, GHB has direct effects on the CNS by binding GHB-specific receptors and GABA_B receptors.

GHB is rapidly metabolized ($t_{1/2} \approx 30$ minutes). Onset of its effects occurs in approximately 15 to 30 minutes and the duration of response is short, typically 1 to 3 hours for a normal dose (1 to 5 g) and 2 to 4 hours with excessive doses.

Analytical Methods

GHB is not detected on most screens but can be identified with the use of GC-FID or GC-MS. Because GHB is metabolized rapidly, timely sample collection is an important facet of GHB assay. Plasma samples should be collected within 6 to 8 hours after ingestion, and urine samples within 10 to 12 hours. Endogenous concentrations of GHB are typically 1.0 mg/L and after exogenous exposure may return to normal levels within 8 to 12 hours after ingestion. Therefore timely presentation of the sexually assaulted victims and physician recognition of GHB symptoms are essential for prosecution of sexual offenders.

Dextromethorphan

DXM is structurally related to the opioids, but it does not bind to opioid receptors at normal dose. The (L-) isomer of DXM, levorphan (not available in the United States), is a potent opioid analgesic and is an example of the stereoselective nature of opioid receptor binding. DXM lacks analgesic activity but does have antitussive activity comparable with that of codeine. DXM is present in numerous over-the-counter (OTC) cough medications, often in combination with other medications.

Analytical Methods

Clinically approved doses of DXM are not detected by most clinical opiate immunoassays, but larger doses may cross-react. ELISA assays are available to detect DXM and its major metabolite, dextrophan. The presence of DXM or dextrophan in a sample is confirmed by GC-MS or LC-MS/MS. Dextrophan is the **enantiomer** of levorphanol, a potent opioid agonist available in the United States (Levo-Dromoran). Unless chiral analytical techniques are used, these enantiomers are not resolved.

PAIN MANAGEMENT

UDT is an essential tool in the field of pain medicine. In the late 1990s, awareness grew about the personal and economic costs of poorly controlled pain. Prominent physicians and professional organizations at local, national, and international levels supported judicious opioid use to address not only acute and cancer-related pain but society's pain at large. In short order, the negative consequences of widespread opioid use surfaced. Since 1999 the number of opioid-related deaths in the United States has more than doubled and now exceeds the number of deaths related to heroin and cocaine abuse combined. In 2012, drug overdose was the leading cause of injury death, surpassing that from motor vehicle crashes between the ages 25 and 64. For every one death from opioid abuse, there are 35 emergency department visits, 161 cases of abuse and 461 cases of misuse, contributing to more than \$55 billion dollars in society and work-related costs.

Despite widespread agreement that treating chronic pain with opioids can be risky and requires commitment to monitoring, controversy in pain medicine exists as to the type and frequency of UDT. This controversy likely stems from the paucity of high-quality research demonstrating that UDT significantly reduces the risks of misuse, abuse, and diversion. In addition, evidence exists that inconsistent UDTs do not necessarily alter prescribing practices. Coincident are concerns about conflicts of interest and physician enticement because UDT is now a multibillion industry that has a history of incentivizing physicians to frequently order testing.

UDT is an important tool in clinical pain medicine. The current epidemic of prescription medication abuse underscores the need for a consistent approach to monitoring that uses both subjective and objective measures. Although some advocate that routine UDT should include all testable substances with abusive potential, such practices are costly and likely unnecessary in many cases. High-risk patients,

classified by using validated clinical screening tools, require more careful and more frequent monitoring. POC and other enzyme immunoassay screening methods cannot differentiate between medications within the same drug class and may completely miss semisynthetic and synthetic opioids. For this reason, confirmatory testing with GC or LC should be performed at least annually and on all inconsistent samples. If misuse, abuse, or diversion is suspected, the physician must act in a way that promotes patient health and safety, while abiding by state and federal law. Such actions should be openly discussed and explicitly written in the opioid prescribing contract signed at the initiation of every opioid treatment plan.

DETECTION OF DRUGS OF ABUSE USING OTHER TYPES OF SPECIMENS

Blood, serum, and urine samples are typically collected for the purpose of determining exposure to various agents. However, sampling of blood is considered invasive, and collection of urine may require some invasion of privacy and loss of dignity. In addition, urine specimens are subject to adulteration or manipulation to evade detection. For these reasons, alternate biologic specimens have been investigated as alternative types of samples for drug analysis.

Meconium

The first intestinal discharge from newborns is meconium, which is a viscous, dark green substance composed of intestinal secretions, desquamated squamous cells, lanugo hair, bile pigments, and blood. Meconium also contains pancreatic enzymes, free fatty acids, porphyrins, interleukin-8, and phospholipase. Meconium begins to form during the second trimester and continues to accumulate until birth; drugs taken by the mother can be detected in the meconium of the newborn. Drug testing is necessary in infants to substantiate the clinical indication of prenatal exposure to illicit drugs.

The disposition of drug in meconium is not well understood. The proposed mechanism is that the fetus excretes drug into bile and amniotic fluid. Drug accumulates in meconium by direct deposition from bile or through swallowing of amniotic fluid. Therefore the presence of drugs in meconium has been proposed to be indicative of in utero drug exposure potentially in the second and third trimesters—a longer historical measure than is possible by urinalysis.

Meconium testing has some limitations. For example, meconium is usually passed by full-term newborns within 1 to 2 days; however, low-birth-weight infants may have delayed passage (median age of 3 days). Thus meconium collection is missed completely, or significant delay is seen in detection of intrauterine drug exposure.

In the clinical laboratory, meconium is a sticky material that is difficult to work with. Meconium drug screening has been adapted to various analytical immunoassays, but as with any immunoassay-based drug screen, confirmatory testing by LC-MS/MS or GC-MS is necessary. Confirmatory assays for meconium are more difficult than those for urine. Recovery of drugs from meconium is low (10% to 50%). Some debate

TABLE 31.12 Drugs and Metabolites of Significance in Meconium

Drug Class	Confirmation Compound
Cocaine	cocaine
	benzoylecgonine
	cocaethylene
	<i>m</i> -hydroxybenzoylecgonine
Opiates	morphine
	codeine
	6-monoacetylmorphine (6-MAM)
	hydromorphone
	hydrocodone
	oxycodone
Cannabinoids	9-carboxy-11-nor- Δ^9 -THC
	11-hydroxy- Δ^9 -tetrahydrocannabinol
	8,11-dihydroxy- Δ^9 -tetrahydrocannabinol
Amphetamines	amphetamine
	methamphetamine
	MDMA
	MDA
	MDEA
Ethanol	fatty acid ethyl esters
PCP	PCP

continues as to which are the most appropriate drug analytes that should be measured in meconium; Table 31.12 attempts to summarize current knowledge. Meconium drug testing is far less standardized than UDT. Assay cutoff limits and units (ng/g meconium or ng/mL extract) may vary; suitable reference or control materials are not yet available.

Overinterpretation of meconium data is a dangerous practice. Numerous reports have described the specificity and sensitivity of different analytes with the use of different testing methods. In our opinion, tremendous, and potentially inappropriate, value has been placed on a meconium result. On occasion, decisions about treatment or custody of the infant have been based solely on meconium drug screen results. It is critical to remember that a positive test could indicate drug exposure. However, a negative result does not rule it out. It is clear that additional work is necessary to address these important issues and to improve our understanding of the disposition of drugs in meconium.

Oral Fluid

Analysis of saliva for drugs was first done almost 30 years ago for the purpose of therapeutic drug monitoring. It has since been evaluated for use in forensic toxicology, with recognition of its advantages over other biologic matrices. Most studies on saliva in humans use whole saliva. It should be noted that the term “oral fluid” is now preferred for the specimen collected from the mouth.

Several advantages are associated with monitoring oral fluid as contrasted with monitoring plasma or serum concentrations. For example, collection of oral fluid is considered to be a noninvasive procedure, direct observation is possible (thus minimizing risk of adulteration), and some of the risks associated with drawing of blood are avoided.

Furthermore, for the patient, the fear, anxiety, and discomfort that may accompany the drawing of blood are diminished. Significant disadvantages of oral fluid are (1) the window of detection is about equivalent to that of blood or serum and is short compared with that of urine, (2) glucuronide metabolites (size and charge) may poorly distribute into oral fluid, (3) pH may affect deposition into oral fluid, (4) protein binding diminish deposition, and (5) small volume of sample collected. The problem of small sample size is usually overcome by using methods that simultaneously extract multiple drug groups.

In principle, oral fluid drug concentration is related to plasma free-drug concentration; therefore oral fluid has the potential to show a relation between behavior/impairment and drug concentration, making it a possible matrix for monitoring drug intoxication or for conducting therapeutic drug management. Because disposition of drugs in oral fluid is dependent upon chemical and metabolic processes, appropriate interpretation is required. In recent years, great interest has been expressed in the use of oral fluid testing for roadside drug screening, monitoring the compliance of individuals on drug maintenance programs, and workplace drug testing. Low concentrations of drugs and metabolites necessitate sensitive screening methods. Many confirmatory methods have been developed for oral fluid testing of abused drugs, including GC-MS, LC-MS, and LC-MS/MS (refer to Chapter 6 for saliva sample collection).

Hair

For longer than 30 years, hair has been analyzed for trace metals, including lead, arsenic, and mercury. This was achieved with the use of atomic absorption spectroscopy. Subsequently, interest in analysis of hair for the purpose of detecting drug use has increased.

Hair is advantageous as a biologic specimen for drug analysis because it is easily obtained with less embarrassment, and it is not easily altered or manipulated to avoid drug detection. Hair also differs from other human materials used for toxicologic analysis in that it has a substantially longer detection window (months to years) depending on the length. The rate of hair growth depends on anatomic location, race, gender, and age. Once deposited in hair, drugs are very stable, and analysis can be performed even after centuries.

The exact mechanism by which chemicals are incorporated into hair is still being studied. However, it has been suggested that passive diffusion may be augmented by binding of the drug to intracellular components of hair cells, such as the hair pigment melanin. Factors that may affect how efficiently drugs are incorporated into hair are not well established but may include rate of hair growth, anatomic location of hair, hair color (melanin content), and hair texture (thick or fine, porous or not). These factors are determined by genetic factors and by the effects of various hair treatments. This may lead to biases in hair testing for drugs of abuse.

Drugs, when deposited in hair, are generally present in relatively low concentrations; thus sensitive analytical techniques are required for detection. Immunoassay procedures

have been modified for use with hair. For confirmatory testing, GC-MS is generally the method of choice; however, various GC-MS/MS or LC-MS/MS methods have been used. External exposure to drugs causes them to be detected in hair; one of the most crucial issues currently facing hair analysts is technical and false positives. The need to distinguish between passive exposure (environmental contamination) and active consumption is fundamental; consequently, decontamination procedures for hair are compulsory. These usually involve a washing step. Needless to say, hair analysis is a complex scientific undertaking.

Sweat

Drugs may be excreted in sweat, and sweat analysis may provide an alternative detection technique. Sweat patch collection devices that resemble an adhesive bandage may be worn for several days to several weeks. During this time, a drug, if present, accumulates in the absorbent pad in the patch, while water vapor escapes through the semipermeable covering. Thus sweat drug testing offers the possibility of monitoring drug use over extended periods without the need for frequent collection of urine. Sweat drug excretion may also be an important mechanism by which drugs enter hair.

REVIEW QUESTIONS

1. The best specimen type used to determine whether a neonate has been exposed to drugs during the second or third trimester of pregnancy is:
 - a. fetal oral fluid.
 - b. meconium.
 - c. fetal hair.
 - d. newborn infant urine.
2. The antidotal therapy for acetaminophen overdose is:
 - a. forced alkaline diuresis.
 - b. inhibition of the GABA channel.
 - c. pralidoxime.
 - d. N-acetylcysteine.
3. The best advantage of using high-performance liquid chromatography (HPLC) over gas chromatography (GC) for comprehensive drug screening for a broad range of chemicals is that:
 - a. HPLC does not require a derivatization step.
 - b. HPLC can be performed at the individual's bedside.
 - c. GC gives diverse color hues and requires considerable technical skill.
 - d. GC drug testing methods are subject to many types of interference.
4. Use of which of the following drugs is not consistently detected in the benzodiazepine immunoassay screen?
 - a. Diazepam
 - b. Clonazepam
 - c. Oxazepam
 - d. Nordiazepam
5. To confirm heroin use, testing of which of the following urinary metabolites is considered unique and specific for this drug?
 - a. Morphine
 - b. Codeine
 - c. Meperidine
 - d. 6-Acetylmorphine
6. For assessment of drugs of abuse, the most widely accepted laboratory method for drug *confirmation* is:
 - a. immunoassay.
 - b. GC-MS.
 - c. HPLC-UV
 - d. Time-of-Flight (TOF) Mass Spectroscopy

Toxic Elements

Frederick G. Strathmann, Lee M. Blum

OBJECTIVES

1. Identify several elements commonly associated with toxicity.
2. Compare available specimen types for applicability in the assessment of elemental toxicity.
3. Give examples of preanalytical concerns regarding elemental testing.
4. Summarize the key information regarding clinical presentation and treatment for elemental toxicity covered in this chapter.

KEY WORDS AND DEFINITIONS

Antidotal treatment The use of any chemical or physiological procedure to prevent, minimize, or terminate the adverse effects of toxicity.

Decontamination Neutralization or removal of toxic substances.

Neuropathy Damage to a nerve that may impair sensation, movement, or other aspects of health.

Signs of toxicity Objective evidence of toxicity to someone other than the exposed individual.

Symptoms of toxicity Subjective evidence of toxicity experienced by the exposed individual.

Toxicokinetics The study of the time course of xenobiotic absorption, distribution, metabolism, and excretion.

BACKGROUND

Elements have been recognized as toxins for centuries. Some elements are essential for life, but if an individual's exposure exceeds a certain threshold, toxicity may develop. When identified early, disease caused by elemental exposure is readily treatable with good outcomes. Conversely, if exposure is not identified and reduced, serious and sometimes irreparable damage to the nervous, renal, and cardiovascular systems can occur. The laboratory plays a key role in this process, and appropriate specimen collection coupled with accurate analysis can make a major difference in correct diagnosis.

CONTENT

This chapter explores toxic elements and the role of the clinical laboratory in diagnosing and monitoring toxicity associated with exposure. A general overview of diagnostic and treatment options for the poisoned patient is followed by detailed descriptions of 10 elements most commonly associated with toxicity. Each section highlights the following areas: (1) sources of exposure, (2) clinical presentation and treatment, (3) preanalytical and analytical aspects, and (4) regulatory and occupational exposure aspects.

Elements are woven into the very fabric of history. For example, arsenic poisoning was a favored way to dethrone

royalty in the Renaissance era, and mercury poisoning was common in 18th-century Europe, where it was associated with the generation of felt from beaver pelts to make the popular top hat and was the origin of the phrase "mad as a hatter." This chapter explores these and other toxic elements with an emphasis on clinical presentation, occupational exposure, and analytical requirements.

PREVALENCE OF ELEMENTAL TOXICITIES

The incidence of elemental poisoning across large populations attributable to arsenic, cadmium, lead, or mercury appears to be on the same scale as the more common inborn errors of metabolism, such as neonatal hypothyroidism and phenylketonuria, and is the same order of magnitude as the incidence of adult-onset hemochromatosis. Screening for these latter diseases is indicated because they are treatable, and treatment significantly reduces long-term morbidity. The same may also be true for elemental toxicities. When identified early, disease caused by elemental exposure is readily treatable with good outcomes. Conversely, if exposure is not identified and reduced, serious and sometimes irreparable damage to the nervous, renal, and cardiovascular systems can occur. Review of the periodic table provides some insight into the determination of a metal's potential toxicity ([Fig. 32.1](#)).

POINTS TO REMEMBER

- The incidence of elemental poisoning across large populations attributable to arsenic, cadmium, lead, or mercury poisoning appears to be on the same scale as the more common inborn errors of metabolism.
- When identified early, disease caused by elemental exposure is readily treatable with good outcomes.

DIAGNOSING TOXICITY

Confirming the diagnosis of elemental toxicity is difficult because **signs** and **symptoms** are similar to those of many non-element-dependent diseases. Diagnosis of elemental toxicity requires demonstration of all of the following factors: (1) a source of elemental exposure must be evident, (2) the patient must demonstrate signs and symptoms typical of the element, and (3) abnormal element concentration in the appropriate tissue must be evident. If one of these features is absent, a conclusive diagnosis of elemental toxicity cannot be made. The laboratory plays a key role in this process and appropriate specimen collection coupled with accurate analysis can make a major difference in correct diagnosis.

In clinical practice, analysis of toxic elements should always be considered in the clinical workup of the patient with (1) renal disease of unexplained origin, (2) bilateral peripheral **neuropathy**, (3) acute changes in mental function, (4) acute inflammation of the nasal or laryngeal epithelium, or (5) a history of exposure. Certain elements should be considered as the active, causative, or deficient agent in specific circumstances.

TREATMENT

The route of exposure is an important aspect in elemental toxicity that can influence treatment and clinical outcomes. The clinical approach to elemental exposure comprises one of the following treatments: (1) removal from exposure if the source is known, (2) **decontamination**, (3) enhanced elimination, or (4) **antidotal treatment**.

Removal from the source of exposure can be complicated if the element responsible is unknown or the source of exposure is in question. For less extreme cases of exposure or if evidence to support more invasive treatments is lacking, removal, often in conjunction with supportive care, may be the only form of treatment available.

Decontamination strategies may include gastric lavage, activated charcoal, and supportive therapies to maintain the ABCs (airway, breathing, blood circulation), as well as attention to water, electrolyte balance, and neurologic complications. Prevention of absorption in the gastrointestinal (GI) tract is one mechanism for treating the chronic copper overload seen in patients with Wilson disease.

Enhancement of elimination can be done through diuresis, biliary excretion, hemodialysis, or exchange transfusion. Distribution of the element, once absorbed, has an impact on the utility of each of these approaches, and for several elements there is a lack of supporting data demonstrating improved outcomes after their use.

Antidotal treatments range from highly specific (e.g., deferoxamine for iron and aluminum) to considerably less specific (e.g., ethylenediaminetetraacetic acid [EDTA] for

most divalent cations). The intent is to counteract the detrimental effects of the toxic element or to sequester it in a less toxic form. Although it is a highly useful method for treating elemental toxicity, the downside to chelation therapy is the potential for depletion of essential elements. The five most commonly used chelators are dimercaprol (British anti-Lewisite [BAL]), dimercaptosuccinic acid (DMSA or succimer), dimercaptopropane sulfonate (DMPS), EDTA, and D-penicillamine.

POINTS TO REMEMBER

Diagnosing Elemental Toxicity

- Confirming the diagnosis of elemental toxicity is difficult because signs and symptoms are similar to those of many non-element-dependent diseases.
- The route of exposure is an important aspect of elemental toxicity that can influence treatment and clinical outcomes.

SPECIFIC ELEMENTS

Aluminum (Al)

In 1972, Alfrey and colleagues first described an encephalopathy in patients undergoing prolonged hemodialysis for renal failure. The disease was characterized by abnormal speech, myoclonic jerks, and seizures. Patients with these signs also showed a predominance of osteomalacic fractures. Subsequently, it was found that exposure of patients to (1) Al-laden dialysis water, (2) Al-containing oral phosphate binders, and (3) Al-laden albumin administered during dialysis are the primary causes of these signs of Al toxicity. Al is also a developmental toxicant if administered parenterally.

Sources of Exposure

Under normal physiologic conditions, the usual daily dietary intake of Al is 5 to 10 mg, which is principally excreted by the kidney. Patients in renal failure lose this ability and are candidates for Al toxicity. The dialysis process is not highly effective at eliminating Al and can also be a significant source of exposure. Furthermore, it is common practice to administer Al-based gels orally to patients in renal failure to reduce the amount of phosphate absorbed from their diet to avoid excessive phosphate accumulation. A small fraction of this Al may be absorbed, and patients in renal failure can accumulate this. After dialysis, the albumin removed during dialysis may be replaced with albumin products that have high Al content resulting from the pharmaceutical purification process of passing the product through Al silicate filters.

Clinical Presentation and Treatment

A biochemical profile that characterizes Al overload disease has been defined. In human subjects with normal renal function, serum Al concentration is typically lower than 6 $\mu\text{g/L}$ (0.2 $\mu\text{mol/L}$), but patients in renal failure invariably have

significantly higher serum Al concentrations. Clinical guidelines published in 2006 suggest that patients with no signs or symptoms of osteomalacia or encephalopathy are likely to have serum Al concentrations less than 20 $\mu\text{g/L}$ (0.74 $\mu\text{mol/L}$) and intact parathyroid hormone (PTH) concentrations of 150 to 300 ng/L (16.5 to 33 nmol/L), typical for secondary hyperparathyroidism associated with renal failure. Patients with signs and symptoms of osteomalacia or encephalopathy typically have serum Al concentrations greater than 60 $\mu\text{g/L}$ (2.2 $\mu\text{mol/L}$) and PTH concentrations less than 65 ng/L (7.15 nmol/L), indicative of Al-related bone disease. Patients with serum Al concentrations greater than 20 and less than 60 $\mu\text{g/L}$ (>0.7 and <2.2 $\mu\text{mol/L}$) were identified as candidates for likely onset of Al-related bone disease. These patients required aggressive efforts to reduce their daily Al exposure, including (1) switching from Al-containing phosphate binders to calcium-containing phosphate binders, (2) ensuring that dialysis water contains less than 10 $\mu\text{g/L}$ (0.4 $\mu\text{mol/L}$) of Al, and (3) ensuring that albumin used during postdialysis therapy is Al-free.

Al-related bone disease has been diagnosed and treated with deferoxamine, an avid chelator of both iron and Al. The deferoxamine infusion test is useful for the ultimate diagnosis of Al overload disease, and the drug has demonstrated utility for treating acute Al overload.

Adverse health effects in workers occupationally exposed to Al compounds have included pneumoconiosis (aluminosis) and fibrosis of the lungs, and toxicity of the central nervous system, including balance disorders, difficulties with memory and concentration, impaired cognitive abilities, irritability, depression, and decreased psychomotor performances. Although rare, contact sensitization of the skin by Al is also possible.

Preanalytical and Analytical Aspects

Preanalytical considerations related to collection of specimens for Al analysis are significant. Most of the common evacuated blood collection devices used in phlebotomy today have rubber stoppers made of Al silicate. Puncture of the rubber stopper for blood collection is sufficient to produce an abnormal concentration of Al due to contamination. Typically, blood collected in standard evacuated blood tubes will be contaminated by 20 to 60 $\mu\text{g/L}$ (0.7 to 2.2 $\mu\text{mol/L}$) of Al; this is readily demonstrated by collecting blood from a healthy volunteer into a standard evacuated phlebotomy tube. Special evacuated blood collection tubes from commercial suppliers are required for Al testing to avoid sample contamination, which leads to misinterpretation and misdiagnosis.

Analysis of Al is routinely performed by inductively coupled plasma-mass spectrometry (ICP-MS). Alternatively, atomic absorption spectrometry with electrothermal atomization may be employed, but considerable attention must be paid to matrix interferences.

Regulatory and Occupational Exposure Aspects

Occupational exposure to Al compounds primarily occurs through inhalation of airborne particles in dusts and fumes.

The solubility of the Al compounds affects its **toxicokinetics** and adds to subsequent health risks. In general, inhaled soluble particles (e.g., aluminum sulfate, hydrated aluminum chloride, and aluminum nitrate) are rapidly absorbed through the lungs, whereas the less or sparsely soluble particles (e.g., aluminum metal, aluminum oxide, aluminum hydroxide, aluminum phosphate, and aluminum silicate) are retained in the lungs and then slowly released into the systemic circulation. The amount of Al absorbed by inhalation also appears to be related to particle size. Al fumes are absorbed more readily than dust particles, and ultrafine nanoparticles of aluminum oxide can penetrate cell membranes.

Biological monitoring of occupational exposure to Al can be determined by analysis of blood, serum, or urine. The concentration of Al in these specimens can be affected by both the intensity of a recent exposure and the Al body burden. Studies of aluminum welders indicate a fair correlation between Al in serum and urine; however, in workers with normal kidney function, urinary Al concentrations are a more sensitive indicator of occupational Al exposure than serum Al levels. After exposures to low-level airborne Al, urinary Al levels are increased, whereas serum concentrations are generally within the range of control subjects. In chronically exposed welders, the Al concentration in urine collected after 1 or 2 exposure-free days is likely a good indicator for determining the magnitude of the Al stored in the body; whereas in newly exposed workers, the urinary Al level is probably more influenced by recent exposures than by the body burden.

Antimony (Sb)

Antimony compounds have been known since ancient Egyptian times and were used as cosmetics by the women of that era. In the 16th century, Sb preparations were thought to be wonder drugs and in the 19th century were prescribed for various conditions.

Sources of Exposure

Pure metallic Sb is very brittle; however, alloys of Sb are used in various fields of technology. For example, addition of Sb to lead, tin, and copper increases the hardness of these elements when used as electrodes, bullets, type metal for printing, and ball bearings. Other uses include fire-resistant chemicals, pigments, and dyes.

Before the introduction of the anthelmintic drug praziquantel, several Sb-containing compounds were used in the treatment of leishmaniasis, a parasitic disease in which protozoa of the genus *Leishmania* are spread by sand flies, and schistosomiasis, a disease carried by freshwater snails infected with one of the five species of the parasitic flatworm *Schistosoma*.

Clinical Presentation and Treatment

Symptoms of acute exposure include a metallic taste, headache, nausea, dizziness, and, after a short interval, vomiting, diarrhea, and intestinal spasms. In chronic intoxication, adverse health effects include cardiac arrhythmias, upper respiratory tract and ocular irritation, spontaneous abortion, premature birth, and dermatitis. Lymphocytosis,

eosinophilia, and a reduction in leukocyte and platelet counts are also seen, and indicate liver and spleen damage. Evidence supports increased risk for the development of lung cancer in Sb smelter workers, but the increased risk may be multifactorial, and may be due to, among other factors, the presence of arsenic in the work environment. It is important to remember that when intoxication occurs with metallic Sb, the effect is caused not only by Sb but also by the lead, arsenic, and other elements that may accompany it.

Preanalytical and Analytical Aspects

Careful selection of specimen tube type, even for certified trace element-free products, is important for the accurate measurement of Sb in blood. ICP-MS is typically used for Sb detection because of its increased sensitivity over that of other instrumentation. Historic methods for Sb measurements in blood have used time-consuming heated acid digestion for achieving better sensitivity, while simplified sample preparation methods have been published more recently.

Regulatory and Occupational Exposure Aspects

For purposes of biological monitoring after exposure to Sb, urine samples are preferable over blood. In one study, urinary Sb concentrations in workers were correlated to the intensity of airborne exposure in nonferrous smelters producing antimony pentoxide and sodium antimonite ($r = 0.86$).

Arsenic

Arsenic (As) is perhaps the best known of the elemental toxins, having gained notoriety from its extensive use by Renaissance nobility as an antisymphilitic agent and an antidote against acute As poisoning. Long-term administration of low As doses protects against acute poisoning by massive doses—a historic example of hepatic enzyme induction. This agent was memorably used in the well-known tale *Arsenic and Old Lace* as a means of terminating undesirable acquaintances. Arsenic is listed as the number 1 toxicant on the Agency for Toxic Substances and Disease Registry (ATSDR) 2013 Substance Priority List of Hazardous Substances based on a combination of frequency, toxicity, and potential for human exposure. Despite their inherent toxicity, As-containing compounds are used for therapeutic reasons.

Sources of Exposure

Nontoxic forms of As are present in many foods with arsenobetaine and arsenocholine, the two most common forms. The foods that most commonly contain significant concentrations of organic As are shellfish and other predators in the seafood chain (e.g., cod, haddock). In a large US population study, for all participants over 6 years of age, the inorganic As metabolite dimethylarsinic acid (DMA) and arsenobetaine had the greatest contribution to the total urinary As output, with arsenobetaine being the primary contributor.

Clinical Presentation and Treatment

The symptoms of As toxicity may be nonspecific and often overlap with symptoms of other toxicants. Acute As toxicity

can be characterized by GI distress, including vomiting and diarrhea, and cardiac arrhythmias. Chronic toxicity may be characterized by renal failure, cardiac arrhythmias, liver dysfunction, and peripheral neuropathy, and As is a known carcinogen. Transverse white bands on the fingernails (Mees lines), hypopigmented macules, hyperpigmentation, and hyperkeratosis have been documented after As exposure.

Arsenic has been shown to interfere with the activity of several heme-biosynthetic enzymes, including aminolevulinate synthase, porphobilinogen deaminase, uroporphyrinogen III synthase, uroporphyrinogen decarboxylase, coproporphyrinogen oxidase, ferrochelatase, and heme oxygenase with resultant increases in copro/uro and copro I/III ratios. Interestingly, the madness of King George III, historically attributed to acute hereditary porphyria, has been hypothesized to instead be a case of arsenic-induced porphyria based on retrospective analyses of hair.

An effective antidote for treating As intoxication is BAL; the active agent in BAL is dimercaprol, a sulfhydryl-reducing agent. BAL was originally developed during World War II in response to the use of Lewisite, an As-based chemical warfare agent. Other dimercaprol derivatives are available for treatment, including DMSA (succimer) and dimercapto-1-propanesulfonic acid (DMPS), although the latter is not currently approved for As chelation therapy in the United States.

Preanalytical and Analytical Aspects

To distinguish among toxic inorganic species, high-performance liquid chromatography (HPLC) techniques for evaluating biological fluids and tissues have been developed. In general, a 24-hour urine specimen with measurable arsenic will have 95% present as the organic, nontoxic species and less than 5% present as the inorganic toxic species. Despite the availability of HPLC-ICP-MS methods for As speciation, it is noted that the use of a screening method for total As before speciation is of outstanding utility in reducing unnecessary costs.

Hair analysis is frequently used to document time of As exposure. Circulating in the blood, it will bind to protein by formation of a covalent complex with sulfhydryl groups of the amino acid cysteine. Because As has a high affinity for keratin, which has high cysteine content, the As concentration in hair or nails is greater than in other tissues. Several weeks after exposure, transverse white striae, called Mees lines, may appear in the fingernails, caused by denaturation of keratin by elements such as As, Cd, Pb, and Hg. Because hair grows at a rate of approximately 1 cm/month, hair collected from the nape of the neck can be used to document recent exposure. Axillary or pubic hair is used to document long-term (6 months to 1 year) exposure. Hair As greater than 1 $\mu\text{g/g}$ dry weight indicates excessive exposure, though reports vary for results determined in hair due to analytical, environmental, and dietary factors. In one study, the highest hair As observed was 210 $\mu\text{g/g}$ dry weight in a case of chronic exposure that was the cause of death.

The body treats As like phosphate, incorporating it wherever phosphate would be incorporated. Absorbed As is rapidly

circulated and distributed into tissue storage sites. Blood is the least useful specimen for identifying As exposure. Blood As concentrations are elevated for only a short time after administration and rapidly disappear into the large body phosphate pool. Abnormal blood As concentrations are detected for only a few hours (<4 hours) after ingestion. This test is useful only to document an acute exposure when the As is likely to be greater than 20 ng/mL (0.3 $\mu\text{mol/L}$) for a short period. Typically, serum As is less than 40 ng/mL (0.5 $\mu\text{mol/L}$).

Arsenic has been accurately measured by ICP-MS. Mass response from the argon plasma is monitored for As (mass-to-charge ratio [m/z] = 75); however, the method must reduce the potential for interference from argon chloride (m/z = 75) with the use of a dynamic reaction cell or collision cell with kinetic energy discrimination. For more details on the ICP-MS technology, refer to [Chapter 13](#). Urine is the sample of choice for As analysis because As is excreted predominantly by the kidney.

Regulatory and Occupational Exposure Aspects

Cardiovascular diseases and cerebrovascular effects are associated with chronic exposures to inorganic As compounds in the workplace. Inhalation exposures to inorganic As compounds have been correlated to an increased incidence of lung cancer. The American Conference of Governmental Industrial Hygienists (ACGIH) classifies As and its inorganic compounds as A1 carcinogens (confirmed human carcinogens). The recommended ACGIH Biological Exposure Index (BEI) for inorganic As plus methylated metabolites is less than 35 $\mu\text{g/L}$ (0.5 $\mu\text{mol/L}$) in an end-of-workweek urine sample after the exposure to As and soluble inorganic compounds (excluding gallium arsenide and arsine). After exposures to poorly soluble inorganic compounds, such as gallium arsenide, the urinary As concentration is more representative of the amount absorbed rather than the total dose inhaled or ingested.

Cadmium (Cd)

An appreciation for the toxicity of Cd extends back to 1858 and the observed GI and respiratory effects after exposure to Cd-containing polishing agents. Famously, Cd toxicity was at the center of itai-itai disease (Japanese for “Ouch-Ouch”), a bone disease associated with fractures and severe pain that was identified after World War II in Japan. No biological function has been identified for Cd in humans; however, Cd serves as a metal cofactor of Cd-carbonic anhydrase in diatoms.

Sources of Exposure

Cd is a by-product of zinc and lead smelting. It is used in industry in electroplating, in the production of rechargeable batteries, as a common pigment in organic-based paints, and in tobacco products. Spray painting of organic-based paints without the use of a protective breathing apparatus is a common source of chronic exposure. Auto repair mechanics are a work group that has significant opportunity for exposure to Cd.

Clinical Presentation and Treatment

Chronic exposure to Cd causes accumulated renal damage. Breathing the fumes of Cd vapors leads to nasal epithelial

deterioration and pulmonary congestion resembling chronic emphysema. Renal dysfunction with proteinuria of slow onset (over a period of years) is the typical presentation. Normal blood Cd concentration is less than 5 ng/mL (44 nmol/L), with most concentrations in the interval of 0.5 to 2 ng/mL (4 to 18 nmol/L). Moderately increased blood Cd (3 to 7 ng/mL or 27 to 62 nmol/L) may be associated with tobacco use. Acute toxicity is observed when the blood concentration exceeds 50 ng/mL (444 nmol/L). Usual daily excretion of Cd is less than 3 µg/day (0.03 µmol/day). Cd concentrations also increase with age and may be involved with senescence.

Preanalytical and Analytical Aspects

Collection of urine samples using a rubber catheter has been known to result in elevated results because rubber contains trace amounts of Cd that are extracted as urine passes through it. Brightly colored plastic urine collection containers should be avoided because the pigment in the plastic may be Cd-based. Cd has historically been quantified by atomic absorption spectrometry, and more recently by ICP-MS.

Regulatory and Occupational Exposure Aspects

Inhalation is the primary route of Cd exposure in the occupational setting, and the amount absorbed from the lungs depends on the solubility of the Cd compound and particle size. Absorption through the GI tract can occur from the clearance of particles deposited in the lungs and from contaminated hands and food. After chronic low-level exposures, approximately half of the Cd body burden is stored in the liver and kidneys. Urine is the main route of elimination, and thus urinary Cd levels are widely used to biomonitor chronic exposures in workers. However, because of the high binding capacity for Cd in the body, a urine level may provide no information about exposure in someone newly exposed to Cd. The lag time needed before the urinary Cd concentration correlates with exposure, depends on the intensity of the integrated exposure. Until sufficient time of chronic Cd exposure has passed before urine testing can be used appropriately (~1 year), blood testing is suggested for newly exposed workers or when changes in exposure occur, because blood levels primarily reflect recent exposures.

The exposure assessment of Cd in the US Occupational Safety and Health Administration (OSHA) Cadmium Standard is part of an overall periodic environmental, medical, and biological monitoring program. Biomonitoring requires testing of urine for both Cd and β_2 -microglobulin with standardization to grams of creatinine for each component (µg/g creatinine) and of blood for Cd with standardization to liters of whole blood (µg/L).

Chromium

Chromium (Cr), from the Greek word *chroma* ("color"), makes rubies red and emeralds green. Among its many uses, it is best known for its application in making stainless steel, which is resistant to corrosion and discoloration. The requirement of Cr for sugar and lipid metabolism has resulted in considerable debate on its potential role in insulin resistance.

Of late, Cr continues to make headlines as one of several metal ions released with wear because of highly publicized recalls of misaligned and accelerated failure rates of specific metal-on-metal (MoM) prosthetics.

Sources of Exposure

Occupational exposure to Cr represents a significant health hazard. Cr is used extensively (1) in the manufacture of stainless steel, (2) in chrome plating, (3) in the tanning of leather, (4) as a pigment in paints and dye for printing and textile manufacture, (5) as a cleaning solution, and (6) as an anticorrosive in cooling systems. The toxic form of Cr is hexavalent Cr^{6+} ($\text{Cr}[\text{VI}]$), and a strong oxidizing environment is required to convert the common form trivalent Cr^{3+} ($\text{Cr}[\text{III}]$) to Cr^{6+} . This can occur when Cr^{3+} is exposed to high temperatures in the presence of oxygen or during high-voltage electroplating.

Considerable attention has been given to Cr toxicity after release of Cr ions during normal and abnormal wear of MoM prosthetics. However, the vast majority of Cr released from MoM prosthetics has been shown to be in the trivalent form, which is considerably less toxic than hexavalent Cr. In May 2011, the US Food and Drug Administration (FDA) issued orders for postmarket surveillance studies to manufacturers of MoM hip replacement systems in response to increasing concern over failed implant devices reported in Europe. In the United States, no guidelines have been established for the assessment of metal ions in asymptomatic patients because of a lack of knowledge regarding the prevalence of adverse events in the US population and no clear threshold levels associated with an adverse event.

Clinical Presentation and Treatment

Symptoms associated with Cr toxicity vary based on the route of exposure, Cr species, and dose, and may include dermatitis, impairment of pulmonary function, gastroenteritis, hepatic necrosis, bleeding, and acute tubular necrosis. In the case of failing MoM prosthetics, elevated Cr in serum or blood is rarely the initial finding and instead is preceded by more telling physical symptoms such as reduced range of motion, swelling and inflammation around the joint, and general discomfort or pain. Although offered by many laboratories, measurement of Cr in joint fluid has relatively little clinical utility.

Preanalytical and Analytical Aspects

Use of a plastic cannula for blood sampling was shown to be unnecessary in the assessment of Cr; however, sporadic contamination from stainless steel needles was observed. Quantification of total Cr in urine can be used to assess exposure to all forms of Cr. The presence of Cr in erythrocytes is suggestive of exposure to Cr^{6+} within the past 120 days, because Cr^{6+} crosses biological membranes but Cr^{3+} does not. Increased serum Cr concentrations are observed in association with orthopedic implants made from Cr alloys. ICP-MS is the preferred technology for quantification of Cr in body fluids but suffers from considerable interference because of polyatomics. Use of dynamic reactive cell technology or a

collision cell with kinetic energy discrimination is required for reproducible and accurate measurements.

Regulatory and Occupational Exposure Aspects

Industrial Cr exposures can involve trivalent and hexavalent forms, which exhibit different toxicokinetics and toxicities in the body. Urine Cr levels are the most useful biomarker for assessing occupational exposure to water-soluble hexavalent Cr compounds; however, other nonoccupational sources of both trivalent and hexavalent Cr from the diet, supplements, and the environment can contribute to the total Cr concentration in urine. Furthermore, because Cr has been shown to accumulate in the body, urine Cr levels can be affected by both recent and past workplace exposures. The measurement of Cr in erythrocytes has been used to gauge the intensity of exposure to hexavalent Cr; however, insufficient data are available to determine a relationship between erythrocyte Cr levels and the risks associated with exposures.

Occupational exposures to hexavalent Cr compounds can cause respiratory irritation and tissue damage of the nose, throat, and lungs after inhalation, and can cause irritation, burns, and ulcers on the skin with contact. Hexavalent Cr has been associated with cancers of the lungs, nose, and nasal sinuses, and is classified as a human carcinogen by the Internal Agency for Research on Cancer. Hexavalent Cr compounds are categorized as human carcinogens by the ACGIH (A1) and the German Research Foundation (DFG) in Germany (category 1). The ACGIH suggests testing total Cr in urine for workplace exposure to hexavalent Cr (water-soluble fumes).

Cobalt

The word cobalt (Co) is derived from the German *kobalt* meaning “goblin” because of its superstitious reputation among miners. Cobalt is widely distributed in the environment, is the essential cofactor in vitamin B₁₂, and has been widely used throughout history for decorative accents to glass and ceramics.

Sources of Exposure

Although relatively rare, Co is widely distributed in nature and is found in green vegetables, animal foods, and seafood. Of the Co in the body, 85% is in the form of cyanocobalamin or vitamin B₁₂, a Co complex similar in structure to that of porphyrins. Cobalt is used in alloys in which the presence of Co results in high melting point, strength, and resistance to oxygen. The addition of Co in MoM prosthetics adds resistance to surfaces undergoing heavy wear, and the release of Co from failed prosthetics remains of outstanding concern. Cobalt is found in rechargeable batteries and provides color to plastics, inks, glass, and paint.

Clinical Presentation and Treatment

Cobalt is not highly toxic, but large exposures will produce pulmonary edema, allergy, nausea, vomiting, hemorrhage, and renal failure. Occupational exposure occurs during production and machining of metal alloys and has been known to result in interstitial lung disease. Cardiomyopathy and

renal failure are symptomatic of acute Co exposure; this was exemplified by an incident of mass population exposure to Co when beer contaminated with cobalt salts was consumed. Chronic exposure may cause pulmonary syndrome, skin irritation, allergy, GI irritation, nausea, cardiomyopathy, hematologic disorders, and thyroid abnormalities. Cobalt exposure alone may not lead to toxicity and must be considered within the context of exposure to multiple elements.

Serum Co concentrations are increased above normal ($>1 \mu\text{g/L}$ or $>17 \text{ nmol/L}$) in patients with well-positioned and functioning orthopedic implants made from Co alloys. Considerable attention has been given to Co toxicity in the context of failed MoM prosthetics, with several case reports of severe neurologic and cardiac abnormalities described. In the case of failing MoM prosthetics, elevated Co in serum or blood is rarely the initial finding and instead is preceded by more telling physical symptoms such as reduced range of motion, swelling and inflammation around the joint, and general discomfort or pain. Although offered by many laboratories, measurement of Co in joint fluid has relatively little clinical utility.

Preanalytical and Analytical Aspects

Quantification of active vitamin B₁₂ is the usual way to assess nutritional status; quantification of serum, blood, or urine Co concentration is not typical for assessing vitamin B₁₂ status. Cobalt deficiency has not been reported in humans. Quantification of Co in urine or biological specimens is accomplished by atomic absorption spectrometry or by ICP-MS.

Regulatory and Occupational Exposure Aspects

Absorption of Co through the lungs from inhalation of dust and fumes is the primary route of exposure in occupational settings, but absorption from dermal contact can occur. Pulmonary absorption of the inhaled Co depends on the particle size and its solubility, with smaller particles deposited in the lower respiratory tract, where they dissolve or are phagocytized and translocated. After inhalation, Co is eliminated from the body in several phases with a relatively rapid initial phase having a half-life ranging from hours to a few days and subsequent slower phases with half-lives ranging from months to years. Cobalt concentrations in urine increase proportionally more than in the blood of workers during Co exposures; Co concentrations in urine are primarily affected by recent exposures, but increase through the workweek under stable exposure conditions.

The skin and respiratory tract are the two main target organs in workers exposed to cobalt metal, cobalt salts, and cobalt-containing dusts. Contact of Co with the skin can cause mild irritation and allergic reactions. Inhaled cobalt dust and fumes can cause shortness of breath. Respiratory symptoms after chronic inhalation of Co can range from cough to respiratory hypersensitivity, progressive dyspnea, decreased pulmonary function, permanent disability, and death. Pathogenic lesions in the parenchymal regions of the lungs, known as “hard metal disease,” can lead to severe

alveolitis that progresses to end-stage pulmonary fibrosis. In the hard metal industry, the coexposure to tungsten and Co has proved more toxic than metallic Co alone.

Lead

Lead (Pb) has been used extensively throughout history, but use has been drastically reduced in the last few decades as a result of a better appreciation for its toxicity, especially during early childhood development.

Sources of Exposure

Lead is present at high concentration (up to 35% w/w) in many paints manufactured before 1972. The Pb content of paints intended for household use was limited to less than 0.5% in 1978, but Pb is still found in paint products intended for non-domestic use and in artists' pigments. Ceramic products for use in homes available from noncommercial suppliers (e.g., local artists) have been known to contain significant amounts of Pb; Pb is leached from the products by weak acids such as vinegar and fruit juices. Leaded crystal contains up to 10% Pb, which is leached during long-term storage of fluids such as fruit juice, wine, and spirits. Lead is also found in dirt from areas adjacent to homes painted with Pb-based paints, in soil near abandoned industrial sites, and on highways where it has accumulated from the use of leaded gasoline in automobiles. Use of leaded gasoline has diminished significantly since the introduction of unleaded gasoline, which has been required in personal automobiles in the United States since 1978. Water transported through Pb or Pb-soldered pipes contains some Pb, with higher concentrations found in water that is weakly acidic. Some foods (e.g., moonshine distilled in Pb pipes) and some traditional home medicines also contain Pb. Exposure to Pb from any of these sources by ingestion, inhalation, or dermal contact has been known to cause significant toxicity.

Clinical Presentation and Treatment

The development of Pb toxicity follows a progressive pattern. Fig. 32.2 describes this progression through a series of symptoms.

The finding that Pb contributes significantly to decreased intellectual capability in the very young is of particular concern. Young children are particularly prone to the effects of Pb because they have greater opportunity for exposure. Children tend to spend a lot of time on the floor. In older homes that have been previously treated with Pb-based paints, Pb-laden paint chips and dust accumulate on the floor, which children are likely to ingest. The Centers for Disease Control and Prevention (CDC) has continued to lower the suggested normal limit for children and is now recommending 5 µg/dL (0.24 µmol/L) based on the 97.5% percentile of nonexposed children. In addition, the term *blood lead level of concern* has been abandoned in favor of the viewpoint that all Pb is potentially harmful and therefore unsafe.

The World Health Organization (WHO) has defined blood Pb concentrations greater than 30 µg/dL (1.5 µmol/L) in adults as indicative of significant exposure. Pb concentrations above 60 µg/dL (2.9 µmol/L) require chelation therapy.

Fig. 32.2 Effects of inorganic lead on children and adults (lowest observable adverse effect concentrations). (Reprinted with permission from Royce, S. E., & Needleman, H. L., [Eds.], *Case studies in environmental medicine: lead toxicity*. Washington, DC: US Public Health Service, Agency for Toxic Substances and Disease Registry; 1990.)

Similar to the situation seen in children, adult blood Pb concentrations have dropped to a mean value of 1.4 µg/dL (0.07 µmol/L) for ages 20 to 49 and a mean value of 1.9 µg/dL (0.09 µmol/L) for ages 50 to 69.

Avoidance of continued exposure to Pb is paramount when blood Pb concentrations exceed acceptable reference intervals. Oral dimercaprol has become a standard therapy and is being used in the outpatient setting for all except those with the most severe Pb poisoning. Although chelation therapy is effective in reducing blood Pb concentrations, a 2003 study indicated that chelation therapy given to preschool children with Pb concentrations in the range of 20 to 44 µg/dL (1 to 2.1 µmol/L) showed no beneficial effect on tests of cognition or behavior. Thus, prevention is the best therapeutic option.

Preanalytical and Analytical Aspects

The definitive test for Pb toxicity is measurement of blood Pb. Analysis of Pb is routinely performed by ICP-MS,

electrothermal atomic absorption spectrometry, or anodic stripping voltammetry. Because Pb is concentrated in the erythrocytes, EDTA-anticoagulated blood is the specimen of choice for Pb analysis. Sodium heparin may also be used; however, samples that are not analyzed within 48 hours are frequently clotted and must be rejected. Care must be taken when obtaining capillary blood. Surface contamination, insufficient collection volume, or inadequate mixing with EDTA results in frequent sample rejection. Urinalysis can also be performed; urine quantification correlates with exposure.

If ICP-MS is used to measure Pb concentrations, it is essential to sum the masses of 206, 207, and 208 m/z to account for the natural isotopic variation of Pb in the environment. Failure to sum masses will skew results above or below the actual concentration because the isotopic abundance of a particular mass in the calibrator might not match the sample. However, this isotopic variation has been exploited to determine the source of Pb exposure. By determining the relative abundances of Pb in blood and of potential sources of exposure (e.g., paint chips, soil), it is possible to identify a matching pattern. The exposure source with the same ratio of major Pb isotopes as that of the blood should then be avoided or removed from the patient's environment.

Regulatory and Occupational Exposure Aspects

Biomarkers of exposure and biomarkers of effect have been used in assessing occupational Pb exposures. The direct measurement of Pb in blood reflects the concentration of Pb in the soft tissues at steady state, and therefore is an indicator of recent exposures. Most of the Pb body burden is stored in bones, so the bone Pb concentrations are a good indicator of cumulative or long-term exposures. X-ray fluorescence techniques are used to measure Pb levels in bone.

Exposures to Pb have been found to cause encephalopathy, peripheral neuropathy, neurologic and neurobehavioral effects, renal effects, hypertension, and reduced fertility. Because of these adverse effects, OSHA has enacted standards to assess inorganic Pb exposure in the workplace. Workers with a single blood Pb level meeting the numerical criteria for medical removal must have their blood Pb level retested within 2 weeks. If a worker is medically removed, a new blood Pb level must be measured monthly during the removal period. Workers are permitted to return to work when their blood Pb level is 40 $\mu\text{g}/\text{dL}$ (1.9 $\mu\text{mol}/\text{L}$) or less according to current guidelines.

According to the OSHA Lead Standards, measurement of zinc protoporphyrin (ZPP) is required on each occasion that a blood Pb measurement is made. OSHA recommends a hematocrit determination to exclude anemia whenever a confirmed ZPP of 50 $\mu\text{g}/100\text{ mL}$ (0.8 $\mu\text{mol}/\text{L}$) is obtained. Zinc protoporphyrin levels in excess of 100 $\mu\text{g}/100\text{ mL}$ (80 $\mu\text{mol}/\text{L}$) are considered elevated. However, ZPP is an insensitive biomarker for blood Pb levels less than approximately 20 $\mu\text{g}/\text{dL}$ or 1 $\mu\text{mol}/\text{L}$.

Mercury

Mercury's elemental symbol, Hg, is derived from the Greek word *hydrargyros*, meaning "water silver," and is commonly

referred to as quicksilver. Mercury is one of only two elements that are liquid at standard temperature and pressure (the other is bromine). The various forms of Hg have remarkably different toxicity profiles from largely benign unless inhaled (elemental Hg), to highly toxic (Hg salts and organic forms). The phrase "mad as a hatter" was first used in reference to the Hg-induced dementia seen in workers with chronic exposure to Hg in the production of felt for hats.

Sources of Exposure

Mercury is widely found in the environment and occurs both naturally and as the result of industrial processes, with the single largest source of Hg being its natural out-gassing from granite rock. Mercury is also found in deposits throughout the world, mostly as cinnabar (mercuric sulfide), which is the source of the red pigment vermilion.

In the past, Hg was extensively used in the manufacture of devices such as thermometers, barometers, manometers, and sphygmomanometers. However, concerns about its toxicity have resulted in the phasing out of Hg-based instruments, which have been replaced with alcohol-filled, digital, or thermistor-based versions. It is still used as a dental amalgam and in lighting as mercury vapor lamps, although these are being replaced by sodium vapor bulbs. Mercury is used in the pulp and paper industry as a whitener, as a catalyst in the synthesis of plastics, and as a potent fungicide in antifouling and latex paints.

Chemically, it is possible to convert Hg from its elemental state to its ionized state; in industry, this is frequently accomplished by exposing Hg^0 to a strong oxidant, such as chlorine. Elemental Hg is also bioconverted to both Hg^{2+} and alkyl Hg by microorganisms that exist in the normal human gut and in the bottom sediment of lakes and rivers. When Hg^0 enters bottom sediment, it is absorbed by bacteria, fungi, and related microorganisms; these organisms metabolically convert it to Hg^{2+} , CH_3Hg^+ , $\text{CH}_3\text{CH}_2\text{Hg}^+$, and similar species. Consequently, the methyl mercurials are accumulated in the aquatic food chain and reach their highest concentrations in predatory fish. The normal bacterial flora present in the mouth converts a fraction of Hg^{2+} to CH_3Hg^+ ; the latter has been shown to be incorporated into body tissue. As a consequence of accumulation of methylmercury in the aquatic food chain, most human exposure to Hg happens through the eating of contaminated fish, shellfish, and sea mammals. For example, commercially distributed fish considered safe for consumption contain less than 0.3 $\mu\text{g}/\text{g}$, but some game fish contain more than 2 $\mu\text{g}/\text{g}$ and, if consumed on a regular basis, contribute to significant body Hg loads.

In the late 1980s, the public became concerned about exposure to Hg from dental amalgams. However, later studies have failed to confirm a causal relationship. Basic to the initial concerns was the fact that restorative dentistry used an Hg-silver amalgam for approximately 90 years as a filling material. In 1989, Hahn and colleagues showed that a small (2 to 20 $\mu\text{g}/\text{day}$) release of Hg^0 from amalgam occurs when it is mechanically manipulated, such as by chewing. In addition, the habit of gum chewing can cause release of Hg from dental

amalgams in even larger amounts. In 2010, the FDA issued rules that classify dental amalgam, reclassify dental mercury, and specify special controls for dental amalgam, mercury, and amalgam alloy.

Concerns have been raised about the possible relationship between Hg exposure from vaccines and autistic disorders. In the United States, the prevalence of autism has risen from 1 in approximately 2500 in the mid-1980s to 1 in approximately 300 children in the mid-1990s. Some investigators believe that this rise occurs because of the Hg that is present in vaccines as the preservative thimerosal (sodium ethyl mercury thiosulfate). However, this causality has been questioned by numerous other studies, which have not been able to confirm this relationship. In 2001, the Committee on Immunization Safety Review of the Board on Health Promotion and Disease Prevention of the Institute of Medicine initiated a study to review the connection between Hg-containing vaccines and neurodevelopmental disorders, including autism. The Committee reported that the hypothesis was biologically plausible, but that evidence was insufficient to accept or reject a causal connection. The findings of this report have been challenged, and thimerosal has been removed from most vaccines in the United States. The evidence linking Hg exposure from vaccines with autistic disorders has been highly criticized and resulted in the journal *Lancet* retracting the article linking autism to measles, mumps, and rubella (MMR) vaccines.

Historically, Hg-containing compounds have been used for therapeutic reasons. For example, Hg has been used in medications that were touted as cures for syphilis and dysentery, to treat constipation, and as diuretics. Intriguingly, the use of Hg-containing laxatives, termed “Thunder Clappers,” on the Corps of Discovery Expedition with Lewis and Clark has left a discoverable trail of their movements, in more ways than one!

Clinical Presentation and Treatment

Each form of Hg manifests differently after a toxic exposure. For elemental Hg, poor absorption in the GI system reduces toxicity but can result in GI distress with prolonged contact or deposition. With repeated injections of elemental Hg, seen in suicide attempts or psychiatric patients, the presentation was predominantly pleuritic chest pain, with other classic Hg-associated symptoms being absent. Common target organs with inorganic Hg poisoning include the GI system, kidneys, and brain.

Experience with Hg poisoning has been gained from investigation of the 1951 to 1963 industrial dumping of Hg-laden waste sludge into Minamata Bay, Japan. Fish in Minamata Bay became heavily laden with Hg through the food chain. The local human population, whose diet depended on fish from the bay, exhibited symptoms of methylmercury poisoning including ataxia, impaired speech, visual field constriction, hearing loss, and somatosensory change, characterized histologically by cerebral cortex necrosis; this is collectively known as Minamata disease.

In adults, cases of methylmercury poisoning are characterized by the focal degeneration of neurons in regions

of the brain such as the cerebral cortex and the cerebellum. Depending on the degree of in utero exposure, methylmercury may result in effects ranging from fetal death to subtle neurodevelopmental delays. Consequently, because pregnant women, women of child-bearing age, and young children are particularly at risk, the FDA recommends that they avoid eating shark, swordfish, mackerel, and tilefish.

Preanalytical and Analytical Aspects

Analysis of blood, urine, and hair for Hg concentrations is used to determine exposure. The quantity of Hg found in blood and urine correlates with the degree of toxicity, although the form of Hg can negatively affect the reliability of the relationship. Hair analysis has been used historically to document the time of peak exposure. However, it should be noted that hair analysis for elements in general is difficult because of contamination. Normal whole-blood Hg concentration is usually lower than 10 µg/L (49 nmol/L). Treatment with BAL or penicillamine will mobilize Hg, allowing for its excretion in the urine. Therapy is usually monitored by following urinary excretion of Hg; therapy may be terminated after the daily urine excretion rate falls below 50 µg/L (249 nmol/L).

Regulatory and Occupational Exposure Aspects

In industry, elemental Hg is present in the air as a vapor and its inorganic salts are present as aerosols. Inhalation is the primary route of uptake from occupational exposures to Hg, although dermal absorption can also occur. Once absorbed, some elemental Hg is oxidized to the divalent form, which can bind to sulfhydryl groups in proteins such as albumin and metallothionein. Elemental Hg is mainly distributed to the kidney and brain, whereas inorganic Hg salts are mostly delivered to the kidney. Mercury is eliminated primarily through the feces and urine. Initially after exposure, more Hg may be eliminated in the feces than in the urine. This may be due to the presence of binding sites in the kidneys. The half-life of Hg in urine is approximately 40 days. Therefore the Hg levels in urine do not necessarily reflect recent exposures in newly exposed workers.

Urinary Hg concentrations are primarily used to monitor long-term exposures to elemental Hg and its inorganic salts, whereas blood Hg concentrations are mainly useful for short-term, higher-level exposures of these compounds. Urine is the preferred specimen for biological monitoring of workplace exposure to elemental Hg and its inorganic compounds, because Hg levels in blood can be affected by the presence of organic Hg compounds from the consumption of dietary fish. Because biological monitoring in urine reflects long-term Hg exposures, the airborne exposure levels and urinary Hg concentration can be correlated, provided the exposures are relatively constant over a sufficiently long period, sample collection is standardized, and biomonitoring is initiated at least 6 months after exposure begins.

Nickel

Found in coins since the mid-19th century, nickel (Ni) remains valuable for its corrosion resistance in plating, but is

often found at the center of reports involving hypersensitivity and allergic reactions to a wider range of products from cell phones to belt buckles.

Sources of Exposure

Ni is frequently used in the production of metal alloys (which are popular for their anticorrosive and hardness properties), in Ni-based rechargeable batteries, and as a catalyst in the hydrogenation of oils. Ni alloyed with transition metals is considered nontoxic, except that it will induce inflammation at the point of contact. Nickel carbonyl ($\text{Ni}[\text{CO}]_4$), used in petroleum refining, is one of the most toxic chemicals known to humans.

In nonindustrial settings, Ni is found in a wide variety of consumer products, including utensils, jewelry, eyeglass frames, clothing buttons, braces, orthopedic implants, and some varieties of cell phones. Despite its incorporation into MoM prosthetics and increased concern with failed MoM devices (see earlier section on “Chromium”), Ni has not been implicated as a significant contributor to the associated clinical presentation.

Clinical Presentation and Treatment

Contact dermatitis is the symptom often associated with Ni exposure in the nonoccupational setting. Ni allergy is the most common contact allergen in women because of its ubiquitous use in jewelry and cosmetic products. Patch test studies have demonstrated a strong dose-response relationship between degree of exposure and severity of symptoms.

Patients exposed to Ni carbonyl exhibit rapid onset of pulmonary congestion and inability to oxygenate hemoglobin, followed by development of lesions of the lung, liver, kidney, adrenal glands, and spleen. Patients undergoing dialysis are exposed to Ni and accumulate Ni in blood and other organs.

Preanalytical and Analytical Aspects

Use of a plastic cannula for blood sampling was shown to be unnecessary in the assessment of Ni; however, sporadic contamination from stainless steel needles was observed.

Regulatory and Occupational Exposure Aspects

Workplace exposures to various forms of Ni occur in a variety of industrial processes. Exposure to sparingly soluble Ni compounds, such as nickel sulfide, nickel oxide, nickel carbonate, and nickel sulfidic ores, generally occurs during the mining of nickel ores, the smelting and refining processes, and the grinding and welding of Ni-containing alloys. The electroplating industry is usually the main source of workplace exposures to soluble forms of Ni such as nickel acetate, nickel chloride, nickel hydroxide, and nickel sulfate. Exposure to nickel carbonyl (or nickel tetracarbonyl), an easily absorbed and highly toxic form of Ni, likely occurs in Ni refining, nickel coatings, plating glass, and as a catalyst in chemical reactions.

Occupational Ni exposure mainly occurs by inhalation of dusts from sparingly soluble Ni compounds, aerosols from soluble Ni solutions, or gaseous Ni generally from nickel carbonyl. Skin contact with airborne Ni and Ni-containing

solutions is also possible, as is oral ingestion in facilities with poor industrial hygiene practices and workers who practice poor personal hygiene. The solubility of the Ni compound will affect the toxicokinetics of Ni in the body. Soluble Ni compounds are more rapidly absorbed and eliminated compared to the poorly soluble forms. Inhaled particles of sparingly soluble Ni compounds can be retained in the lung tissue and regional lymph nodes, where they can accumulate and gradually be released over time. The major elimination route for absorbed Ni is through the kidneys and into the urine.

The toxicities of most significance after occupational exposure to Ni are the allergenic and carcinogenic effects. Ni exposure can cause sensitization of the skin (e.g., contact dermatitis) and respiratory tract. Occupational exposure to Ni compounds can also increase the risk for lung and nasal cancer in workers. The International Agency for Research on Cancer (IARC) classifies Ni compounds as human carcinogens (group 1). Biological monitoring of Ni concentrations in body fluids after occupational Ni exposure has been extensively studied in workers, and Ni concentrations in body fluids are affected by the chemical species of the Ni to which the individual was exposed, and the time of sample collection. In general, except for exposure to nickel carbonyl, urinary Ni levels can be useful in assessing the severity of the poisoning. However, elevated Ni concentrations in body fluids may not be directly correlated to exposure levels or risk for disease and only provide information about Ni uptake.

Thallium

Thallium (Tl) is often referred to as the “poisoner’s poison” because it is nearly tasteless and highly toxic in low doses. Isotopes of Tl are used in diagnostic imaging and were once used medicinally to treat ringworm.

Sources of Exposure

Thallium is a by-product of zinc and lead smelting and cadmium production. Interest in Tl derives primarily from its former use as a rodenticide, with accidental exposure the most likely reason for toxicity. Acute and often fatal poisoning has been reported after criminal use and suicide attempts. Additionally, environmental concerns are growing because Tl is a waste product of coal combustion and the manufacturing of cement. Thallium is used in photoelectric cells, lamps, semiconductors, and scintillation counters.

Clinical Presentation and Treatment

The clinical presentation of Tl toxicity varies based on dose, age, and acute or chronic exposure. Patients exposed to high doses of Tl (>1 g) demonstrate alopecia (hair loss), peripheral neuropathy, seizures, and renal failure. Peripheral neuropathy of the feet and less commonly the hands occurs within 1 week after exposure, and hair loss begins at the same time and continues for several weeks. GI symptoms, including pain, diarrhea, and constipation have been reported in acute ingestion, in addition to myalgias, pleuritic chest pain, insomnia, optic neuritis, hypertension, cardiac abnormalities, Mees lines, and liver injury.

Preanalytical and Analytical Aspects

Typical serum concentrations in the absence of significant exposure are less than 10 ng/mL (49 nmol/L), and daily urine excretion is less than 10 µg/day (49 nmol/day). Exposed patients have been observed to have serum concentrations as high as 50 ng/mL (245 nmol/L), with urine output in excess of 500 µg/day (2446 nmol/day). Tl is routinely measured by ICP-MS in blood and urine.

Regulatory and Occupational Exposure Aspects

Urine is the suggested specimen for biological monitoring of Tl. Although there is insufficient information available

correlating occupational exposure levels and urinary Tl concentrations to establish a threshold value, the biological monitoring of Tl in urine can assist in assessing the effectiveness of workplace control measures, especially because the ACGIH gives Tl and Tl compounds a “skin” notation designating the potential for a significant contribution to the overall exposure by the cutaneous route. For exposures to Tl and inorganic Tl compounds, the Finnish Institute of Occupational Health (FIOH) has no established biomonitoring action limit but recommends testing for Tl in a post-shift urine specimen.

REVIEW QUESTIONS

1. An individual has eaten a large meal of seafood including shellfish and haddock before submitting a urine specimen for metal analysis. What metal would likely be present in a high concentration in his urine specimen?
 - a. Arsenic
 - b. Copper
 - c. Mercury
 - d. Cadmium
2. Lead inhibits _____, an enzyme that catalyzes synthesis of heme from porphyrin.
 - a. ATPase
 - b. RNA polymerase
 - c. glutathione peroxidase
 - d. aminolevulinic acid dehydratase
3. Which of the following reasons best explains why elemental toxicity is difficult to diagnose?
 - a. Physicians are poorly informed about prevalence of toxic elements.
 - b. Laboratories are unable to properly test for toxic elements.
 - c. Signs and symptoms in elemental toxicity mirror numerous disease states.
 - d. Elemental toxicity is relatively rare in developed countries.
4. Analysis of toxic elements is recommended in which of the following presentations?
 - a. Renal disease due to chronic hypertension
 - b. Unexplained, bilateral neuropathy
 - c. Chronic inflammation of the liver
 - d. No history of exposure on record
5. Which of the following correctly identifies an accepted approach to elemental exposure?
 - a. Wait and see if symptoms become more severe
 - b. Prospective chelation challenges with postchelation laboratory assessments
 - c. Enhanced absorption
 - d. Antidotal treatment
6. The toxicity of Cd, As, Hg, and Pb are similar in regard to damage of which organ?
 - a. Eye
 - b. Kidney
 - c. Pancreas
 - d. Distal phalanges
7. Which element in its hexavalent state is toxic while in its trivalent state is considered largely benign?
 - a. Cr
 - b. Hg
 - c. Pb
 - d. As
8. Which element in its elemental state is largely benign unless inhaled while its inorganic form is the basis for the phrase “mad as a hatter”?
 - a. As
 - b. Cr
 - c. Pb
 - d. Hg
9. Regarding Ni exposure, _____ Ni compounds are more rapidly absorbed and eliminated compared to the _____ forms.
 - a. soluble, gaseous
 - b. insoluble, soluble
 - c. soluble, less soluble
 - d. alloyed, pure
10. The measurement of biological samples from a worker for elements found in a workplace following occupational exposure assesses which of the following?
 - a. The air concentration of the measured element
 - b. The nutritional status of the worker
 - c. The worker's ability to schedule time off
 - d. The effectiveness of environmental control strategies used in the workplace

Diabetes Mellitus

David B. Sacks

OBJECTIVES

- Define the following:
 - Advanced glycation end product
 - Albuminuria
 - C-peptide
 - Diabetes mellitus
 - Epinephrine
 - Fatty acid
 - Fructosamine
 - Gestational diabetes mellitus
 - Glucagon
 - Glucose tolerance
 - Glycated albumin
 - Glycated hemoglobin
 - Hemoglobin A_{1c}
 - Hyperglycemia
 - Insulin
 - Insulin-like growth factor 1
 - Insulin resistance syndrome
 - Ketoacidosis
 - Ketone bodies
 - Proinsulin
- Compare and contrast type 1 and type 2 diabetes mellitus including the following:
 - Causes
 - Symptoms
 - Insulin concentration in blood
 - Appearance of symptoms versus clinical diagnosis
 - Development of chronic complications
 - Genetic factors
- Compare impaired glucose tolerance with impaired fasting glucose and the usefulness of these classifications as risk factors for diabetes and cardiovascular disease.
- List the three important functions of insulin.
- Summarize how the following hormones specifically affect blood glucose concentration: insulin, glucagon, epinephrine, cortisol, somatostatin, and growth hormone.
- Briefly describe the function of the facilitative glucose transporters, including the importance of GLUT4 in glucose uptake by skeletal muscle.
- List five antibodies that are involved in the pathogenesis of type 1 diabetes mellitus.
- Describe insulin resistance and the role it plays in the pathogenesis of type 2 diabetes mellitus; explain how loss of β -cell function results in development of type 2 diabetes mellitus.
- State how diet and exercise are related to development of type 2 diabetes mellitus.
- State the basic criteria for the diagnosis of diabetes mellitus including fasting and random plasma glucose concentration, oral glucose tolerance test, and glycated hemoglobin results.
- Outline the procedure for and interpretation of an oral glucose tolerance test for the diagnosis of type 2 diabetes mellitus, impaired glucose tolerance, and gestational diabetes mellitus.
- Summarize the role of the clinical laboratory in the diagnosis and short- and long-term management of diabetes mellitus.
- Describe the assay principles of a whole blood glucose meter; calculate the difference between whole blood and plasma glucose concentrations.
- List five variables that affect the accuracy and reproducibility of blood glucose meters; state how dehydration affects the reliability of a blood glucose meter.
- Describe a typical implanted sensor for monitoring blood glucose including assay method, calibration, and usefulness in a person with type 1 diabetes.
- Discuss the metabolic relationships among glucose, ketones, fatty acids, and metabolic acids including how they are altered, the effects of increased counterregulatory hormones, and the clinical significance of ketonemia and ketonuria in uncontrolled diabetes mellitus.
- Describe the glycation of hemoglobin; state the percentage of hemoglobin A₁ constituted by A_{1c}.

18. Explain how measurement of glycated hemoglobin is useful in the diagnosis and monitoring of diabetes; state the cutoff value of hemoglobin A_{1c} used to diagnose diabetes.
19. Specify the effects that young and old erythrocytes have on hemoglobin A_{1c} values.
20. List and discuss three techniques used to determine hemoglobin A_{1c} values including principles of analysis, possible interference by hemoglobin variants, and specimen requirements.
21. Describe the effects of hyperglycemia on advanced glycation end products and how these end products contribute to certain complications of diabetes.
22. State how urinary albumin excretion is useful in determining diabetic nephropathy; list the specimen collection requirements for this urine test.
23. Describe three semiquantitative analyses of urinary albumin.
24. State the healthy reference intervals used for fasting plasma glucose, oral glucose tolerance, and hemoglobin A_{1c} analyses.
25. Analyze and solve case studies related to the different types of diabetes and impaired glucose tolerance using descriptions of symptoms and results of laboratory analyses.

KEY WORDS AND DEFINITIONS

Advanced glycation end products (AGEs) Proteins that have been irreversibly modified by nonenzymatic attachment of glucose; may contribute to the chronic complications of diabetes.

Diabetes mellitus A group of metabolic disorders of carbohydrate metabolism in which glucose is underutilized, producing hyperglycemia.

Gestational diabetes mellitus (GDM) Carbohydrate intolerance with onset during pregnancy.

Glucose A six-carbon simple sugar that is the premier fuel for most organisms and an important precursor of other body constituents.

Glycated hemoglobin Hemoglobin that has a sugar residue attached; HbA_{1c} is the major fraction of glycated hemoglobin.

Glycogen A polysaccharide with a formula of (C₆H₁₀O₅) used by muscle and liver for carbohydrate storage.

Hyperglycemia Increased glucose concentrations in the blood.

Hypoglycemia Decreased glucose concentrations in the blood.

Insulin A protein hormone produced by β-cells of the pancreas that decreases blood glucose concentrations.

Ketones Compounds that arise from free fatty acid breakdown; insulin deficiency leads to increased serum ketones, which are the major contributors to the metabolic acidosis that occurs in individuals with diabetic ketoacidosis.

Diabetes mellitus is a group of metabolic disorders characterized by **hyperglycemia** resulting from defects in **insulin** secretion, insulin action, or both. Some patients may experience acute life-threatening hyperglycemic episodes, such as ketoacidosis or hyperosmolar coma. Acute life-threatening hypoglycemic episodes may occur as a result of therapy. As the disease progresses, patients are at increased risk for the development of specific complications, including *retinopathy* leading to blindness, *nephropathy* leading to renal failure, and *neuropathy* (nerve damage), collectively known as microvascular complications, as well as *atherosclerosis*, which is considered a *macrovascular complication*. The last may result in stroke, gangrene, or coronary artery disease.

Diabetes is a common disease, although the exact prevalence is unknown. The number of people with diabetes has increased dramatically worldwide. It is estimated that approximately 380 million people currently have diabetes, and by 2035 this number is predicted to reach 592 million, 80% of whom will live in low- and middle-income countries. In the United States, the prevalence in 1999–2002 was 9.3% and by 2005–2006, this had increased to 12.9% (equivalent to ≈40 million people). Similarly, the prevalence of diabetes

in Asian populations has increased rapidly in recent decades, with China and India ranked first and second, respectively, among countries with the largest diabetic populations. Recent analysis in Chinese adults suggests that in 2010 the estimated prevalence of diabetes and prediabetes was 11.6% and 50.1%, respectively, which is equivalent to 113.9 million persons with diabetes and 493.4 million with prediabetes. The prevalence varies widely among countries, reaching as high as 25% in the Middle East and 35% in the Western Pacific. Further statistics about individual countries, compiled by the International Diabetes Federation (IDF), can be found at <http://www.diabetesatlas.org/>. These data led to a description of diabetes as “one of the main threats to human health in the twenty-first century.” It is estimated that approximately 50% of individuals with diabetes worldwide remain undiagnosed. The prevalence of undiagnosed diabetes in the United States was reduced to 11% between 2006 and 2010 and has remained fairly stable in recent years. The prevalence of diabetes mellitus increases with age, and approximately half of all cases occur in people older than 55 years. In the United States, more than 20% of the population older than 65 years have diabetes. A racial predilection has been noted, and by the age

of 65, 33%, 25%, and 17% of Hispanics, blacks, and whites, respectively, in the United States have diabetes. In 2012, diabetes mellitus was estimated to be responsible for \$245 billion in healthcare expenditures in the United States. The estimated economic burden for undiagnosed diabetes, prediabetes, and **gestational diabetes mellitus (GDM)** in 2012 was \$78 billion, producing a total economic burden of more than \$322 billion. Worldwide diabetes caused at least \$612 billion in health expenditures and an estimated 4.9 million deaths in 2014. Acute and chronic complications make diabetes the fourth most common cause of death in the developed world.

CLASSIFICATION

Diabetes was initially diagnosed by the oral glucose tolerance test (OGTT). The 1979 classification scheme by the National Diabetes Data Group recognized two major forms of diabetes: type 1 (insulin-dependent) diabetes mellitus (IDDM) and type 2 (non-insulin-dependent) diabetes mellitus (NIDDM). The terms *juvenile-onset* and *adult-onset diabetes* were abolished. To base the classification on cause rather than on treatment, the American Diabetes Association (ADA) reexamined the classification and diagnosis of diabetes mellitus in 1995. The revised classification, published in 1997, eliminates the terms *insulin-dependent diabetes mellitus* and *non-insulin-dependent diabetes mellitus*, which now are termed *type 1* and *type 2 diabetes*, respectively (Box 33.1).

Type 1 Diabetes Mellitus

Approximately 5% to 10% of all cases of diabetes mellitus are included in this category. Patients usually have abrupt onset of symptoms (e.g., polyuria, polydipsia, rapid weight loss). They have insulinopenia (a deficiency of insulin) caused by destruction of pancreatic islet β -cells and are dependent on insulin to sustain life and prevent ketosis. Most patients have antibodies that identify an autoimmune process (see later discussion); some have no evidence of autoimmunity and are classified as type 1 idiopathic. The peak incidence occurs in childhood and adolescence. Approximately 75% acquire the disease before the age of 18, but onset in the remainder may occur at any age. Age at presentation is not a criterion for classification.

Type 2 Diabetes Mellitus

This group accounts for approximately 90% of all cases of diabetes. Patients have minimal symptoms, are not prone to ketosis, and *are not dependent on insulin* to prevent ketonuria.

BOX 33.1 Classification of Diabetes Mellitus

- I. Type 1 diabetes
- II. Type 2 diabetes
- III. Gestational diabetes mellitus (GDM)
- IV. Specific types of diabetes due to other causes

From the American Diabetes Association. (2017). Classification and diagnosis of diabetes. *Diabetes Care*, 40 (Suppl 1), S11–S24.

Insulin concentrations may be normal, decreased, or increased, and most people with this form of diabetes have impaired insulin action. *Obesity* is commonly associated, and weight loss alone usually improves hyperglycemia in these persons. However, many individuals with type 2 diabetes may require dietary intervention, oral antihyperglycemic agents, or insulin to control hyperglycemia. Most patients acquire the disease after age 40, but it may occur in younger people. Type 2 diabetes in children and adolescents is an emerging, significant problem. Among children in Japan, type 2 diabetes is now more common than type 1.

Gestational Diabetes Mellitus

This is defined as any degree of **glucose** intolerance (i.e., hyperglycemia) *with onset or first recognition during pregnancy* (i.e., diabetic women who become pregnant are not included in this category). Estimates of the frequency of abnormal glucose tolerance during pregnancy range from less than 1% to 28%, depending on the population studied and the diagnostic tests employed. In the United States, GDM occurs in 6% to 8% of pregnancies ($\approx 240,000$ cases annually). The prevalence of GDM is increasing, at least in part, due to the considerable increase in obesity. Women with GDM are at significantly greater risk for the subsequent development of type 2 diabetes mellitus, which occurs in 15% to 60%. The risk is particularly high in women who have marked hyperglycemia during or soon after pregnancy, women who are obese, and those whose GDM was diagnosed before 24 weeks' gestation. At 6 to 12 weeks postpartum, all patients who had GDM should be evaluated for diabetes using nonpregnant OGTT criteria. If diabetes is not present, patients should be reevaluated for diabetes at least every 3 years.

Specific Types of Diabetes Due to Other Causes

This subclass includes uncommon patients in whom hyperglycemia is due to a specific underlying disorder, such as genetic defects of β -cell function; genetic defects in insulin action; diseases of the exocrine pancreas (e.g., cystic fibrosis); endocrinopathies (e.g., Cushing syndrome, acromegaly, glucagonoma); administration of hormones or drugs known to induce β -cell dysfunction (e.g., Dilantin, pentamidine) or to impair insulin action (e.g., glucocorticoids, thiazides, β -adrenergics); infection; uncommon forms of immune-mediated diabetes; or other genetic conditions (e.g., Down syndrome, Klinefelter syndrome, porphyria). This was formerly termed *secondary diabetes*.

CATEGORIES OF INCREASED RISK FOR DIABETES

People who have blood glucose concentrations above normal, but less than those required for a diagnosis of diabetes mellitus, fall into an intermediate category. In 1979, this was termed impaired glucose tolerance (IGT), and was defined as a 2 hours postload plasma glucose following an OGTT of 140 to 199 mg/dL (7.8 to 11.1 mmol/L). An OGTT is required to assign a patient to this class. To avoid an OGTT, the category

of impaired fasting glucose (IFG) was added in 1997 by the ADA and by the World Health Organization (WHO) in 1999. IFG is diagnosed by a fasting glucose value between 100 and 125 mg/dL (5.6 and 6.9 mmol/L). (Note that the WHO and a number of other diabetes organizations define the cutoff for IFG at 110 mg/mL [6.1 mmol/L]).

In 2009, hemoglobin A_{1c} (HbA_{1c}) was added as a criterion to diagnose diabetes. People with HbA_{1c} values below the cutoff for diabetes, that is, 6.5% (48 mmol/mol), but above the upper reference limit, that is, 5.6% (38 mmol/mol), are at high risk of developing diabetes. For example, the incidence of diabetes in people with HbA_{1c} of 5.5% to 6.0% (37 to 42 mmol/mol) is 3- to 8-fold higher than the general population, while in those with HbA_{1c} between 6.0 and less than 6.5% (42 and 48 mmol/mol) it is increased more than 10-fold.

Individuals with IFG and/or IGT and/or intermediate HbA_{1c} (5.7% to 6.4%; 39 to 46 mmol/mol) have been referred to as having “prediabetes,” because they are at high risk for progressing to diabetes. Moreover, they are at increased risk for the development of cardiovascular disease. Nevertheless, there is considerable controversy surrounding prediabetes. For example, IFG, IGT, and HbA_{1c} do not always identify the same individuals. There is also lack of agreement on the cut-points for IFG and HbA_{1c}. This is due, in large part, to the continuous nature of the risk for the development of diabetes and the concentration of glucose or HbA_{1c}.

HORMONES THAT REGULATE BLOOD GLUCOSE CONCENTRATION

During a brief fast, a precipitous decline in the concentration of blood glucose is prevented by breakdown of **glycogen** stored in the liver and synthesis of glucose in the liver. Some glucose is derived from gluconeogenesis in the kidneys.

These organs contain glucose-6-phosphatase, which is necessary to convert glucose 6-phosphate (derived from gluconeogenesis or glycogenolysis) to glucose. Skeletal muscle lacks this enzyme; muscle glycogen therefore cannot contribute directly to blood glucose. With more prolonged fasting (>42 hours), gluconeogenesis accounts for essentially all glucose production. In contrast, after a meal, the absorbed glucose is converted to glycogen (for storage in the liver and skeletal muscle) or fat (for storage in adipose tissue). Despite large fluctuations in the supply and demand of carbohydrates, the concentration of glucose in the blood is normally maintained within a fairly narrow range by hormones that modulate the movement of glucose into and out of the circulation. These include insulin, which decreases blood glucose, and the counterregulatory hormones (glucagon, epinephrine, cortisol, and growth hormone), which increase blood glucose concentrations (Fig. 33.1). Normal glucose disposal depends on (1) the ability of the pancreas to secrete insulin, (2) the ability of insulin to promote uptake of glucose into peripheral tissue, and (3) the ability of insulin to suppress hepatic glucose production. The major insulin target organs are liver, skeletal muscle, and adipose tissue. These organs exhibit some differences in their responses to insulin. For example, the hormone stimulates glucose uptake through a specific glucose transporter—GLUT4—into muscle and fat cells, but not into liver cells.

Insulin

Insulin is a protein hormone produced by the β -cells of the islets of Langerhans in the pancreas. Insulin was the first protein hormone to be sequenced, the first substance to be measured by radioimmunoassay (RIA), and the first compound produced by recombinant DNA technology for clinical use. It is an anabolic hormone that stimulates the uptake of glucose

Fig. 33.1 Hormonal regulation of blood glucose. Key: +, stimulation; –, inhibition. Cortisol, growth hormone, and epinephrine antagonize the effects of insulin.

into fat and muscle, promotes the conversion of glucose to glycogen or fat for storage, inhibits glucose production by the liver, stimulates protein synthesis, and inhibits protein breakdown. Human insulin (molecular mass 5808 Da) consists of 51 amino acids in two chains (A and B) joined by two disulfide bridges, with a third disulfide bridge within the A chain. Insulin from most animals is immunologically and biologically similar to human insulin, and in the past, patients were treated with insulin purified from beef or pig pancreas. Virtually all patients are now treated with recombinant human insulin.

Preproinsulin, a protein of about 100 amino acids, is not detectable in the circulation under normal conditions because it is rapidly converted by cleaving enzymes to proinsulin. Proinsulin is stored in secretory granules in the Golgi complex of the β -cells, where *proteolytic cleavage to insulin and connecting peptide (C-peptide) occurs*. At the cell membrane, insulin and C-peptide are released into the portal circulation in equimolar amounts. In addition, small amounts of proinsulin and intermediate cleavage forms enter the circulation.

Proinsulin, which has relatively low biological activity (approximately 10% of insulin potency), is the major storage form of insulin. Normally, only small amounts (about 3% of the amount of insulin, on a molar basis) of proinsulin enter the circulation.

C-peptide is devoid of biological activity but appears necessary to ensure the correct structure of insulin. Fasting C-peptide concentrations are 5- to 10-fold higher than those of insulin because of the longer half-life of C-peptide (≈ 35 minutes). The liver does not extract C-peptide, which is removed from the circulation by the kidneys and is degraded, with a fraction excreted unchanged in the urine.

Glucose Transport

One of the fundamental effects of insulin is to increase glucose uptake into cells. The molecular mechanism of this action of insulin is extremely complex. The transport of

glucose into cells is modulated by two families of proteins. The sodium-dependent glucose transporter promotes the uptake of glucose and galactose from the lumen of the small bowel and their reabsorption from urine in the kidney. The second family of glucose carriers, termed *facilitative glucose transporters (GLUTs)*, is located on the surface of all cells (Table 33.1). These transporters are designated GLUT1 to GLUT14, according to the order in which they were identified. Eleven have been shown to mediate glucose transport. On the basis of sequence similarities, they can be divided into three subfamilies: class I (GLUT 1 to 4), class II (GLUT 5, 7, 9, and 11), and class III (GLUT 6, 8, 10, 12, and 14). GLUT1 is widely expressed and provides many cells with their basal glucose requirement. GLUT1 in the blood-brain barrier and GLUT3 in neuronal cells provide the constant high concentrations of glucose required by the brain. GLUT2 is expressed in hepatocytes, β -cells of the pancreas, and basolateral membranes of intestinal and renal epithelial cells. It is a low-affinity, high-capacity transport system that allows non-rate-limiting movement of glucose into and from these cells. GLUT4 catalyzes the rate-limiting step for glucose uptake and metabolism in skeletal muscle, the major organ of glucose consumption.

When circulating insulin concentrations are low, most of the GLUT4 is localized in intracellular compartments and is inactive. After a meal, the pancreas releases insulin, which stimulates the translocation of GLUT4 to the plasma membrane, thereby promoting glucose uptake into skeletal muscle and fat. Insulin-stimulated glucose transport into skeletal muscle is impaired in individuals with type 2 diabetes, but the mechanism of the defect has not been established. GLUT5 is responsible for fructose uptake in the intestine. Less is known about the other GLUTs. Glucose transport has been reported for GLUT 6, 8, 11, and 12.

Insulin-Like Growth Factors

Insulin-like growth factors 1 and 2 (IGF-1 and IGF-2) are polypeptides structurally related to insulin. These hormones (previously referred to as *nonsuppressible insulin-like activity*

TABLE 33.1 Facilitative Human Glucose Transporters

Name	Class	Tissue	Function
GLUT1	I	Erythrocytes, brain, blood-brain barrier, fetal tissues	Basal glucose transport, particularly in erythrocytes, brain, and placenta
GLUT2	I	Liver, β -cells of pancreas, small intestine, kidney, brain	Non-rate-limiting glucose transport
GLUT3	I	Brain (neurons), testis	Glucose transport in neurons
GLUT4	I	Skeletal muscle, cardiac muscle, adipose tissue (white and brown)	Insulin-stimulated glucose transport
GLUT5	II	Small intestine, kidney	Transports fructose (not glucose)
GLUT6	III	Brain, spleen, leukocytes	
GLUT7	II	Small intestine, colon, testis, prostate	
GLUT8	III	Testis, brain, adrenal gland, liver, spleen, brown adipose tissue, lung	
GLUT9	II	Kidney, liver, small intestine, placenta, lung, leukocytes	Transports urate
GLUT10	III	Heart, lung, brain, liver, pancreas, placenta, kidney	
GLUT11	II	Heart, skeletal muscle	
GLUT12	III	Heart, prostate, skeletal muscle, placenta	
HMIT (GLUT13)	III	Brain, adipose tissue	Transports <i>myo</i> -inositol (not glucose)
GLUT14	I	Testis	

or *somatomedin*) exhibit metabolic and growth-promoting effects similar to those of insulin. Accumulating evidence implicates the IGF axis in the development of several common cancers. IGF-1 (previously known as *somatomedin C*) is an important mediator of growth hormone action and is one of the major regulators of cell growth and differentiation. The physiological role of IGF-2 is not known. Synthesis of IGF-1 depends on growth hormone and occurs predominantly in the liver. In addition, many other cells produce IGF-1 that does not enter the circulation but acts locally. Circulating IGF concentrations are approximately 1000-fold higher than insulin concentrations, and the hormone is kept inactive by binding to a family of at least six specific binding proteins. These proteins regulate IGF by protecting the ligands in the circulation and delivering them to their target tissue. In contrast to insulin, which is unbound in the circulation, less than 10% of total serum IGF-1 is free. The biological actions of IGF are exerted through specific IGF receptors or the insulin receptor. The IGF-1 receptor is closely related to the insulin receptor in structure and biochemical properties. In contrast, the IGF-2 receptor is quite different, and its physiological relevance is not understood.

The significance of IGFs in normal carbohydrate metabolism is not known. Exogenous administration produces **hypoglycemia**, whereas a deficiency of IGF-1 results in dwarfism (pygmies and Laron dwarfs). Clinically, IGF-1 testing is primarily used to evaluate growth hormone deficiency and to detect and monitor treatment of growth hormone excess (acromegaly). IGF-2 may be produced in excess by extrapancreatic neoplasms, and patients may have fasting hypoglycemia.

Counterregulatory Hormones

Several hormones have actions opposite to those of insulin. These counterregulatory hormones are catabolic and increase hepatic glucose production initially by enhancing the breakdown of glycogen to glucose (glycogenolysis), and later by stimulating the synthesis of glucose (gluconeogenesis). The initial response (within minutes) to low blood glucose is an increase in glucose production, stimulated by glucagon and epinephrine. Over time (3 to 4 hours), growth hormone and cortisol increase glucose mobilization and decrease glucose use (see [Fig. 33.1](#)). Evidence suggests that glucose production by the liver is an inverse function of ambient glucose concentration, independent of hormonal factors (*glucose autoregulation*). The role of other hormones or neurotransmitters is not clear but appears relatively unimportant.

Glucagon

Glucagon is a 29–amino acid polypeptide secreted by α -cells of the pancreas. It is derived from proglucagon, which is hydrolyzed by prohormone convertase 2 (PC2). The major target organ for glucagon is the liver, where it binds to a specific G protein–coupled receptor, which is expressed abundantly in liver and kidney, and to a lesser extent in other tissues, including heart, adipose, pancreas, and brain. Glucagon stimulates the production of glucose in the liver

predominantly by glycogenolysis. Gluconeogenesis is also activated, and glycogenesis is inhibited. Glucagon secretion is regulated primarily by plasma glucose concentrations, with low and high plasma glucose being stimulatory and inhibitory, respectively. Long-standing diabetes mellitus impairs the glucagon response to hypoglycemia, resulting in an increased incidence of hypoglycemic episodes. Stress, exercise, and amino acids induce glucagon release. Insulin inhibits glucagon release from the pancreas and decreases glucagon gene expression, thereby attenuating its biosynthesis. Increased glucagon concentrations, secondary to insulin deficiency, are believed to contribute to the hyperglycemia and ketosis of diabetes. In addition to its effects on glycemia, glucagon directly regulates triglyceride, free fatty acid, and bile metabolism. For example, it enhances fatty acid oxidation and ketogenesis in the liver.

Proglucagon is also produced in the distal gut by enteroendocrine L cells and neurons in the nucleus of the solitary tract. In the intestinal L cells, proglucagon is cleaved by PC1/3 to glucagon-like peptide-1 (GLP-1), GLP-2, oxyntomodulin, glicentin, and intervening peptide 2 (IP2). Food ingestion stimulates secretion of GLP-1, which acts on β -cells of the pancreas to stimulate insulin gene transcription, potentiate glucose-induced insulin secretion, and inhibit glucagon secretion. GLP-1 and gastric inhibitory peptide (GIP; synthesized in and secreted from the duodenum and proximal jejunum) are incretin hormones that are responsible for up to 70% of postprandial insulin secretion. GLP-1 receptors are widely expressed and GLP-1 also regulates glucose concentration through extrapancreatic mechanisms, including inhibiting glucose production and food intake. For these reasons, GLP-1 analogs are used in the treatment of type 2 diabetes, and four (exenatide, liraglutide, albiglutide, and dulaglutide) have received US Food and Drug Administration (FDA) approval for use in the United States.

Epinephrine

Epinephrine (also called adrenaline), a catecholamine secreted by the adrenal medulla, stimulates glucose production (glycogenolysis) and decreases glucose use, thereby increasing blood glucose concentrations. It also stimulates glucagon secretion and inhibits insulin secretion by the pancreas (see [Fig. 33.1](#)). Epinephrine appears to have a *key role in glucose counterregulation when glucagon secretion is impaired* (e.g., in type 1 diabetes mellitus). Physical or emotional stress increases epinephrine production, releasing glucose for energy. Tumors of the adrenal medulla, known as *pheochromocytomas*, secrete excess epinephrine or norepinephrine and produce moderate hyperglycemia as long as glycogen stores are available in the liver. For more details, see [Chapter 26](#).

Growth Hormone

Growth hormone is a polypeptide secreted by the anterior pituitary gland. It stimulates gluconeogenesis, enhances lipolysis, and antagonizes insulin-stimulated glucose uptake. For more details, see [Chapter 40](#).

Cortisol

Cortisol, secreted by the adrenal cortex in response to adrenocorticotrophic hormone (ACTH), stimulates gluconeogenesis and increases the breakdown of protein and fat. Patients with Cushing syndrome have increased cortisol production as a result of tumor or hyperplasia of the adrenal cortex and may become hyperglycemic. In contrast, people with Addison disease have adrenocortical insufficiency caused by destruction or atrophy of the adrenal cortex and may exhibit hypoglycemia. For more details, refer to [Chapter 41](#).

Other Hormones Influencing Glucose Metabolism Thyroxine

Thyroxine, secreted by the thyroid gland, is not directly involved in glucose homeostasis, but it stimulates glycogenolysis and increases the rates of gastric emptying and intestinal glucose absorption. These factors may produce glucose intolerance in thyrotoxic individuals, but patients usually have a fasting plasma glucose (FPG) concentration in the reference interval. For more details, refer to [Chapter 42](#).

Somatostatin

Somatostatin, also called growth hormone-inhibiting hormone, is a 14-amino acid peptide found in the gastrointestinal tract, the hypothalamus, and the δ -cells of the pancreatic islets. Although somatostatin does not appear to have a direct effect on carbohydrate metabolism, it inhibits the release of growth hormone from the pituitary. In addition, somatostatin inhibits secretion of glucagon and insulin by the pancreas, thus modulating the reciprocal relationship between these two hormones.

MEASUREMENT OF INSULIN, PROINSULIN, C-PEPTIDE, AND GLUCAGON

Although interest in the possible clinical value of measurement of the concentrations of insulin and its precursors continues, the assays are useful primarily for research purposes. There is no role for routine testing for insulin, proinsulin, or C-peptide in most patients with diabetes mellitus. Measurement of C-peptide is sometimes necessary in the United States for patients to obtain insurance coverage for continuous subcutaneous insulin infusion pumps. Occasionally, C-peptide measurements may help distinguish type 1 from type 2 diabetes in ambiguous cases (e.g., patients who have type 2 phenotype, but present with ketoacidosis). It must be emphasized that the diagnostic criteria for diabetes mellitus do not include hormone measurements.

Various methods are used to measure insulin, proinsulin, C-peptide, and glucagon. A brief overview is provided here. For additional details, readers are referred to the expanded version of this chapter in the 6th edition of *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics*.

Insulin

The primary clinical application of insulin measurement is in the evaluation of patients with fasting hypoglycemia (discussed in more detail in [Chapter 22](#)). Measurement of

circulating insulin could be helpful in evaluating insulin resistance and insulin secretion. Increased concentrations of insulin in nondiabetic individuals are an independent predictor of the development of coronary artery disease. Nevertheless, it is not clear whether the increased insulin is responsible for the risk of coronary disease, and the clinical value of measuring it in this context is questionable.

In the past, measurement of insulin was advocated by some in the evaluation and management of patients with polycystic ovary syndrome. Women with this condition have insulin resistance and abnormal carbohydrate metabolism that may respond to oral antihyperglycemic agents. However, it is not clear whether assessing insulin resistance by measuring insulin concentrations affords any advantage over clinical signs of insulin resistance (body mass index, acanthosis nigricans), and the American College of Obstetricians and Gynecologists (ACOG) does not recommend routine measurements of insulin. Although a few investigators have recommended measuring insulin along with glucose during an OGTT as an aid to the early diagnosis of diabetes mellitus, this approach is not recommended.

Although insulin has been assayed for more than 50 years, no highly accurate, precise, and reliable procedure is available to measure insulin. The results of the most widely used commercial immunoassays are considerably inconsistent with within-assay coefficients of variation (CVs) ranging from 3.7% to 39% and among-assay CVs of 12% to 66%. The term *immunoreactive insulin* is used in reference to assays that may recognize, in addition to insulin, substrates that share antigenic epitopes with insulin. Examples include proinsulin, proinsulin conversion intermediates, and insulin derivatives produced by glycation or dimerization. Antisera raised against insulin show some cross-reactivity with proinsulin but not with C-peptide. Specificity is not a problem in healthy individuals because the low proinsulin concentrations do not appreciably affect the absolute values of insulin. In certain situations (e.g., patients with diabetes or islet cell tumors), proinsulin is present at higher concentrations, and direct assay of plasma may falsely overestimate the true insulin concentration. Because proinsulin has very low activity, incorrect conclusions regarding the availability of biologically active insulin may be reached in patients with diabetes. The magnitude of the error depends on the concentration of proinsulin and the extent of cross-reactivity of the antiserum with proinsulin. The various immunoassays also show different cross-reactivities with pharmacological insulins.

A stable isotope dilution mass spectrometry (IDMS) assay has been developed to measure the concentrations of insulin, proinsulin, and C-peptide. The difference in mass among the three analytes allows specific measurement of each protein. Comparison of patient samples revealed that most, but not all, results were higher by immunoassay than by mass spectrometry. Thus, immunoassays may overestimate insulin, particularly at low concentrations. The high protein concentration in the serum requires extraction of proteins (e.g., by immunoaffinity) and purification by high-performance liquid chromatography (HPLC) before quantification by mass

spectrometry. This method is not suitable for routine laboratory analysis, but it is the best higher-order measurement procedure available and can be used as a candidate reference measurement procedure.

Reference intervals vary among assays. After an overnight fast, insulin concentrations in healthy, normal, nonobese people range from 12 to 150 pmol/L (2 to 25 μ IU/mL). (Fasting is defined as no caloric intake for at least 8 hours.) More specific assays that have minimal cross-reactivity with proinsulin reveal a fasting plasma insulin concentration less than 60 pmol/L (10 μ IU/mL). Concentrations up to 1200 pmol/L (200 μ IU/mL) can be reached during a glucose tolerance test. Fasting insulin values are higher in obesity and lower in trained athletes.

Proinsulin

High proinsulin concentrations are usually noted in patients with benign or malignant β -cell tumors of the pancreas. Most patients with β -cell tumors have increased insulin, C-peptide, and proinsulin concentrations, but occasionally only proinsulin is increased. Despite its low biological activity, proinsulin production may be adequate to produce hypoglycemia. In addition, a rare form of familial hyperproinsulinemia, produced by impaired conversion to insulin, has been described. Measurement of proinsulin can be useful to determine the amount of proinsulin-like material that cross-reacts in an insulin assay. Patients with type 2 diabetes have increased proportions of proinsulin and proinsulin conversion intermediates, high concentrations of which are associated with cardiovascular risk factors. Even relatively mild hyperglycemia produces hyperproinsulinemia, with values greater than 40% of insulin concentration in type 2 diabetes. Similarly, women with GDM have higher concentrations of proinsulin and split-32, 33-proinsulin than pregnant normoglycemic control subjects. Increased proinsulin concentrations may also be detected in patients with chronic renal failure, cirrhosis, or hyperthyroidism.

Accurate measurement of proinsulin has been difficult for several reasons: the blood concentrations are low; antibody production is difficult; most antisera cross-react with insulin and C-peptide, which are present in much higher concentrations; the assays measure intermediate cleavage forms of proinsulin, and reference preparations of pure proinsulin are not readily available. Biosynthetic proinsulins have more recently allowed the production of monoclonal antibodies to proinsulin and have been used in the manufacture of proinsulin calibrators and reference preparations.

Reference intervals for proinsulin are highly dependent on the method of analysis, the degree of cross-reactivity of the antisera, and the purity of proinsulin calibrators. Each laboratory should establish its own reference intervals. Reference intervals in healthy, fasting individuals reported in the literature vary from 1.1 to 6.9 pmol/L to 2.1 to 12.6 pmol/L.

C-Peptide

Measurement of C-peptide has several advantages over insulin measurement. Because hepatic metabolism is negligible, C-peptide concentrations are better indicators of

β -cell function than is peripheral insulin concentration. Furthermore, C-peptide assays do not measure exogenous insulin and do not cross-react with insulin antibodies, which interfere with the insulin immunoassay.

The primary reason for measuring C-peptide is to evaluate fasting hypoglycemia. Some patients with insulin-producing β -cell tumors, particularly if hyperinsulinism is intermittent, may exhibit increased C-peptide concentrations with normal insulin concentrations. When hypoglycemia is due to surreptitious insulin injection, *insulin* concentrations will be high, but C-peptide values will be low; this occurs because C-peptide is not found in commercial insulin preparations and exogenous insulin suppresses β -cell function.

Basal or stimulated (by glucagon or glucose) C-peptide concentrations provide estimates of a patient's insulin secretory capacity and rate. Although valuable in clinical research, C-peptide measurement has a negligible role in the routine management of patients with diabetes. Medicare patients in the United States must have low C-peptide concentrations to be eligible for insurance coverage of insulin pumps.

Measurement of C-peptide is used to monitor patients' response to pancreatic surgery. C-peptide should be undetectable after a radical pancreatectomy and should increase after a successful pancreas or islet cell transplant. In addition, C-peptide concentration is used as an endpoint in immunomodulatory trials for the prevention of type 1 diabetes.

Measurements of urine C-peptide are useful when continuous assessment of β -cell function is desired, or when frequent blood sampling is not practical. The 24-hour urine C-peptide content (in the absence of renal failure, which produces increased concentrations) correlates well with fasting serum C-peptide concentration. However, the fraction of secreted C-peptide that is excreted in the urine exhibits high between-subject and within-subject variability. Some have advocated a C-peptide-to-creatinine ratio in a single urine sample to avoid these issues.

Assays are not affected by anti-insulin antibodies, but methodological problems produce large between-method variation. These difficulties include variable specificity among different antisera, variable cross-reactivity with proinsulin, and various types of C-peptide preparations used as a calibrator. A comparison of 40 serum samples using nine commercial C-peptide assay methods showed within- and between-run CVs ranging from less than 2% to greater than 10%, and from less than 2% to greater than 18%, respectively. Some methods had high imprecision, with between-run CVs exceeding 15%. Two IDMS methods for measuring C-peptide have been developed. Calibrating C-peptide measurements to an IDMS reference method increased comparability among laboratories.

Fasting serum concentrations of C-peptide in healthy people range from 0.78 to 1.89 ng/mL (0.25 to 0.6 nmol/L). After stimulation with glucose or glucagon, values range from 2.73 to 5.64 ng/mL (0.9 to 1.87 nmol/L), or three to five times the prestimulation value. Urinary C-peptide is usually in the range of 74 ± 26 μ g/L (25 ± 8.8 μ mol/L).

Glucagon

Very high concentrations of glucagon are seen in patients with α -cell tumors of the pancreas called *glucagonomas*. Patients with this tumor frequently have weight loss, necrolytic migratory erythema, diabetes, stomatitis, and diarrhea. Skin lesions often occur first and are frequently overlooked. Most tumors have metastasized when finally diagnosed. Low glucagon concentrations are associated with chronic pancreatitis and long-term sulfonylurea therapy.

A competitive RIA is available for measuring glucagon. Calibrator values are assigned at the manufacturer using the WHO glucagon international standard (69/194). Immunoassays that do not use radioactivity have been developed. A recent comparison of 10 commercially available assays reveals that some show cross-reactivity with other peptides from proglucagon, and all lack sensitivity at low glucagon concentrations.

Fasting plasma concentrations of glucagon vary depending on the method, ranging from 0 to 20 ng/L to up to 135 ng/L (0 to 5.7 pmol/L to 38.7 pmol/L). Values up to 500 times the upper reference limit may be found in patients with autonomously secreting α -cell neoplasms.

PATHOGENESIS OF TYPE 1 DIABETES MELLITUS

Type 1 diabetes mellitus results from autoimmune destruction of the insulin-secreting cells of pancreatic β -cells by chronic mononuclear cell infiltration, called insulinitis. In the vast majority of patients, destruction is mediated by T cells. The α -cells, δ -cells, and other islet cells are preserved. The autoimmune process begins months or years before the clinical presentation, and an 80% to 90% reduction in the volume of β -cells is required to induce symptomatic type 1 diabetes. The rate of islet cell destruction is variable and is usually faster in children than in adults.

Autoimmune Antibodies

Circulating antibodies can be detected in the serum years before the onset of hyperglycemia. The best characterized islet autoantibodies are as follows:

1. Islet cell cytoplasmic antibodies (ICAs) react with aialoglycoconjugate antigen present in the cytoplasm of all endocrine cells of the pancreatic islets. These antibodies are detected in the serum of 0.5% of normal subjects and 75% to 85% of patients with newly diagnosed type 1 diabetes. The antibodies are detected by immunofluorescence microscopy on frozen sections of human pancreatic tails. The ICA assay is cumbersome, labor intensive, and difficult to standardize. Few clinical laboratories are likely to implement this assay, which has marked interlaboratory variability in sensitivity and specificity.
2. *Insulin autoantibodies* (IAAs) are present in more than 90% of children who develop type 1 diabetes before age five, but in less than 40% of individuals who develop diabetes after age 12. Their frequency in healthy people is similar to that of ICA. An important caveat is that insulin antibodies

develop after insulin therapy, even in those persons who use human insulin.

3. *Antibodies to the 65 kDa isoform of glutamic acid decarboxylase* (GAD65) have been found up to 10 years before the onset of clinical type 1 diabetes and are present in approximately 60% of patients with newly diagnosed type 1 diabetes.
4. *Insulinoma-associated antigens* (IA-2A and IA-2 β A), directed against two tyrosine phosphatases, have been detected in more than 50% of newly diagnosed type 1 diabetes patients.
5. *Zinc transporter ZnT8* was identified in 2007 as a major autoantigen in type 1 diabetes. Initial analysis identified ZnT8 in 60% to 80% of patients with new-onset type 1 diabetes compared with less than 2% of controls and less than 3% of individuals with type 2 diabetes.

Autoantibody markers of immune destruction are present in 85% to 90% of individuals with immune-mediated diabetes when fasting hyperglycemia is initially detected. Approximately 5% to 10% of white adult patients who have the type 2 diabetes phenotype also have islet cell autoantibodies, particularly to GAD65. This condition has been termed latent autoimmune diabetes of adulthood (LADA) (previously termed type 1.5 diabetes or slow-onset diabetes in adults). Up to 1% to 2% of healthy individuals have a single autoantibody and are at low risk of developing immune-mediated diabetes. Because the prevalence of immune-mediated diabetes is low (~0.3% in the general population in most countries), the positive predictive value of a single autoantibody will be extremely low. Screening for islet autoantibodies is controversial because no acceptable therapy has been documented to reliably prevent or delay the clinical onset of diabetes in islet cell autoantibody-positive individuals.

Genetics

Susceptibility to type 1 diabetes is inherited, but the mode of inheritance is complex and has not been defined. It is a multigenic trait, and the major locus is the major histocompatibility complex on chromosome 6. At least 11 other loci on 9 chromosomes also contribute, with the regulatory region of the insulin gene *INS* on chromosome 11p15 being an important locus. The human leukocyte antigen (HLA)-DQ and -DR genetic factors are by far the most important determinants for risk of type 1 diabetes. The concordance rate between identical twins is approximately 30%. Approximately 95% of whites with type 1 diabetes express HLA-DR3 or HLA-DR4 histocompatibility antigens. However, up to 40% of the non-diabetic population also express these alleles. In contrast, the HLA-DQB1*0602 allele significantly decreases the risk of type 1 diabetes. HLA typing can indicate absolute risk of diabetes. The risk of a sibling developing diabetes is 1%, 5%, and 10% to 20% if the number of haplotypes shared is none, one, and two, respectively. However, only 10% of patients with type 1 diabetes have an affected first-degree relative. More than 40 non-HLA-susceptibility gene markers have been confirmed, but these have smaller effects than HLA. Non-HLA genetic factors that increase risk include the insulin gene (*INS*),

cytotoxic T-lymphocyte-associated protein 4 (*CTLA4*), and protein tyrosine phosphatase non-receptor type 22 (lymphoid) (*PTPN22*). The multiplicity of independent chromosomal regions associated with a predisposition to type 1 diabetes suggests that other susceptibility genes will be identified. Routine measurement of genetic markers is not of value at this time for the diagnosis or management of patients with type 1 diabetes.

Environment

Reports describe that environmental factors are involved in initiating diabetes. Viruses, such as rubella, mumps, enterovirus, and Coxsackie virus B, have been implicated. It seems likely that autoimmunity to β -cells is initiated by a viral protein (that shares an amino acid sequence with a β -cell protein) or some other environmental insult. Genetic susceptibility and other host factors (e.g., HLA type) determine the progression of the β -cell destruction. Epidemiological studies have implicated early exposure to cows' milk as a trigger of type 1 diabetes. This model is contentious and has been debated for decades.

PATHOGENESIS OF TYPE 2 DIABETES MELLITUS

At least two major identifiable pathological defects have been reported in patients with type 2 diabetes. One is a decreased ability of insulin to act on peripheral tissue. This is called *insulin resistance*. The other is *β -cell dysfunction*, which is an inability of the pancreas to produce sufficient insulin to compensate for the insulin resistance. Thus, a relative deficiency of insulin occurs early in the disease and absolute insulin deficiency late in the disease. The debate over whether type 2 diabetes is due primarily to a defect in β -cell secretion or to peripheral resistance to insulin, or to both, has been raging for decades. Nevertheless, type 2 diabetes is an extremely heterogeneous disease, and no single cause is adequate to explain the progression from normal glucose tolerance to diabetes. The fundamental molecular defects in insulin resistance and insulin secretion result from a combination of environmental and genetic factors.

Loss of β -Cell Function

Increased β -cell demand induced by insulin resistance is ultimately associated with progressive loss of β -cell function that is necessary for the development of fasting hyperglycemia. The major defect is a loss of glucose-induced insulin release, which is termed *selective glucose unresponsiveness*. Hyperglycemia appears to render the β -cells increasingly unresponsive to glucose (called glucotoxicity), and the degree of dysfunction correlates with both glucose concentration and duration of hyperglycemia. Restoration of euglycemia rapidly resolves the defect. Increased free fatty acids in serum have also been implicated in β -cell failure (lipotoxicity). Other insulin secretory abnormalities in type 2 diabetes include disruption of the normal pulsatile release of insulin and an increased ratio of plasma proinsulin to insulin. The number of β -cells is also reduced in patients with type 2 diabetes.

Insulin Resistance

Insulin resistance is defined as “a decreased biological response to normal concentrations of circulating insulin”; it is found in obese, nondiabetic individuals and in patients with type 2 diabetes. The underlying pathophysiologic defect(s) has (have) not been identified, but insulin resistance is usually attributed to a defect in insulin action. Measurement of insulin resistance in a routine clinical setting is difficult, and surrogate measures, namely, fasting insulin concentration or the euglycemic insulin clamp, are used to provide an indirect assessment of insulin function. The euglycemic clamp is performed in hospital under close supervision. The subject receives a constant intravenous infusion of insulin in one arm with concurrent intravenous infusion of variable amounts of glucose in the other arm to maintain blood glucose at a normal fasting concentration. A broad clinical spectrum of insulin resistance ranges from euglycemia (with marked increase in endogenous insulin) to hyperglycemia (despite large doses of exogenous insulin). Several rare clinical syndromes are also associated with insulin resistance. The prototype is the type A insulin resistance syndrome, which is characterized by hyperinsulinemia, acanthosis nigricans, and ovarian hyperandrogenism (see more on polycystic ovarian syndrome in Chapter 43).

The insulin resistance syndrome (also known as syndrome X, or the metabolic syndrome) is a constellation of associated clinical and laboratory findings, consisting of insulin resistance, hyperinsulinemia, obesity, dyslipidemia (high triglyceride and low high-density lipoprotein [HDL] cholesterol), and hypertension. Individuals with this syndrome are at increased risk for cardiovascular disease. The metabolic syndrome is diagnosed if three or more of the following criteria are met:

- Increased waist circumference (population- and country-specific), for example, Europe, Canada, and the United States: greater than 35 inches (>88 cm) (women) or greater than 40 inches (>102 cm) (men).
- Triglycerides greater than 150 mg/dL (>1.7 mmol/L).
- HDL cholesterol less than 51 mg/dL (<1.3 mmol/L) (women) or less than 39 mg/dL (<1.0 mmol/L) (men).
- Blood pressure greater than or equal to 130/85 mm Hg.
- FPG ≥ 100 mg/dL (≥ 5.6 mmol/L).

The “metabolic syndrome” concept has been questioned by several experts, including the person who first described it and major clinical diabetes organizations. A WHO Expert Consultation concluded that although the metabolic syndrome may be useful as an educational concept, it has limited practical utility for diagnosis and management, and further efforts to redefine it are inappropriate.

Environment

Environmental factors, such as diet and exercise, are important determinants in the pathogenesis of type 2 diabetes. Convincing evidence links obesity to the development of type 2 diabetes, but the association is complex. Although 60% to 80% of patients with type 2 diabetes are obese, diabetes develops in greater than 15% of obese

individuals. In contrast, virtually all obese subjects, even those with normal carbohydrate tolerance, have hyperinsulinemia and are insulin resistant. Other factors, such as family history of type 2 diabetes (genetic predisposition), the duration of obesity, and the distribution of fat are important. Nevertheless, the rising prevalence of diabetes is believed to be a consequence of the increase in obesity (defined as a body mass index ≥ 30 kg/m²), which was reported to be 37.7% in US adults in 2014.

An inverse relationship has been noted between the degree of physical activity and the prevalence of type 2 diabetes. For every 500 kcal increase in daily energy expenditure, a 6% decrease in age-adjusted risk of type 2 diabetes occurs. This effect is independent of both body weight and a parental history of diabetes. The mechanism of the protective effect of exercise is thought to be increased sensitivity to insulin in skeletal muscle and adipose tissue.

Type 2 Diabetes Susceptibility Genes

Genetic factors contribute to the development of type 2 diabetes. For example, the concordance rate for type 2 diabetes in identical twins approaches 100%. Type 2 diabetes is 10 times more likely to occur in an obese person with a parent who has diabetes than in an equally obese person without a diabetic family history. However, the mode of inheritance is unknown, and type 2 diabetes has been described as a “geneticist’s nightmare.” It is genetically more complex than Mendelian disorders and is not inherited according to simple Mendelian rules. Multiple genetic factors interact with exogenous influences (such as environmental factors) to produce the phenotype.

Multiple factors complicate the search for susceptibility genes in type 2 diabetes. A variety of approaches have produced several genes that are associated with type 2 diabetes. Recent genome-wide association studies (GWAS) have substantially contributed to our understanding of the genetic architecture of type 2 diabetes, with more than 60 genetic loci now identified. Most of these genetic loci are associated with the insulin secretion pathway, rather than with insulin resistance. Despite considerable effort to identify the genetic basis of type 2 diabetes mellitus, genetic defects identified to date account for only approximately 5% of patients with type 2 diabetes. Therefore, the gene or genes causing common forms of type 2 diabetes remain unknown. Moreover, the risk alleles in these loci all have relatively small effects (odds ratios, 1.1 to 1.3). Combined analysis of 48 different type 2 risk loci did not significantly affect the time from diagnosis to prescription of the first drug.

DIAGNOSIS OF DIABETES

The diagnostic criteria of diabetes mellitus are shown in [Box 33.2](#). For type 1 diabetes, the diagnosis is usually easy because hyperglycemia appears abruptly, is severe, and is accompanied by serious metabolic derangements. Diagnosis of type 2 diabetes may be difficult because hyperglycemia often is not severe enough for the patient to notice symptoms

BOX 33.2 Criteria for the Diagnosis of Diabetes Mellitus

Any one of the following is diagnostic:

1. Hemoglobin A_{1c} (HbA_{1c}) $\geq 6.5\%$ (≥ 48 mmol/mol)^a OR
2. Fasting plasma glucose (FPG) ≥ 126 mg/dL (≥ 7.0 mmol/L)^b OR
3. Symptoms of hyperglycemia and random plasma glucose ≥ 200 mg/dL (≥ 11.1 mmol/L)^c OR
4. 2-hour plasma glucose ≥ 200 mg/dL (≥ 11.1 mmol/L) during an oral glucose tolerance test (OGTT)^d

In the absence of unequivocal hyperglycemia, these criteria should be confirmed by repeating the same test on a different day. Mixing different methods to diagnose diabetes should be avoided.

^aThe test should be performed in a laboratory using a method that is National Glycohemoglobin Standardization Program (NGSP)-certified and standardized to the DCCT assay. Point-of-care assays should not be used for diagnosis.

^bFasting is defined as no calorie intake for at least 8 h.

^cThe classic symptoms of hyperglycemia include polyuria, polydipsia, and unexplained weight loss. Random is defined as any time of day without regard to time since last meal.

^dThe OGTT should be performed as described by the World Health Organization (WHO), using a glucose load containing the equivalent of 75 g of anhydrous glucose dissolved in water.

From the American Diabetes Association. (2017). Classification and diagnosis of diabetes. *Diabetes Care*, 40 (Suppl 1), S11–S24.

of diabetes. Nevertheless, the risk of complications makes it important to identify people early with the disease.

Fasting Plasma Glucose Concentrations

FPG concentrations of 126 mg/dL (7.0 mmol/L) or greater on more than one occasion are diagnostic of diabetes mellitus (see [Box 33.2](#)). However, some investigators believe that fasting hyperglycemia may be a relatively late development in the course of type 2 diabetes, delaying the diagnosis and leading to underestimation of the prevalence of diabetes mellitus in the population. Complications, such as retinopathy, proteinuria, and neuromuscular disease, are present in approximately 30% of patients at clinical diagnosis of type 2 diabetes, and onset of type 2 diabetes probably occurs at least 4 to 7 years before clinical diagnosis. Screening of high-risk individuals for diabetes is now recommended by some clinical organizations. Fasting glucose (or HbA_{1c}) should be measured in all asymptomatic persons at age 45 (or younger in subjects at increased risk), with follow-up testing every 3 years (see discussion later in this chapter). However, no published evidence indicates that treatment based on screening is efficacious.

Oral Glucose Tolerance Test

Although more sensitive than FPG determinations, glucose tolerance testing is affected by multiple factors that result in *poor reproducibility* ([Box 33.3](#)). Moreover, approximately 20% of OGTTs fall into the nondiagnostic category (e.g., only one blood sample exhibits increased glucose concentration).

BOX 33.3 Factors Other Than Diabetes That Influence the Oral Glucose Tolerance Test

Patient Preparation

Duration of fast
Prior carbohydrate intake
Medications (e.g., thiazides, oral contraceptives, corticosteroids)
Trauma
Intercurrent illness
Age
Activity
Weight

Administration of Glucose

Form of glucose (anhydrous or monohydrate)
Quantity of glucose ingested
Volume of glucose administered
Rate of ingestion

During the Test

Posture
Anxiety
Caffeine
Smoking
Activity
Time of day
Sample preservation

Unless results are grossly abnormal initially, the OGTT should be performed on two separate occasions to establish the diagnosis of diabetes.

The following conditions should be met before an OGTT is performed: discontinue, when possible, medications known to affect glucose tolerance; perform in the morning after 3 days of unrestricted diet (containing at least 150 g of carbohydrate per day) and activity and perform the test after a 10- to 16-hour fast only in ambulatory outpatients (bed rest impairs glucose tolerance), who should remain seated during the test without smoking cigarettes. Glucose tolerance testing should not be performed on hospitalized, acutely ill, or inactive patients. The test should begin between 7.00 a.m. and 9.00 a.m.. Venous plasma glucose should be measured after fasting, then 2 hours after an oral glucose load. For adults, the recommended glucose load is 75 g, which may not be a maximum stimulus; for children, 1.75 g/kg, up to 75 g maximum is given. The glucose should be dissolved in 300 mL of water and ingested over 5 minutes. A commercial, more palatable form of glucose may be ingested, but whether the anhydrous or monohydrate form of glucose should be used is still in question.

An OGTT is not widely used in clinical practice for the diagnosis of diabetes in the United States because of its lack of reproducibility and inconvenience. The sensitivity of FPG concentrations is lower than the OGTT for diagnosing diabetes, and some authors claim that the OGTT better identifies patients at risk for developing complications of diabetes.

An FPG value less than 100 mg/dL (<5.6 mmol/L) or a random glucose concentration less than 140 mg/dL (<7.8 mmol/L) is sufficient to rule out the diagnosis of diabetes mellitus.

DIAGNOSIS OF GESTATIONAL DIABETES MELLITUS

Normal pregnancy is associated with increased insulin resistance, especially in the late second and third trimesters. Euglycemia is maintained by increased insulin secretion, with GDM developing in those women who fail to augment insulin sufficiently. Risk factors for GDM include a family history of diabetes in a first-degree relative, obesity, advanced maternal age, glycosuria, and selected adverse outcomes in a previous pregnancy (e.g., stillbirth, macrosomia). Recommendations for laboratory diagnosis of GDM remain controversial and lack consensus. The Hyperglycemia in Pregnancy and Adverse Outcome (HAPO) study was a large ($\approx 25,000$ pregnant women), prospective, multinational study published in 2008. The study revealed strong, graded, linear associations between maternal glycemia and adverse outcomes. Based on these data, it was recommended that all pregnant women not previously known to have diabetes should be evaluated for GDM by a 75-g OGTT at 24 to 28 weeks' gestation. Diagnostic cutpoints for fasting, 1- and 2-hour plasma glucose concentrations have been established (Table 33.2).

These new criteria, which increase the incidence of GDM by approximately 2.5-fold, have not been accepted by all clinical organizations around the globe. For example, in the United States, ACOG continues to advocate prior diagnostic criteria (see Table 33.2). These state that all pregnant women should be evaluated by a two-step method:

1. Screen by a 50-g oral glucose load (the patient does not need to be fasting). A plasma glucose value greater than or equal to 140 mg/dL (7.7 mmol/L) at 1 hour after glucose ingestion indicates the necessity for definitive testing. Approximately 15% of pregnant women meet this criterion and require a full OGTT. This subgroup includes approximately 80% of all women with GDM. Some experts recommend a cutoff of 130 mg/dL, which increases sensitivity for GDM to 90% but includes approximately 25% of all pregnant women.
2. The diagnosis of GDM can be made on the basis of the result of the 100-g, 3-hour OGTT. This should be performed on a different day from the 50-g OGTT.

Although usually asymptomatic and not life-threatening to the mother, GDM is associated with increased neonatal mortality and morbidity, including hypocalcemia, hypoglycemia, and macrosomia. Maternal hyperglycemia causes the fetus to secrete more insulin, resulting in stimulation of fetal growth and macrosomia. Recognition is important because therapy can reduce perinatal morbidity and mortality. Maternal complications include a high rate of cesarean delivery and

TABLE 33.2 Screening for and Diagnosis of Gestational Diabetes Mellitus

- I One-step**
1. Perform between 24 and 28 weeks' gestation in the morning after an overnight fast of at least 8 h.
 2. Measure fasting venous plasma glucose.
 3. Give 75 g of glucose orally.
 4. Measure plasma glucose hourly for 2 h after glucose is given.
 5. At least one value must meet or exceed the following:

	Glucose Concentration
Fasting	92 mg/dL (5.1 mmol/L)
1 h	180 mg/dL (10.0 mmol/L)
2 h	153 mg/dL (8.5 mmol/L)

- II Two-step**
- A. Screening (step 1)**
1. Perform between 24 and 28 weeks' gestation^a in all pregnant women not previously diagnosed with diabetes.
 2. Give 50 g oral glucose load without regard to time of day or time of last meal.
 3. Measure venous plasma glucose at 1 h.
 4. If glucose is ≥ 140 mg/dL (7.8 mmol/L)^b, proceed to Step 2 and perform glucose tolerance test.
- B. Diagnosis (step 2)**
1. Perform in the morning after an overnight fast of at least 8 h.
 2. Measure fasting venous plasma glucose.
 3. Give 100 g of glucose orally.
 4. Measure plasma glucose hourly for 3 h after glucose is given.
 5. At least two values must meet or exceed the following:

	Carpenter & Coustan	NDDG
Fasting	95 mg/dL (5.3 mmol/L)	105 mg/dL (5.8 mmol/L)
1 h	180 mg/dL (10.0 mmol/L)	190 mg/dL (10.6 mmol/L)
2 h	155 mg/dL (8.6 mmol/L)	165 mg/dL (9.2 mmol/L)
3 h	140 mg/dL (7.8 mmol/L)	145 mg/dL (8.0 mmol/L)

NDDG, National Diabetes Data Group.

^aThe WHO states that this test can be performed at any time during pregnancy.

^bSome experts recommend a cutoff of 135 mg/dL (7.5 mmol/L). Modified from the American Diabetes Association. (2017). Classification and diagnosis of diabetes. *Diabetes Care*, 40 (Suppl 1), S11–S24.

hypertension. In addition, mothers with GDM are at significantly increased risk of subsequent type 2 diabetes.

Distinct from GDM is pregnancy in a patient with preexisting diabetes. This is associated with an increased incidence of congenital malformation, but meticulous glycemic control during the first 8 weeks of pregnancy can significantly decrease the risk of congenital malformation. Tight control results in an increased incidence of maternal hypoglycemia, which is teratogenic in animals but does not cause malformation in humans.

Women with GDM should be screened for diabetes 6 to 12 weeks postpartum using nonpregnant OGTT criteria (see

Box 33.2). (HbA_{1c} is not recommended because of the antepartum therapy for hyperglycemia.) If glucose values are normal, glycemia should be reassessed at least every 3 years using glucose or HbA_{1c}.

CHRONIC COMPLICATIONS OF DIABETES MELLITUS

Patients with type 1 or type 2 diabetes are at high risk for the development of chronic complications. Diabetes-specific microvascular pathology in the retina, renal glomeruli, and peripheral nerves produces retinopathy, nephropathy, and neuropathy, respectively. As a result, diabetes is the most frequent cause of new cases of blindness in the industrialized world in persons between 25 and 74 years of age and is the leading cause of end-stage renal disease. Diabetes is also associated with a marked increase in atherosclerotic macrovascular disease involving cardiac, cerebral, and peripheral large vessels. Therefore, patients with diabetes have a high rate of myocardial infarction (the major cause of mortality in diabetes), stroke, and limb amputation.

Type 1 Diabetes

Although it was theorized for many years that better glyce-mic control would decrease rates of long-term complications of diabetes, it was not until the publication of the Diabetes Control and Complications Trial (DCCT) in 1993 that this hypothesis was verified. The DCCT was a multicenter, randomized trial that compared the effects of intensive and conventional therapy on the development and progression of complications in 1441 patients with type 1 diabetes, all of whom required insulin. During the study period, which averaged 6.5 years, intensively managed patients maintained significantly lower mean blood glucose concentrations. Compared with conventional therapy, intensive therapy reduced the risks of retinopathy, nephropathy, and neuropathy by 40% to 75%. Intensive therapy delayed the onset and slowed the progression of these complications, regardless of age, gender, or duration of diabetes. Absolute risks of retinopathy and nephropathy were proportional to the mean HbA_{1c} (discussed later in the chapter). Although intensive therapy also reduced the development of hypercholesterolemia, macrovascular complications were not significantly decreased in the initial assessment. However, analysis after 17 years of follow-up documented a 42% lower incidence of cardiovascular disease in the intensively treated group. This landmark study has had a considerable impact on therapeutic goals and comprehension of the pathogenesis of complications of diabetes.

At the conclusion of the DCCT, 95% of participants enrolled in the long-term follow-up study, termed the Epidemiology of Diabetes Interventions and Complications (EDIC). Five years after the end of the DCCT, no difference in metabolic control (as assessed by HbA_{1c} measurements) was noted between the former conventional and intensively treated groups. Nevertheless, further progression of retinopathy and neuropathy was significantly lower in the former

intensive group, demonstrating that the beneficial effects of intensive treatment persisted for at least several years beyond the period of strictest intervention.

Type 2 Diabetes

The role of hyperglycemia in the development of complications in individuals with type 2 diabetes was established in the United Kingdom Prospective Diabetes Study (UKPDS). The UKPDS was a major, randomized, multicenter clinical study that included 5102 patients with newly diagnosed type 2 diabetes who were followed for an average of 10 years. Analogous to the findings of the DCCT, the UKPDS demonstrated that in patients with type 2 diabetes, intensive treatment diminishes the development of microvascular complications by approximately 10% to 40%. Intensive treatment also decreased the rate of occurrence of macrovascular complications. Although the reduction was not statistically significant initially, follow-up 10 years after the study ended showed a significant reduction in myocardial infarction among patients who had received intensive therapy. Analogous to the EDIC findings, long-term benefits for microvascular complications were observed with follow-up of patients in the UKPDS despite loss of glycemic separation between intensive and standard cohorts after the study ended. An important caveat of both the DCCT and the UKPDS was that intensive therapy produced a 3-fold increase in the incidence of severe hypoglycemia.

ROLE OF THE CLINICAL LABORATORY IN DIABETES MELLITUS

The clinical laboratory has a vital role in both the diagnosis and management of diabetes (Table 33.3). The National Academy of Clinical Biochemistry (NACB) published evidence-based guidelines for laboratory analysis in diabetes. These guidelines were reviewed and endorsed by the ADA in 2011 as a Position Statement. A brief overview is presented.

Diagnosis

Preclinical (Screening)

Several large clinical trials are underway to assess a variety of therapeutic strategies designed to delay or prevent the onset of type 1 diabetes. Until effective intervention becomes available and cost-effective screening strategies are developed for young children, screening for antibodies and determining HLA type is not currently warranted, except in clinical research studies. A decrease in glucose-stimulated insulin secretion is the first functional abnormality in both type 1 and type 2 diabetes. Nevertheless, tests of insulin secretion are not currently recommended for routine clinical use.

Screening asymptomatic individuals for type 2 diabetes has been the subject of much controversy. The ADA, which previously did not support screening, now advocates screening in all asymptomatic individuals over the age of 45 years. If the HbA_{1c} is less than 5.7% (39 mmol/mol) or the FPG is less than 100 mg/dL (5.6 mmol/L), testing should be repeated at 3-year intervals.

TABLE 33.3 Role of the Laboratory in the Management of Diabetes Mellitus

Diagnosis

Preclinical (Screening)	Immunologic markers
	ICA IAA GAD antibodies Protein tyrosine phosphatase antibodies (IA-2) Zinc transporter ZnT8 antibodies Genetic markers (e.g., HLA) Insulin secretion Fasting Pulses In response to a glucose challenge Blood glucose OGTT
Clinical	HbA _{1c}
	Blood glucose OGTT HbA _{1c} Ketones (urine and blood) Other (e.g., insulin, C-peptide, stimulation tests)

Management

Acute	Glucose Blood Urine Ketones Blood Urine Acid-base status (pH), bicarbonate Lactate Other abnormalities related to cellular dehydration or therapy (e.g., potassium, sodium, phosphate, osmolality)
	Chronic
Chronic	Glucose Blood (fasting, random) Urine Glycated proteins HbA _{1c} Fructosamine Glycated serum albumin 1,5-AG Urinary protein Albuminuria (previously termed "microalbuminuria") Proteinuria Evaluation of complications (e.g., creatinine, cholesterol, triglycerides) Evaluation of pancreas transplant (C-peptide, insulin) Eligibility for insulin pump (C-peptide)

1,5-AG, 1,5-Anhydroglucitol; HbA_{1c}, hemoglobin A_{1c}; HLA, human leukocyte antigen; IAA, insulin autoantibodies; ICA, islet cell cytoplasmic antibodies; OGTT, oral glucose tolerance test.

Clinical

The laboratory diagnosis of diabetes is made exclusively by the demonstration of hyperglycemia, as evidenced by measurements of venous plasma glucose or HbA_{1c}. Although other tests (e.g., C-peptide, insulin analysis) have been proposed to assist in the diagnosis and classification of the disease, they do not at present have a role outside of research studies.

Management

Acute

In diabetic ketoacidosis, hyperosmolar nonketotic coma, and hypoglycemia, the clinical laboratory has an essential role in both diagnosis and monitoring of therapy. Several analytes are frequently measured to guide clinicians in treatment regimens to restore euglycemia and correct other metabolic disturbances. The metabolic abnormalities of these conditions are beyond the scope of this book, and interested readers are referred to a standard textbook of medicine. The NACB guidelines also provide information on the tests that are used.

Chronic

The DCCT and UKPDS studies documented a correlation between blood glucose concentrations and the development of long-term complications of diabetes. Measurement of glucose and glycated proteins provides an index of short- and long-term glycemic control, respectively (see section on glycated proteins later in the chapter). Detection of and monitoring for complications are achieved by assaying creatinine, urine albumin, and serum lipids. The success of newer therapies, such as islet cell or pancreas transplantation, can be monitored by measuring serum C-peptide or insulin concentrations.

SELF-MONITORING OF BLOOD GLUCOSE

Patients with diabetes, especially those who need insulin, require careful monitoring to maintain control of blood glucose. Therapeutic regimens include multiple daily insulin injections, insulin pumps, and continuous subcutaneous insulin injections. *Testing urine for glucose is not adequate for monitoring patients on insulin therapy.* Although some evidence suggests that it may be effective for monitoring type 2 diabetes, the ADA states that limitations of urine testing make blood glucose measurements the preferred method for assessing glycemic control.

Portable meters for measurement of blood glucose concentrations are used in three major settings: in acute and chronic care facilities (at the patient's bedside and in clinics or hospitals); in physicians' offices, and by patients or their caregivers at home, work, and school. Patients measure their own blood glucose concentrations and modify their insulin doses based on the result. In 2006, the overall rate of daily self-monitoring of blood glucose (SMBG) was 63.4% among all adults with diabetes in the United States and 86.7% among those treated with insulin.

A large number of simple test strips permit rapid glucose measurements on a drop of whole blood. More than 80 different blood glucose meters are commercially available. These meters vary in size, weight, calibration method, and other features, and use the same enzyme-catalyzed reactions, predominantly glucose oxidase or glucose dehydrogenase, as described in Chapter 22 for glucose analysis. The reagents are combined in dry form on a small surface area of a test strip.

To perform the measurement, a sample of blood (usually from a fingerstick, but anticoagulated whole blood collected in ethylenediaminetetraacetic acid [EDTA] or heparin may be used) is placed on the test pad, which is attached to a plastic support. The test strip is then inserted into the meter. (In some devices, the strip is inserted into the meter before the sample is applied.) After a fixed time, the result appears on a digital display screen. These meters use reflectance photometry or electrochemistry to measure the rate of the reaction or the final concentration of the products. Reflectance photometry measures the amount of light reflected from a test pad containing reagent. In electrochemical systems, the enzymatic reaction produces a flow of electrons in an electrode incorporated on the test strip. The current, which is directly proportional to the amount of glucose in the sample, is converted to a digital readout. Large variability has been noted among meters as to the test time (5 to 45 seconds) and the claimed reading range (30 to 500 mg/dL to 0 to 600 mg/dL; 1.7 to 28 mmol/L to 0 to 33 mmol/L). Calibration is automatic on some devices, whereas others use lot-specific code chips or strips. All manufacturers supply control solutions. Recent advances in technology facilitate data analysis and sharing. Some meters have Bluetooth capabilities (enabling transmission of data to a smartphone or computer), cellular connections that automatically send data to the "cloud," USB ports, and/or communication with an insulin pump. Strict adherence to the instructions is necessary to obtain accurate results. Some meters have a porous membrane that separates erythrocytes, and analysis is performed on the resultant plasma. Whole blood glucose concentrations are approximately 10% to 15% lower than plasma or serum concentrations, but meters can be calibrated to report plasma glucose values, even when the sample is whole blood. An International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) working group recommended that glucose meters be harmonized using a factor of 1.11× to report the concentration of glucose in plasma, irrespective of the sample type or technology.

Analytical Goals for Glucose Meters

Multiple analytical goals have been proposed for the performance of glucose meters. The recommendations promulgated in 2002 by the Clinical and Laboratory Standards Institute (CLSI) (previously called the National Committee for Clinical Laboratory Standards [NCCLS]) and in 2003 by the International Organization for Standardization (ISO) are that 95% of results should fall within 20% of laboratory-measured glucose concentrations when greater than 75

mg/dL (>4.2 mmol/L) and within 15 mg/dL (0.83 mmol/L) of a laboratory glucose measurement if the glucose concentration is less than 75 mg/dL (<4.2 mmol/L). In both CLSI and ISO guidelines, 5% of these results can be considerably outside these limits. Note that the CLSI guideline is for meter use in acute and chronic care facilities (mainly hospitals), while the ISO guidelines pertain to meters for self-testing (i.e., SMBG). Many experts believe these acceptance criteria are too wide. The CLSI and ISO documents were revised in 2013, with tightening of acceptance criteria. The current CLSI guideline POCT12-A3 indicates that for 95% of the samples, the difference between meter and laboratory measurement should be less than 12.5% when the laboratory glucose value is greater than 100 mg/dL (≥ 5.6 mmol/L) and less than 12 mg/dL (<0.67 mmol/L) when the glucose concentration is less than 100 mg/dL (<5.6 mmol/L). In addition, no more than 2% of results can differ by more than 20% at greater than 75 mg/dL (≥ 4.2 mmol/L) and by greater than 15 mg/dL (>0.83 mmol/L) when the glucose concentration is less than 75 mg/dL (<4.2 mmol/L). The revised ISO goals, also issued in 2013, are that for 95% of the samples, the difference between meter and laboratory measurement should be less than 15% when the laboratory glucose value is greater than 100 mg/dL (≥ 5.6 mmol/L) and less than 15 mg/dL (<0.83 mmol/L) when the glucose concentration is less than 100 mg/dL (<5.6 mmol/L). Moreover, 99% of results must be within zones A and B of the consensus error grid (see following paragraph). In the United States, the FDA issued guidance in 2016 for glucose meters. Two separate documents were released, one for home (SMBG) use and the other for hospitals. The analytic goals are more stringent than either the CLSI or ISO guidelines.

A different method uses an error grid to try to define clinically important errors by identifying fairly broad target ranges. An approach using simulation modeling concluded that meters that achieve both a CV and a bias less than 5% rarely lead to major errors in insulin dosage. Lack of consensus on quality goals for glucose meters reflects the absence of agreed-upon objective criteria. When biological variation criteria are used, a goal for total error (including both bias and imprecision) of 6.9% or less has been proposed.

Glucose meters are also used to calculate insulin dose in patients without diabetes on tight glucose control protocols in intensive care units (ICUs). Evidence in 2001 showed that intensive insulin therapy significantly reduced mortality and morbidity of critically ill patients in the surgical ICU. Although some subsequent studies were unable to replicate these findings, aggressive glucose control with intravenous infusion of insulin is used extensively in hospital ICUs. Many factors, such as hypoxia, shock, and low hematocrit, are common in these patients and can compromise glucose analysis in capillary blood samples. The use of glucose meters in these settings has been questioned by some experts. Some meters may have adequate analytical performance (as noted above), but the use of skin puncture (fingerstick) samples introduces serious error in patients who have conditions such as shock.

Performance of Glucose Meters

The most common errors in SMBG, such as proper application, timing, and removal of excess blood, have been reduced by advances in technology but can still occur. Additional innovations that reduce operator error include (1) systems that abort testing if the sample volume is inadequate, (2) built-in programs that simplify quality control, and (3) increased memory that allows the instrument to store up to several hundred glucose readings that can be downloaded into a computer.

Several factors affect the accuracy and reproducibility of SMBG. These include (1) user variability—up to 50% of values may vary by more than 20% from reference values; (2) hematocrit—the presence of anemia (false increase) or polycythemia (false depression) may result in up to 30% variability; and (3) defective reagent strips or instrument malfunction (rare). Other variables include changes in altitude, environmental temperature, or humidity; hypotension; hypoxia; and high triglyceride concentrations. In addition, *these assays are unreliable at very high and very low glucose concentrations* (<60 and >500 mg/dL; <3.3 and >28 mmol/L). Because dehydration, a common feature of diabetic ketoacidosis, greatly increases blood viscosity, inaccurately low blood glucose results may be obtained. Several drugs interfere, but not with all meters. Another important factor is the lack of correlation among meters, even from a single manufacturer, caused by different assay methods and architecture. Moreover, results from 2 m of the same brand have been observed to differ substantially. Patient factors are also important, particularly adequate training when the meter is used for SMBG. Recurrent education at clinic visits and comparison of SMBG with concurrent laboratory glucose analysis improved the accuracy of patients' blood glucose readings. It is important to evaluate the patient's technique at regular intervals.

Meter performance varies widely. Under carefully controlled conditions in which all assays were performed by a single medical technologist, approximately 50% of analyses met the ADA criterion of less than 5% deviation from reference values. Performance of older meters was substantially worse. Note that medical technologists perform better than patients. Comparison with laboratory values of almost 22,000 measurements of capillary glucose by patients using meters revealed no significant improvement in meter performance between 1989 and 1999.

An analysis in 2012 revealed that only 18 of 34 (53%) glucose meters approved for use in Europe fulfilled the minimum accuracy requirements of the 2013 ISO standard. The imprecision of most meters precludes their use in the diagnosis of diabetes.

ALTERNATIVES TO METERS FOR MONITORING OF BLOOD GLUCOSE

A major limitation to performing SMBG is that it is painful and inconvenient. Since the 1960s, attempts have been made to develop a painless method for monitoring blood glucose

concentrations. Three general approaches have been used, namely, implanted sensors, minimally invasive monitoring, and noninvasive monitoring.

Implanted Sensors

Several implanted biosensors have been developed. Detection systems are based on enzymes, electrodes, or fluorescence. The most widely studied method is an electrochemical sensor that is usually implanted subcutaneously. All monitoring devices use glucose oxidase to measure glucose every 1 to 5 minutes. The values are sent to a monitor. Results are recorded, can be downloaded later in the physician's office, and are usually available to the patient in real time. These devices are subject to some limitations. Implantation of a needle type of sensor into the subcutaneous tissue induces inflammatory responses in the host, requiring sensors to be replaced every 7 to 14 days. The sensors require calibration by the user initially and at least twice a day with a glucose meter and are subject to the imprecision of the meter. New sensors have been developed that eliminate calibration by users. In addition, changes in glucose concentration in the interstitial fluid occur 4 to 20 minutes later than changes in the blood. Nevertheless, real-time continuous glucose monitoring improves long-term glycemic control in a subset of patients with type 1 diabetes. Newer features, such as automated suspension of insulin delivery for up to 2 hours when glucose concentrations reach a preset low threshold, have recently been shown to significantly reduce the rate of hypoglycemia and improve HbA_{1c} in patients with type 1 diabetes. Automated closed-loop insulin delivery (also termed the "artificial pancreas") are a focus of intense research. The system employs a control algorithm that modulates insulin delivery according to real-time interstitial glucose measured by a sensor. Closed-loop systems have been shown to be superior to conventional insulin pump therapy.

Minimally Invasive Glucose Monitoring

The concept underlying these methods is that the concentration of glucose in the interstitial fluid correlates with the blood glucose concentration. The principle of the GlucoWatch Biographer involves the application of a low-level electrical current to the skin. This induces movement by electroosmosis of glucose across the skin, where it is measured by a glucose oxidase detector. Glucose concentrations in transdermal fluid and plasma are highly correlated and studies revealed reasonable correlation of the GlucoWatch with SMBG. The clearest application of the GlucoWatch appears to be in the detection of unsuspected hypoglycemia. This device has been withdrawn from the market, but it is likely to stimulate enhanced efforts to bring other technologies into clinical use.

Noninvasive Glucose Monitoring

Noninvasive in vivo monitoring of glucose has been an area of active investigation for many years. Near-infrared spectroscopic devices measure absorption or reflection of light from subcutaneous tissue. Although glucose has a specific

absorption at 1035 nm, many substances interfere. A computer, individually calibrated, screens out interfering information to obtain the glucose result. Alternative approaches include Raman scattering spectroscopy and photoacoustic spectroscopy. Notwithstanding the investment of considerable resources, no noninvasive sensing technology is approved by the FDA for glucose measurement in patients.

KETONE BODIES

The development of ketosis requires changes in both adipose tissue and the liver. *The primary substrates for ketone body formation are free fatty acids* from adipose stores. Normally, long-chain fatty acids are taken up by the liver, reesterified to triglycerides, and stored in the liver or incorporated in very low-density lipoproteins and returned to the plasma. In contrast to other tissues, the brain cannot use free fatty acids for energy. When glucose is unavailable, ketone bodies supply the vast majority of the brain's energy. After a 3-day fast, ketone bodies provide 30% to 40% of the body's energy requirements. In uncontrolled diabetes, the low insulin concentrations result in increased lipolysis and decreased reesterification, thereby increasing plasma free fatty acids. In addition, the increased glucagon/insulin ratio enhances fatty acid oxidation in the liver. Increased counterregulatory hormones also augment lipolysis and ketogenesis in fat and liver, respectively. Thus, increased hepatic ketone production and decreased peripheral tissue metabolism lead to acetoacetate accumulation in the blood. A small fraction undergoes spontaneous decarboxylation to form acetone, but most of it is converted to β -hydroxybutyrate.

The relative proportions in which the three ketone bodies are present in blood vary, depending on the redox state of the cell. In healthy people, β -hydroxybutyrate and acetoacetate—which are present at approximately equimolar concentrations—constitute virtually all the serum ketones. Acetone is a minor component. In severe diabetes, the ratio of β -hydroxybutyrate to acetoacetate may increase to 6:1 because of the presence of a high concentration of nicotinamide adenine dinucleotide (NADH), which favors β -hydroxybutyrate production.

Clinical Significance of Ketones

Excessive formation of ketone bodies results in increased blood concentrations of **ketones** (*ketonemia*) and increased excretion of ketones in the urine (*ketonuria*). This process is observed in conditions associated with decreased availability of carbohydrates (such as starvation or frequent vomiting) or decreased use of carbohydrates (such as diabetes mellitus, glycogen storage disease [von Gierke disease], and alkalosis). The popular high-fat, low-carbohydrate diets are ketogenic and increase ketone bodies in the circulation. Diabetes and alcohol consumption are the most common causes of ketoacidosis. Urine ketone test results are positive in more than 30% of first-morning-void specimens from pregnant women. Semiquantitative determination of ketone bodies in blood is more accurate than determination of these compounds in urine in the treatment of diabetic ketoacidosis. Although not always excreted in proportion to blood ketone concentrations, urine ketones are widely used for monitoring control in patients with type 1 diabetes because of convenience. Patients with type 1 diabetes should test for ketones during acute illness or stress, with consistent increases in blood glucose (>300 mg/dL; 16.7 mmol/L), during pregnancy, or when symptoms of ketoacidosis are present.

Most of the tests for ketone bodies described in [Chapter 22](#) detect or measure acetoacetate only. This may produce a paradoxical situation. When a patient initially presents in ketoacidosis, the test results for ketones may be only weakly positive. With therapy, β -hydroxybutyrate is converted to acetoacetate, and the ketosis appears to worsen.

GLYCATED PROTEINS

Measurement of glycated proteins, primarily glycated hemoglobin (GHb), is effective in monitoring long-term glucose control in people with diabetes mellitus. It provides a retrospective index of integrated plasma glucose values over an extended period of time and is not subject to the wide fluctuations observed when blood glucose concentrations are assayed. GHb concentrations are therefore a valuable and widely used adjunct to blood glucose determinations for monitoring long-term glycemic control. In addition, GHb has recently been recommended for the diagnosis of diabetes and is a measure of risk for the development of microvascular complications of diabetes.

Glycated Hemoglobins

Glycation is the nonenzymatic addition of a sugar residue to amino groups of proteins. Human adult hemoglobin (Hb) usually consists of HbA ($\approx 97\%$ of the total), HbA₂ (2.5%), and HbF (0.5%). HbA is made up of four polypeptide chains, two α -chains and two β -chains. Chromatographic analysis of HbA identifies several minor hemoglobins, namely, HbA_{1a}, HbA_{1b}, and HbA_{1c}, which are collectively referred to as HbA₁, *fast hemoglobins* (because they migrate more rapidly than HbA in an electrical field), *glycohemoglobins*, or **glycated hemoglobins**. The Joint Commission on Biochemical Nomenclature of the International Union of Pure and Applied Chemistry recommends the term *neoglycoprotein* for such derivatives and the term *glycation* to describe this process. Therefore, although *glycosylated* and *glucosylated* have been widely used in the literature, the term *glycated* is preferred. HbA_{1c} is formed by the condensation of glucose with the N-terminal valine residue of each β -chain of HbA to form an unstable Schiff base (aldimine, pre-HbA_{1c}; [Fig. 33.2](#)). The Schiff base may dissociate or may undergo an Amadori rearrangement to form a stable ketoamine, HbA_{1c}. HbA_{1a1} and HbA_{1a2}, which make up HbA_{1a}, have fructose-1,6-diphosphate and glucose-6-phosphate, respectively, attached to the amino terminal of the β -chain. HbA_{1b} contains pyruvic acid linked to the amino terminal valine of the β -chain, probably by a ketamine bond. *HbA_{1c} is the major fraction*, constituting approximately 80% of HbA₁.

Glycation may also occur at sites other than the end of the β -chain, such as lysine residues or the α -chain. The sum of all GHbs, referred to as total glycated hemoglobin, cannot be separated from nonglycated hemoglobin by methods based on charge, but are measured by boronate affinity chromatography.

Formation of GHb is essentially irreversible, and the concentration in the blood depends on both the life span of the red blood cell (RBC; average 120 days) and the blood glucose concentration. Because the rate of formation of GHb is directly proportional to the concentration of glucose in the blood, *the GHb concentration represents integrated values for glucose over the preceding 8 to 12 weeks*. This provides an additional criterion for assessing glucose control because GHb values are free of day-to-day and hour-to-hour glucose fluctuations and are unaffected by exercise or food ingestion immediately

Fig. 33.2 Formation of hemoglobin (Hb)A_{1c}.

before collection of the blood sample. The contribution of the plasma glucose concentration to GHb depends on the time interval, with more recent values (such as during the preceding month) providing a larger contribution than earlier values (such as 3 months earlier). The plasma glucose in the preceding 1 month determines 50% of the HbA_{1c}, whereas days 60 to 120 determine only 25%. After a sudden alteration in blood glucose concentrations, the rate of change in HbA_{1c} is rapid during the initial 2 months, followed by a more gradual change approaching steady state 3 months later.

Interpretation of GHb depends on RBCs having a normal life span. Patients with hemolytic disease or other conditions with shortened RBC survival exhibit a substantial reduction in HbA_{1c}. HbA_{1c} can still be used to monitor these patients, but values must be compared with previous values from the same patient—not with published reference intervals. Similarly, individuals with recent significant blood loss have falsely low values because of a higher fraction of young erythrocytes. High HbA_{1c} concentrations have been reported in iron-deficiency anemia. The effects of hemoglobin variants (such as HbF, HbS, and HbC) depend on the specific method of analysis used (discussed later). Depending on the particular hemoglobinopathy and assay, results may be spuriously increased or decreased. Most manufacturers of HbA_{1c} assays have modified their assays to eliminate interference from many of the common hemoglobin variants. Therefore, HbA_{1c} can be accurately measured by selecting an appropriate instrument, provided the RBC life span is not altered (see www.NGSP.org for additional information). Another source of error in selected methods is *carbamylated hemoglobin*, formed by attachment of urea. It is present in large amounts in renal failure, which is common in people with diabetes. Carbamylated hemoglobin does not interfere with most modern methods. Most interferents produce small effects, and HbA_{1c} can be measured accurately in the vast majority of patients with diabetes.

Hemoglobin A_{1c} in Diagnosis of Diabetes

In 2009, an International Expert Committee advised that HbA_{1c} could be used for the diagnosis of diabetes (see [Box 33.2](#)). An HbA_{1c} value greater than 6.5% was selected as the decision point, based on the prevalence of retinopathy. This recommendation has been endorsed by both the ADA and the WHO. HbA_{1c} concentrations 5.7% to 6.4% indicate individuals at high risk of developing diabetes. HbA_{1c} was also recommended as an alternative to glucose for screening for diabetes. This last recommendation has been accepted by the ADA.

Hemoglobin A_{1c} in Monitoring of Diabetes

HbA_{1c} is firmly established as an index of long-term blood glucose concentrations and a measure of the risk for developing microvascular complications in patients with diabetes. Absolute risks of retinopathy and nephropathy are directly proportional to the mean HbA_{1c} concentration. In persons without diabetes, HbA_{1c} is directly related to risk of cardiovascular disease.

Methods for Determination of Glycated Hemoglobins

More than 150 different methods have been described for the determination of GHbs. Most methods separate GHb from nonglycated hemoglobin using techniques based on charge differences (ion-exchange chromatography, HPLC, electrophoresis, and isoelectric focusing) or structural differences (affinity chromatography and immunoassay). Chemical analysis (enzymatic, photometry, and spectrophotometry) has also been used. Recently, methods have become commercially available that use capillary electrophoresis or an enzymatic assay that specifically measure HbA_{1c}. The result is expressed as a percentage of total hemoglobin. Most laboratories in the United States use immunoassay or HPLC and report HbA_{1c}. The selection of method by a laboratory is influenced by several factors, including sample volume, patient population, and cost. It is advisable to consult clinicians in this process. The ADA recommends that laboratories use only HbA_{1c} assays that are certified by the NGSP (previously termed the National Glycohemoglobin Standardization Program) as traceable to the DCCT reference. These assays are listed on the NGSP website (www.NGSP.org/ accessed) and are updated several times a year.

High-performance liquid chromatography. HbA_{1c} and other hemoglobin fractions are separated by HPLC, with cation exchange chromatography. Several fully automated systems are commercially available. Assays require only 5 μ L of whole blood, and fingerstick samples can be collected in a capillary tube for analysis. Anticoagulated blood is diluted with a hemolysis reagent containing borate. Samples are incubated at 37°C for 30 minutes to remove the Schiff base and are inserted into the autosampler. (Some instruments have a shorter preincubation step, and others separate labile GHb chromatographically, eliminating the step to remove the Schiff base.) A step gradient using three phosphate buffers of increasing ionic strength is passed through the column. Detection is performed at 415 and 690 nm, and results are quantified by integrating the areas under the peaks. Analysis time is as short as 3 minutes. HbA_{1c} by HPLC was used for analysis of all patient samples in the DCCT.

Immunoassay. Assays for HbA_{1c} have been developed using antibodies raised against the Amadori product of glucose (ketoamine linkage) plus the first few (four to eight) amino acids at the N-terminal end of the β -chain of hemoglobin. A widely used assay measures HbA_{1c} in whole blood by inhibition of latex agglutination. The agglutinator, a synthetic polymer containing multiple copies of the immunoreactive portion of HbA_{1c}, binds the anti-HbA_{1c} monoclonal antibody that is attached to latex beads. This agglutination produces light scattering, measured as an increase in absorbance. HbA_{1c} in the patient's sample competes for the antibody on the latex, inhibiting agglutination, thereby decreasing light scattering. Immunoassays are generally calibrated to give values that match HPLC values. The antibodies do not recognize labile intermediates or other GHbs (such as HbA_{1a} or HbA_{1b})

because both the ketoamine with glucose and specific amino acid sequences are required for binding. Similarly, several hemoglobin variants, such as HbF, HbA₂, HbS, and carbamylated hemoglobin, are not detected. The procedure has been adapted for capillary blood samples using a bench-top analyzer with reagent cartridges designed for use in physicians' office laboratories.

Affinity chromatography. Affinity gel columns are used to separate GHb, which binds to *m*-aminophenylboronic acid on the column, from the nonglycated fraction. The boronic acid reacts with the *cis*-diol groups of glucose that is bound to hemoglobin to form a reversible five-member ring complex, thus selectively holding the GHb on the column. Nonglycated hemoglobin does not bind. Sorbitol is added to elute the GHb. Absorbance of bound and nonbound fractions, measured at 415 nm, is used to calculate the percentage of GHb.

The major advantages of affinity chromatography are as follows: no interference from nonglycated hemoglobins and negligible interference from the labile intermediate form of HbA_{1c}. It is unaffected by variations in temperature and has reasonably good precision. Hemoglobin variants such as HbS, HbC, HbD, or HbE produce little effect.

Affinity methods measure total GHb. This includes components other than HbA_{1c} because the assay detects ketoamine structures on lysine and valine residues on both α - and β -chains of hemoglobin.

Although the method detects all GHbs, most commercial systems are calibrated to report a standardized HbA_{1c} value. The value is derived from an equation obtained from linear regression between total GHb and HbA_{1c} analysis by HPLC. A linear relationship has been demonstrated, and standardized HbA_{1c} values are thus comparable with values obtained by methods specific for HbA_{1c}. Columns and reagents are commercially available.

Capillary electrophoresis. Advantages of capillary electrophoresis include high resolving ability (due to the high voltage that can be applied) and small sample volume (see detail in [Chapter 11](#)). Briefly, charged molecules are separated by their electrophoretic mobility in an alkaline buffer (pH 9.4), and by electrolyte pH and electroosmotic flow. Hemoglobins are detected by absorption spectroscopy at the cathodic end of the capillary. An automated liquid-flow capillary electrophoresis method to measure HbA_{1c} is commercially available and has been approved by the FDA in the United States.

Enzymatic. Enzymatic assays to measure HbA_{1c} have been developed recently based on a colorimetric method in which fructosyl peptide oxidase catalyzes the oxidative deglycation of *N*-(deoxyfructosyl)-Val-His. The procedure has been adapted for analysis on a high-throughput automated analyzer and has been approved by the FDA for use in the United States.

Assay Standardization

Clinical laboratories measure GHb with diverse assays that use multiple methods and quantify different components. The DCCT results accentuated the need for accurate GHb

measurement and provided a strong impetus for standardization of GHb assays. Committees were established under the auspices of the American Association for Clinical Chemistry (AACC) in 1993 and the IFCC in 1995 to standardize GHb assays.

The NGSP was established in 1996 to implement the protocol developed by the AACC to calibrate GHb results to DCCT-equivalent values. Employing a network of reference laboratories, the NGSP interacts with manufacturers of GHb methods to help them calibrate their methods and trace values to the DCCT. Manufacturers apply for certification by performing precision testing and report results in DCCT-equivalent HbA_{1c} values. This calibration effort has markedly improved harmonization of results and has reduced imprecision. Results obtained using NGSP-certified assays can be compared directly with results of the DCCT and UKPDS, allowing alignment with clinical outcomes data. The ADA recommends that clinical laboratories in the United States use only assays certified by the NGSP and participate in proficiency testing offered by the College of American Pathologists (CAP). The CAP GHb survey uses pooled whole blood specimens at several HbA_{1c} concentrations. Target values are assigned by the NGSP network. Thus, individual laboratories can directly compare their HbA_{1c} results with those of the DCCT and UKPDS.

A different approach was adopted by the IFCC. A working group was established to devise a reference system for standardization based on HbA_{1c}. The IFCC group developed a mixture of purified HbA_{1c} and HbA₀ as primary reference material. Two candidate reference methods, namely, electrospray ionization mass spectrometry (ESI-MS) and capillary electrophoresis, were proposed. These specifically measure the glycated N-terminal valine of the β -chain of hemoglobin. Analysis is performed by digesting the hemoglobin molecule with endoproteinase Glu-C, which cleaves the β -chain between Glu-6 and Glu-7, releasing the N-terminal hexapeptide. Glycated and nonglycated hexapeptides are separated and quantified by HPLC-ESI-MS or by HPLC and capillary electrophoresis. HbA_{1c} is measured as the ratio between glycated and nonglycated N-terminal hexapeptides. The IFCC Working Group has established a network of laboratories to implement and maintain the reference system. Comparisons between IFCC and NGSP reference methods (and reference systems from Japan and Sweden) indicate a close and stable relationship and allow manufacturers to calibrate their instruments to a higher-level reference method. However, HbA_{1c} results obtained using IFCC reference methods are 1.5% to 2% absolute HbA_{1c} units lower than those of the NGSP (and lower than other reference systems). The IFCC method is not suitable for routine analysis of patient samples.

Units for Reporting of HbA_{1c}

HbA_{1c} is reported in the NGSP system as a percentage of total hemoglobin. These values, which are equivalent to those reported in the DCCT and the UKPDS, represent the most widely used reporting system in patient care and in the published literature. The IFCC method reports HbA_{1c} in System

International (SI) units, namely, mmol HbA_{1c}/mol total Hb. Comparison between the IFCC and NGSP networks produced a master equation that permits conversion between the two reference systems. For example, an HbA_{1c} result of 7% (in NGSP/DCCT/UKPDS units) is equivalent to 53 mmol/mol (in IFCC units). A calculator to convert between units is available at <http://www.ngsp.org/convert1.asp>. Some countries have elected to report HbA_{1c} exclusively in SI units.

In some countries, an estimated average glucose (eAG) is reported together with HbA_{1c}. A conversion table is available at <http://www.ngsp.org/A1ceAG.asp>. A large, prospective clinical study revealed a significant correlation between HbA_{1c} and mean plasma glucose concentrations. The concept of reporting eAG with HbA_{1c} is not accepted by all and is controversial.

Performance Goals

Some expert groups have proposed goals for HbA_{1c} assay accuracy and precision and these have tightened over the years. Within-subject biological variation (CV_i) of HbA_{1c} is less than 2%. Recent ADA guidelines recommend an intralaboratory CV of less than 2% and an interlaboratory CV of less than 3.5%. For a single method, the goal should be an interlaboratory CV of less than 3.5%.

Specimen Collection and Storage

Patients need not be fasting. Venous blood should be collected in tubes containing EDTA, oxalate, or fluoride. Sample stability depends on the assay method used. Whole blood may be stored at 4°C for up to 1 week. Above 4°C, HbA_{1a+b} increases in a time- and temperature-dependent manner, but HbA_{1c} is only slightly affected. Samples are not stable at -20°C. For most methods, whole blood samples stored at -70°C or colder are stable for at least 18 months.

Reference Intervals

Values for GHbs are expressed as a proportion of total blood hemoglobin. HbA_{1c} should be reported. The reference interval (using an NGSP-certified method) is 4% to 5.6% (20 to 38 mmol/mol).

Results are not affected by acute illness. Intraindividual variability is minimal (CV ≈ 1%). HbA_{1c} increases slightly with age and differs among racial groups (e.g., higher in African Americans and Hispanics than Caucasians). It is not known whether this has clinical significance. In patients with poorly controlled diabetes, values rarely exceed 15%. HbA_{1c} greater than 15% or below 4% should prompt additional studies to determine the possible presence of variant hemoglobin. Note that target values derived from DCCT and UKPDS, not the reference values, are used to evaluate metabolic control in patients with diabetes.

There is no specific value of HbA_{1c} below which the risk of diabetic complications is eliminated completely. The ADA states that for most patients the goal of treatment should be to maintain HbA_{1c} at less than 7% (53 mmol/mol). (Some organizations recommend an HbA_{1c} target of less than 6.5% [48 mmol/mol].) These goals are applicable only if the assay

method is certified as traceable to the DCCT reference. Each laboratory should establish its own reference interval. Assay precision is important because each 1% change in HbA_{1c} represents an approximate 30-mg/dL (1.7 mmol/L) change in average blood glucose.

No consensus has been reached on optimum frequency of testing. The ADA recommends for patients with type 1 or type 2 diabetes that *HbA_{1c} should be routinely monitored at least every 6 months in patients meeting treatment goals (and who have stable glycemic control).*

Glycated Serum Proteins

In selected patients with diabetes (e.g., GDM), assays may be needed that are more sensitive than HbA_{1c} to shorter-term alterations in average blood glucose concentrations. Nonenzymatic attachment of glucose to amino groups of proteins other than hemoglobin (e.g., serum proteins, membrane proteins, lens crystallins) to form ketoamines also occurs. Because serum proteins turn over more rapidly than erythrocytes (the circulating half-life for albumin is about 20 days), *the concentration of glycated serum albumin reflects glucose control over a period of 2 to 3 weeks.* Therefore deterioration of control and improvement with therapy are evident earlier than with HbA_{1c}.

Fructosamine

Fructosamine is the generic name for plasma protein ketoamines. The name refers to the structure of the ketoamine rearrangement product formed by the interaction of glucose with the ε-amino group on lysine residues of albumin. Analogous to HbA_{1c}, fructosamine may be used as an index of the average concentration of blood glucose over an extended time.

Because all glycated serum proteins are fructosamines and albumin is the most abundant serum protein, measurement of fructosamine is thought to be largely a measure of glycated albumin (GA), but this has been questioned by some investigators. Although the fructosamine assay can be automated and is cheaper and faster than HbA_{1c}, *there is a lack of consensus on its clinical utility.* The clinical value of fructosamine has not been firmly established, and no convincing evidence relates its concentration to the chronic complications of diabetes. An important limitation is the lack of long-term prospective studies with clinical outcomes.

Fructosamine may be useful in circumstances where HbA_{1c} is of little value, such as in patients with hemoglobin variants that are associated with decreased erythrocyte life span. Gross changes in protein concentration and half-life may have large effects on the proportion of protein that is glycated. Thus, fructosamine results may be invalid in patients with nephrotic syndrome, cirrhosis of the liver, or dysproteinemias, or after rapid changes in acute-phase reactants. *There is no role for fructosamine in the diagnosis of diabetes.*

Determination of Fructosamine

Methods for measuring glycated proteins include (1) affinity chromatography using immobilized phenylboronic acid (similar to the GHb assay); (2) HPLC of glycated lysine

residues after hydrolysis of the glycated proteins; (3) a photometric procedure in which mild acid hydrolysis releases 5-hydroxymethylfurfural—proteins are precipitated with trichloroacetic acid and the supernatant is reacted with 2-thiobarbituric acid; and (4) other procedures using phenylhydrazine and ϵ -N-(2-furoylmethyl)-L-lysine (furosine). None of these assays is popular because they are not suitable for routine clinical laboratories. Prolonged storage at ultra-low temperatures (-96°C) prevents in vitro glycation of serum proteins.

An alternative method of measuring fructosamine is based on the principle that under alkaline conditions, fructosamine undergoes an Amadori rearrangement. The resultant compounds have reducing activity that can be differentiated from other reducing substances. In the presence of carbonate buffer, fructosamine rearranges to the eneaminol form, which reduces nitroblue tetrazolium (NBT) to a formazan. Absorbance at 530 nm is measured at two time points, and the absorbance change is proportional to the fructosamine concentration. A 10-minute preincubation period is necessary to allow fast-reacting interfering reducing substances to react. The assay is easily automated and has excellent between-batch analytical precision. Hemoglobin (>100 mg/dL; 1 g/L) and bilirubin (>4 mg/dL; ~ 68 $\mu\text{mol/L}$) may interfere; therefore moderate to grossly hemolyzed and icteric samples should not be used. Ascorbic acid concentrations greater than 5 mg/dL may cause negative interference.

Reference Intervals for Fructosamine

Values in a nondiabetic population are 205 to 285 $\mu\text{mol/L}$ using a colorimetric assay. The reference interval corrected for albumin is 191 to 265 $\mu\text{mol/L}$.

Glycated Albumin

Albumin, which comprises approximately 60% of total serum protein, makes up more than 80% of total glycated serum proteins. The N-terminus and 59 lysine residues are potential glycation sites and it is not known how many of these are glycated in vivo. Analysis of human plasma by HPLC tandem mass spectrometry and [$^{13}\text{C}_6$]-glucose labeling identified 35 different glycation sites on albumin. Assays that measure only glycated albumin (GA), rather than all glycated serum proteins (i.e., fructosamine), are commercially available.

The clinical use of GA is limited by the same caveats that apply to fructosamine: limited evidence relating it to the complications of diabetes and lack of long-term prospective studies with clinical outcomes. Further studies are required to determine whether it is useful for routine monitoring of patients' glycemic control.

Determination of Glycated Albumin

Methods that have been used to quantify GA include: a colorimetric procedure in which mild acid hydrolysis releases 5-hydroxymethylfurfural—proteins are precipitated with trichloroacetic acid and the supernatant is reacted with 2-thiobarbituric acid; RIA using beads coated with antibody to albumin, and ^{125}I -labeled antibody directed against

glucitolysine epitopes of GA previously reduced by sodium borohydride (NaBH_4) to reduce the Schiff base; enzyme-linked immunosorbent assay (ELISA) in which GA binds to a monoclonal antibody coated on a plate, followed by incubation with an enzyme-linked antihuman albumin antibody; enzyme-linked boronate immunoassay where boronic acid-HRP conjugate binds to the cis-diols of GA, which is immobilized by an antihuman albumin antibody coated onto a microtiter plate; affinity chromatography using immobilized phenylboronic acid, followed by elution and measurement of albumin; boronate affinity chromatography; HPLC with anion exchange chromatography to separate albumin, followed by boronate affinity chromatography to separate glycated from nonglycated albumin; enzymatic assay using ketoamine oxidase; and mass spectrometry.

Probably the most widely used method globally is enzymatic. The assay has two steps. In the first, glycated amino acids are eliminated by oxidation with ketoamine oxidase. In the second step, GA is hydrolyzed by an albumin-specific proteinase to glycated amino acids, which are subsequently oxidized by ketoamine oxidase to glucosone, producing hydrogen peroxide. This is quantified with a chromogen by measuring absorbance at 546/700 nm. Total albumin is measured with bromocresol purple and GA is expressed as a percentage of total albumin. This assay is commercially available in a few countries and has been used in numerous published studies. It was approved in 2017 by the FDA for use in the United States.

Reference Intervals for Glycated Albumin

Reference intervals vary considerably, depending on the method, ranging from 0.8% to 1.4% to 18% to 22%. The reference interval for the enzymatic assay, which is expressed as a percentage of total albumin, is 11.9% to 15.8%.

No significant gender differences have been observed, but values in blacks are significantly higher than in whites. Within-subject biological variation is low (CV_i, 2.1%), but between-subject variation is reported to be 10.6%. In patients with poorly controlled diabetes, values may increase by up to 5-fold. Factors that influence albumin metabolism have been reported to alter GA independently of glycemia. These include the nephrotic syndrome, thyroid disease, cirrhosis of the liver, smoking, hyperuricemia, and hypertriglyceridemia. Samples can be stored as long as 23 years at -70°C .

Advanced Glycation End Products

The molecular mechanism by which hyperglycemia produces toxic effects is unknown, but glycation of tissue proteins may be important. Nonenzymatic attachment of glucose to long-lived proteins, lipids, or nucleic acids produces stable Amadori early-glycated products. These undergo a series of additional rearrangements, dehydration, and fragmentation reactions, resulting in stable **advanced glycation end products (AGEs)**. The amounts of these products do not return to normal when hyperglycemia is corrected, and they accumulate continuously over the life span of the protein. Hyperglycemia accelerates the formation of protein-bound AGE, and patients with diabetes thus have more AGE than healthy subjects. Through

effects on the functional properties of protein and the extracellular matrix, AGEs may contribute to the microvascular and macrovascular complications of diabetes.

Measurement of AGEs in the circulation has also been used as a biomarker to monitor the complications of diabetes. However, the diverse structures and composition of AGEs has resulted in assay difficulties. Analysis by ELISA has lacked standardization, yielding variable results. The development of stable isotope dilution analysis liquid chromatography-tandem mass spectrometry, in conjunction with careful preanalytic sample preparation, shows potential to resolve these problems. Some AGE products fluoresce, which forms the basis of noninvasive measurement of skin autofluorescence with a portable reader. Some studies have revealed a positive association of skin autofluorescence with complications of diabetes, but adjustment for HbA_{1c} rendered associations nonsignificant. Limitations of skin autofluorescence measurements include lack of specificity for AGE and most AGEs are not fluorescent. The clinical role of AGE is undefined.

1,5-Anhydroglucitol

Another marker of long-term glycemia is 1,5-anhydroglucitol (1,5-AG), which reflects glucose concentrations over the preceding 2 to 14 days. It is a 1-deoxy form of glucose that originates predominantly from the diet, with the vast majority (>99.9%) normally being reabsorbed from the glomerular filtrate by the SGLT4 sodium-dependent glucose transporter. When blood glucose concentrations exceed the renal threshold (usually ~180 mg/dL [$\sim$ 10.0 mmol/L]), reabsorption of 1,5-AG decreases, leading to a rapid reduction in serum 1,5-AG concentrations. Therefore, low 1,5-AG indicates hyperglycemia, correlating particularly with postprandial blood glucose concentration. An automated colorimetric assay is commercially available (and FDA approved for use in the United States). The reference interval is 10.2 to 33.8 μ g/mL (males) and 5.9 to 31.8 μ g/mL (females). Several factors unrelated to glycemia may alter 1,5-AG values, including diet, medications, renal disease, and liver disease. The evidence linking it to outcomes is limited and the clinical value of measuring 1,5-AG remains to be established.

ALBUMINURIA

Clinical Significance

Patients with diabetes mellitus are at high risk of developing renal damage. End-stage renal disease requiring dialysis or transplantation develops in approximately one-third of patients with type 1 diabetes, and diabetes is the most common cause of end-stage renal disease in the United States and Europe. Although nephropathy is less common in patients with type 2 diabetes, approximately 60% of all cases of diabetic nephropathy occur in these patients because of the higher incidence of this form of diabetes. Persistent proteinuria detectable by routine screening tests (equivalent to a urinary albumin excretion rate [AER] >200 μ g/min or >300 mg/24 h) indicates overt diabetic nephropathy. This is usually associated with long-standing disease and is unusual less

than 5 years after the onset of type 1 diabetes. Once diabetic nephropathy occurs, renal function deteriorates rapidly and renal insufficiency evolves. Treatment at this stage can retard the rate of progression without stopping or reversing the renal damage. Preceding this stage is a period of increased AER not detected by routine dipstick methods. This range of 20 to 200 μ g/min (or 30 to 300 mg/24 h) of increased AER has been called microalbuminuria. The term microalbuminuria, although widely used, is misleading. It implies a small version of the albumin molecule rather than an excretion rate of albumin greater than normal but less than that detectable by routine methods. Current nomenclature has eliminated the terms microalbuminuria and macroalbuminuria.

The presence of increased AER denotes an increase in the transcapillary escape rate of albumin and is therefore a marker of microvascular disease. Persistent AER greater than 20 μ g/min represents a 20-fold greater risk for the development of clinically overt renal disease in patients with type 1 and type 2 diabetes. Prospective studies have demonstrated that increased urinary albumin excretion precedes and is highly predictive of diabetic nephropathy, end-stage renal disease, cardiovascular mortality, and total mortality in patients with diabetes mellitus. Intensive glucose-lowering therapy can significantly reduce the risk of development of increased AER and overt nephropathy in individuals with diabetes. In addition, increased AER identifies a group of nondiabetic subjects at increased risk for coronary artery disease. Interventions, such as control of blood glucose concentrations and blood pressure, particularly with angiotensin-converting enzyme (ACE) inhibitors, slow the rate of decline in renal function.

Specimen Collection and Storage

Variations in urine flow rate in a person may be corrected by expressing albumin as a ratio to creatinine (i.e., ACR). AER is increased by physiological and other factors (e.g., exercise within 24 hours, posture, diuresis), infection, fever, marked hyperglycemia, and marked hypertension. Samples should not be collected after exertion, in the presence of urinary tract infection, during acute illness, immediately after surgery, or after an acute fluid load. All the following urine samples are currently acceptable: 24-hour collection; overnight (8 to 12 hours, timed) collection; 1- to 2-hour timed collection (in laboratory or clinic), and first morning sample for simultaneous albumin and creatinine measurement. The AER is more practical and convenient for the patient than timed specimens and is the recommended method. A first morning void sample is best because it has lower within-person variation than a random urine sample. At least three separate specimens, collected on different days, should be assayed because of high within-subject biological variation (CVi of 30% to 50%) and diurnal variation (50% to 100% higher during the day). Urine should be stored at 4°C after collection. Alternatively, 2 mL of 50 g/L sodium azide can be added per 500 mL of urine, but preservatives are not recommended for some assays. Bacterial contamination and glucose have no effect. Specimens are stable in untreated urine for 1 week at 4°C and for 5 months at -80°C . The albumin concentration decreases by 0.27%/day at -20°C .

An estimated glomerular filtration rate (eGFR) should also be calculated from serum creatinine in patients who have a positive screening test. Serum creatinine and eGFR should be performed at least annually in all adults with diabetes because some patients have decreased GFR without albuminuria.

Semiquantitative Assays

Several semiquantitative assays are available for screening for albuminuria. These test strips, most of which are optimized to read “positive” at a predetermined albumin concentration, have been recommended for screening programs. In view of the wide variability in AER, a “normal” value does not rule out renal disease. Because these assays measure albumin concentration, dilute urine may yield a false negative test result. Refrigerated urine samples should be allowed to reach at least 10°C before analysis.

Quantitative Assays

All sensitive, specific assays for urine albumin use immunochemistry with antibodies to human albumin. Four methods are available: RIA, ELISA, radial immunodiffusion, and immunoturbidimetry. Each method has advantages and disadvantages, and the choice depends on local experience and technical support. In general, these *methods have similar imprecisions, detection limits, and reference intervals*. Details of these methods are found in an expanded version of this chapter in the 6th edition of *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics*.

Reference Intervals

	Albuminuria ^a			
	$\mu\text{g}/\text{min}$	$\text{mg}/24\text{ h}$	$\text{mg}/\text{g Creatinine}$	$\text{mg}/\text{mmol Creatinine}$
Normal	<20	<30	<30	<3.5
High albuminuria	20–200	30–300	30–300	3.5–30
Very high albuminuria ^b	>200	>300	>300	>30

^aLaboratories should verify that these ranges are appropriate for use in their own settings.

^bAlso termed overt nephropathy. Previously called clinical albuminuria.

The ADA recommends initial albuminuria measurement in patients with type 1 diabetes who have had diabetes for 5 years or longer, and in all type 2 diabetic patients. Because of the difficulty involved in dating the onset of type 2 diabetes, screening should commence at diagnosis. Analysis should be performed annually in all patients who have a negative screening result. Screening may be performed with a semiquantitative assay. If the screening result is positive, albuminuria should be evaluated by a quantitative assay. Diagnosis requires the demonstration of albuminuria in at least two of three samples measured within a 3- to 6-month period. If the confirmatory test result is positive, treatment should be initiated.

POINTS TO REMEMBER

HbA_{1c}

- Glycated hemoglobin is formed by nonenzymatic attachment of glucose to hemoglobin.
- HbA_{1c} has glucose attached to the N-terminal Val of the beta chain of hemoglobin.
- The concentration of HbA_{1c} depends on the concentration of glucose in the blood and the erythrocyte lifespan.
- The average erythrocyte lifespan is 120 days, and HbA_{1c} therefore reflects the average blood glucose concentration over the preceding 8–12 weeks.
- Any condition that substantially changes erythrocyte lifespan will alter HbA_{1c}.
- HbA_{1c} is used to diagnose diabetes, monitor glycemic control, evaluate the need to change therapy, and predict the development of microvascular complications.

Glucose

- Hyperglycemia results from defects in insulin secretion and/or insulin action.
- Blood glucose homeostasis is regulated by several hormones, including insulin, glucagon, epinephrine, and cortisol.
- Blood glucose concentrations fluctuate widely during the day, depending on food ingestion, exercise, and other factors (e.g., stress).
- Self-monitoring of blood glucose using portable meters in patients with diabetes who require insulin has been shown to improve patient outcomes.
- Self-monitoring of blood glucose in noninsulin treated patients is not yet proven to be effective.
- The use of continuous glucose monitoring systems (CGMS), which use subcutaneously implanted glucose sensors, by patients on insulin is increasing.

Type 2 diabetes

- Type 2 diabetes is the most common form of diabetes, accounting for ~90% of all cases.
- The onset is insidious, and patients have minimal symptoms.
- Many patients have irreversible complications at the time of diagnosis.
- Patients exhibit both insulin resistance and inadequate insulin secretion.
- Insulin resistance is very difficult to measure, and at diagnosis, the patient may have normal, increased, or decreased insulin concentrations.
- The molecular defects are a consequence of both genetic and environmental factors.
- The gene (or genes) that causes the common forms of type 2 diabetes have not been identified.
- Obesity is linked to the development of type 2 diabetes and lifestyle changes (weight loss and exercise) can delay the onset of the disease.

AT A GLANCE

Diagnosis of Diabetes

Diabetes is diagnosed if at least one of the following criteria is met:

- Fasting plasma glucose (FPG) ≥ 126 mg/dL (7.0 mmol/L)
- 2-hour plasma glucose ≥ 200 mg/dL (11.1 mmol/L) during an oral glucose tolerance test
- HbA_{1c} $\geq 6.5\%$ (48 mmol/mol)

The same test should be repeated on a different day to confirm the diagnosis.

Glucose should be measured in venous plasma.

Glycolysis should be minimized by placing the tube immediately after collection in an ice-water slurry and separating plasma from cells within 30 min. If that cannot be achieved, blood should be collected in a tube containing a rapidly effective glycolysis inhibitor, for example, citrate buffer.

Plasma glucose and HbA_{1c} should be measured in an accredited laboratory; point-of-care devices are not suitable for screening or diagnosis.

In the United States, HbA_{1c} analysis should be performed using a method that is National Glycohemoglobin Standardization Program (NGSP)–certified and standardized to the Diabetes Control and Complications Trial (DCCT) assay.

REVIEW QUESTIONS

1. Hemoglobin A_{1c} (HbA_{1c}) indicates compliance of a patient with diabetes with his or her insulin-taking regimen by monitoring glucose control. HbA_{1c} concentration represents the integrated glucose value in the blood over what period?
 - a. 8 to 12 days
 - b. 8 to 12 weeks
 - c. 8 to 12 months
 - d. 1 day
2. Which of the following values obtained during an oral glucose tolerance test (OGTT) is diagnostic of diabetes mellitus?
 - a. 2-Hour specimen = 125 mg/dL (6.9 mmol/L)
 - b. Fasting glucose = 138 mg/dL (7.7 mmol/L)
 - c. Fasting glucose = 110 mg/dL (6.1 mmol/L)
 - d. 2-Hour specimen = 80 mg/dL (4.4 mmol/L)
3. Type 2 diabetes:
 - a. is associated with resistance to the action of insulin.
 - b. is caused by destruction of pancreatic β -cells.
 - c. is also known as insulin-dependent diabetes mellitus.
 - d. occurs less frequently than type 1 diabetes.
4. All of the following results are confirmatory and diagnostic laboratory values for diabetes mellitus *except*:
 - a. nonfasting blood glucose >200 mg/dL. (11.1 mmol/L)
 - b. 2-hour oral glucose tolerance values >200 mg/dL. (11.1 mmol/L)
 - c. urine glucose >250 mg/dL. (13.9 mmol/L)
 - d. fasting plasma glucose >126 mg/dL. (7.0 mmol/L)
5. Release of glucose from its storage form is referred to as:
 - a. glycogenesis.
 - b. glycogenolysis.
 - c. glycolysis.
 - d. glycconeogenesis.
6. Which of the following hormones produces *hyperglycemia*?
 - a. Epinephrine
 - b. Glucagon
 - c. Thyroid hormone
 - d. All of the above hormones produce hyperglycemia
7. Whole blood glucose values are approximately what percent different from plasma glucose values?
 - a. 20% higher
 - b. 11% lower
 - c. 11% higher
 - d. There is no difference between whole blood glucose and plasma glucose values
8. The development of ketosis in uncontrolled diabetes is a result of:
 - a. increased lipolysis of fatty acids from adipose stores and decreased reesterification of these fatty acids to triglycerides.
 - b. increased nonenzymatic addition of glucose to proteins, lipids, and nucleic acids that form ketoamines.
 - c. increased formation of advanced glycation end products that do not return to normal levels when diabetes is controlled.
 - d. formation of circulating antibodies that are formed against the excess adipose tissue present in a person with diabetes.
9. Which of the following hormones promotes *decreased* blood glucose?
 - a. Epinephrine
 - b. Glucagon
 - c. Cortisol
 - d. Insulin
10. The purpose of examining urinary albumin excretion in an individual with type 1 or type 2 diabetes is to:
 - a. assess the ability of the pancreas to synthesize sufficient insulin.
 - b. determine the rate of formation of advanced glycation end products.
 - c. assess the possibility of overt diabetic nephropathy.
 - d. examine the health of the liver in its ability to synthesize albumin.

Cardiovascular Disease

Fred S. Apple, Jens Peter Goetze, Allan S. Jaffe

OBJECTIVES

1. Define the following terms:
 - Acute coronary syndrome (ACS)
 - Acute myocardial infarction (AMI)
 - Angina
 - Atherosclerosis
 - Cardiac biomarker
 - Congestive heart failure (CHF)
 - Coronary artery disease (CAD)
 - High-sensitivity cardiac troponin assay
 - Electrocardiogram (ECG)
 - Ischemia
 - Myocardium
 - Myocardial infarction
 - Myocardial injury
 - Natriuretic peptide (NP)
 - Plaque
 - Reperfusion
 - Troponin (cTn)
2. Describe the anatomy of the heart, including layers, chambers, and protein makeup of muscle.
3. List the events in the process of atherosclerotic plaque formation.
4. Describe an ideal cardiac biomarker, including necessary characteristics, analytical considerations, and persistence in blood following an AMI.
5. Compare cardiac troponin I and T, including structural differences, physiological function, localization, and usefulness in diagnosing an AMI.
6. Define the two analytical criteria required to designate a cTn assay as highly sensitive.
7. For the following cardiac biomarkers, list and describe their location within heart tissue, physiological function if known, clinical utility for diagnosing disease, tissue specificity, other pathophysiology conditions that cause increased values, and the specimen requirements needed for laboratory analysis:
 - B-type natriuretic peptide (BNP)
 - cTn I and T
 - N-terminal portion of proBNP (NT-proBNP)
8. List four preanalytical considerations that must be assessed by a clinical laboratory that uses NP assays and state what units must be used to report these analytes.
9. List four preanalytical considerations that must be assessed by a clinical laboratory that uses NP assays; state what units must be used to report these analytes.
10. Evaluate and analyze case studies related to cardiovascular disease and the use of cardiac biomarkers in the diagnosis of cardiovascular disease.

KEY WORDS AND DEFINITIONS

99th percentile upper reference limit (URL) A statistically derived cTn concentration determined from a minimum number of a normal, apparently healthy reference population.

Acute coronary syndrome (ACS) A sudden cardiac disorder that varies from angina (chest pain on exertion with reversible tissue injury), to unstable angina (with minor myocardial injury), and to myocardial infarction (with extensive tissue necrosis, which is irreversible).

Acute myocardial infarction (AMI) An acute obstruction of circulation of the heart muscle occurring during the period when circulation to a region of the heart is obstructed and necrosis is occurring.

Angina A condition marked by severe pain in the chest, often also spreading to the shoulders, arms, and neck, caused by an inadequate blood supply to the heart.

Arrhythmia Any variation from the normal rhythm of the heartbeat; alternative (and broader) term: dysrhythmia, especially to indicate an abnormally slow or fast heartbeat that may have rhythmic beating.

Atherosclerosis Any of a group of diseases characterized by thickening and loss of elasticity of arterial walls.

Atherosclerotic plaque A pearly white area within the wall of an artery that causes the intimal (interior) surface to bulge into the lumen; composed of lipid, cell debris, smooth muscle cells, collagen, and sometimes calcium; also known as an atheroma; vulnerable to rupture that causes the formation of a platelet- and fibrin-rich thrombus leading to myocardial infarction and ischemic stroke.

Cardiac biomarker A biological compound whose measurement is useful in the diagnosis/detection of

cardiac disease; used to (1) detect cardiac disorders, (2) detect risk of developing cardiac disorders, (3) monitor the disorder, or (4) predict the response of a disorder to a treatment.

Congestive heart failure (CHF) A clinical syndrome due to heart disease, characterized by breathlessness and abnormal sodium and water retention, often resulting in edema; also called heart failure.

Coronary arteries The two main arteries that provide blood to the heart, surrounding the heart like a crown, coming out of the aorta, arching down over the top of the heart, and dividing into two branches.

Electrocardiogram (ECG) A graphic recording of the electrical activity produced by the heart.

Myocardial injury Any mechanism of injury to the heart that results in an increase in cTnI or cTnT blood concentrations above the 99th percentile upper reference limit.

Myocardial ischemia Deficiency of blood supply to the heart muscle due to obstruction or constriction of the coronary arteries.

Myocardium The middle and thickest layer of the heart wall, composed of cardiac muscle.

Necrosis The sum of the morphological changes indicative of cell death and caused by the progressive degradative action of enzymes.

Non-ST segment elevation myocardial infarction (NSTEMI) A myocardial infarction in which the ST segment is not elevated in one lead or several leads of the ECG.

Percutaneous coronary intervention (PCI) The management of coronary artery occlusion by any of various catheter-based techniques.

Risk stratification A statistical process used to determine detectable characteristics of a biomarker associated with an increased chance of experiencing adverse outcomes.

ST segment elevation myocardial infarction (STEMI) Any type of myocardial infarction in which the ST segment is elevated in one lead or several leads of the ECG.

Thrombolysis Lysis of a thrombus or thrombi.

Unstable angina Angina that occurs unpredictably or suddenly increases in severity or frequency.

Ventricles (right and left) The two lower chambers of the heart, responsible, respectively, for pumping blood into the lungs via the pulmonary artery and into the systemic circulation via the aorta.

Acute ischemic disease and heart failure are the two most common cardiovascular diseases that rely on a biochemical diagnosis. The cardiac biomarkers cardiac troponin (cTn) and natriuretic peptides (NP), respectively, used in their diagnosis and management, are the major focus of this chapter.

The most serious form of ischemic heart disease is **acute myocardial infarction (AMI)**. AMI occurs when there is an imbalance between supply and demand for oxygen in the **myocardium** (heart muscle) resulting in injury to and the eventual death of muscle cells (myocytes). When the blood supply to the muscle in a region of the heart is blocked for more than a few minutes, many or most of the muscle cells in the affected region die. This is called **necrosis** (cell death) of the myocardium. Other events of lesser severity may be missed entirely or be called **angina**, which ranges from stable to **unstable angina**. The ischemic events in the heart, ranging from angina (no cell death) to AMI (cell death), are known as **acute coronary syndromes (ACS)**.

In the United States, approximately 92.1 million (1 in 3) individuals have some form of heart disease. Of those, 7.4 million have or have had a myocardial infarction (MI) and approximately 8.7 million have angina pectoris. Cardiovascular disease accounts for more deaths (31%) than any other disease. It also leads to more hospitalizations than any other disease, with between 5 and 6 million admissions yearly. Approximately 695,000 patients will have a coronary artery event, 580,000 will have an AMI annually, and another 325,000 will have a recurrent event. Blacks have a greater number of events than whites. It is estimated that another 165,000 MIs occur silently. Coronary heart disease causes more than 1 in 7 deaths in the

United States. Deaths that occur acutely result from ventricular **arrhythmias** or pump dysfunction and **congestive heart failure (CHF)** with or without cardiogenic shock. Death rates are sharply age dependent, both during hospitalization and in the year after infarction. The US yearly economic burden of cardiovascular disease is in excess of \$316 billion for coronary heart disease and stroke and by 2030 is estimated to be \$918 billion.

In acute ischemic heart disease, the clinical laboratory plays an important role in detection of **myocardial injury**. The measurement of cTn is an important test for this purpose. These proteins are found almost exclusively in heart muscle cells (cTnT has been shown to be expressed in diseased skeletal muscle from some patients with neuromuscular diseases) and released into the circulation when cells die. Increased concentrations of cTn in the blood are sensitive signs of damage to heart muscle. Conversely, reference concentrations (**≤99th percentile upper reference limit [URL]**) provide powerful evidence for the healthcare provider that a patient's symptoms are not related to cardiac injury.

Heart failure is often termed CHF. In the United States, CHF is the only cardiovascular disease with an increasing incidence. The National Heart, Lung, and Blood Institute estimates current prevalence at 4.8 million Americans and 23 million worldwide with CHF. There are approximately 580,000 new cases each year, with approximately 1 million admissions to hospitals for CHF per year. CHF is the leading cause of hospitalization in individuals 65 years of age and older.

Clinical chemistry testing has become important in detection of CHF. The key blood tests are B-type natriuretic peptide (BNP) and the N-terminal portion of proBNP

(designated NT-proBNP), which are breakdown products of proBNP. BNP and NT-proBNP are released from the stressed heart following upregulation of proBNP. Unlike cTn, which are intracellular proteins that escape from heart muscle cells only because the cells are dead or seriously injured (irreversible injury), BNP is a hormone that is secreted into the blood, stimulated by the stretch of the heart wall that occurs in heart failure. (Note that the general use of the term NP in this chapter refers to either BNP or NT-proBNP unless specifically indicated.)

ANATOMY AND PHYSIOLOGY OF THE HEART

The average human adult heart weighs approximately 325 g in men and 275 g in women. It is enclosed in a sac called the pericardium. The cardiac wall is composed of three layers: the epicardium (the outer most layer), a middle layer, and an inner layer called the endocardium. The heart has four chambers. The two upper chambers are termed the right and left atria, and the two lower chambers are termed the **right and left ventricles** (Fig. 34.1). The endocardium is the layer most

Fig. 34.1 Anatomy of the heart. (From Dorland, W. A. [2003]. *Dorland's Illustrated Medical Dictionary* [30th ed.]. Philadelphia: WB Saunders: Panel 20.)

susceptible to **myocardial ischemia**, a condition where the heart tissue is slowly or suddenly starved of oxygen and other nutrients. Note that the **coronary arteries**, which supply the blood to the wall of the heart, are on the epicardium. The work of the heart is generated by the alternating contraction and relaxation of striated muscle fibers. The fibers contain the

contractile proteins actin, myosin, and troponins that regulate contraction. Two of the troponins, the cardiac forms of troponins I and T, have become the definitive biomarkers of cardiac injury.

A typical cardiac cycle consists of two intervals known as systole and diastole (Fig. 34.2). During systole, the blood

Fig. 34.2 The cardiac cycle. (From Dorland, W. A. [2003]. *Dorland's Illustrated Medical Dictionary* [30th ed.]. Philadelphia: WB Saunders, with permission from the National Kidney Foundation.)

pressure (BP) in the aorta is typically about 120 mm Hg. During diastole, the BP falls to about 70 mm Hg. At rest, the heart pumps between 60 and 80 times per minute. The cardiac cycle is tightly controlled by the cardiac conducting system, which initiates electrical impulses and carries them, via a specialized conducting system, to the myocardium. The **electrocardiogram (ECG)** records changes in electrical potential and is a graphic tracing of the variations in electrical potential caused by the excitation of the heart muscle. Clinically, the ECG is used to identify (1) anatomic, (2) metabolic, (3) ionic, and (4) hemodynamic changes. The clinical sensitivity and specificity of ECG abnormalities for detecting ACSs are influenced by a wide spectrum of physiological and anatomical changes and the clinical situation.

Under normal circumstances, each cardiac cycle's electrical potential changes, with each being similar to that of every other cycle, and includes three major components (Fig. 34.3): the atrial depolarization (the P wave), ventricular depolarization (the QRS complex), and repolarization (the ST segment and T wave). A routine ECG is composed of 12 leads. Each lead records the same electrical impulse but in a different position relative to the heart. Areas of pathology shown on the ECG are localized by analyzing differences between the tracing in question and what is considered normal in the 12 different leads.

Cardiac Disease

Acute Coronary Syndrome

ACS includes patients who have a variety of forms of unstable ischemic heart disease. In the severe form of AMI, the ECG typically shows elevation of a portion called the ST segment. The associated clinical picture is known as **ST segment elevation myocardial infarction (STEMI)**. Partial loss of coronary perfusion, if severe, also leads to necrosis, but the magnitude of cell death is generally less and the ECG does not show elevation of the ST segment. The condition is known as **non-ST segment elevation myocardial infarction (NSTEMI)**, or non-STEMI. Patients with STEMI will usually develop Q waves on their ECGs (see Fig. 34.3), hence the term Q-wave MI. If they do not have STE but have biochemical evidence of cardiac injury (e.g., an increased cTnI or cTnT

in blood), they are called NSTEMI. Those who have unstable ischemia and do not show evidence of cardiac necrosis (cell death indicated by increased blood concentrations of a cTn) are classified as having unstable angina. Most of these syndromes occur in response to an acute event in the coronary artery that obstructs circulation to a region of the heart. If the obstruction blocks much of the passageway for blood in the vessel and persists, then necrosis usually results. Because necrosis is known to take some time to develop, it is apparent that opening the blocked coronary artery in a timely fashion will often prevent some of the death of myocardial tissue.

The major cause of ACS is **atherosclerosis**. This is a disease caused by plaque (a deposit of fatty material) being formed on the inner lining of the coronary arteries that feed the surface of the heart, which contributes to significant narrowing of the artery's lumen. Such plaques are vulnerable to rupture that results in the formation of a platelet- and fibrin-rich thrombus leading to MI and ischemic stroke. **Atherosclerotic plaque** has a tendency to break open (plaque disruption) and form blood clots (thrombi) within the vessel, further blocking or completely stopping blood flow. Myocardial ischemia and subsequent infarction usually begin in the endocardium and spread toward the epicardium. Irreversible cardiac injury consistently occurs when the occlusion is complete for at least 15 to 20 minutes. Most of the damage occurs within the first 2 to 3 hours.

Restoration of coronary blood flow within the first 60 to 90 minutes results in the maximal salvage of tissue, but treatment even up to 4 to 6 hours is associated with increased survival. For patients with STEMI, earlier opening of the vessel can be achieved with clot-dissolving agents (**thrombolysis**) and/or **percutaneous coronary intervention (PCI)**, which is a non-surgical method used to open narrowed arteries that supply the heart muscle with blood. Administration of clot-dissolving medications without the use of PCI still plays a major role in treatment. In addition, it is now apparent that urgent invasive revascularization also benefits those with NSTEMI.

Precipitating Factors

A precipitating factor is defined as an element that causes or contributes to the occurrence of a disorder. In many patients with AMI, the following precipitating factors have been observed for patient activities at the onset of AMI: (1) heavy physical exertion, 13%; (2) modest or usual exertion, 18%; (3) surgical procedure, 6%; (4) rest, 51%; and (5) sleep, 8%.

Role of Clinical History in Diagnosis of Acute Coronary Syndrome

The clinical history remains of substantial value in establishing a diagnosis. A prodromal history of angina is elicited in 40% to 50% of patients with AMI. Approximately one-third have had symptoms from 1 to 4 weeks before hospitalization. In the remaining two-thirds, symptoms predate admission by a week or less, with one-third of these patients having had symptoms for 24 hours or less. In most patients, the pain of an ACS is severe but rarely intolerable. Such pain is described as (1) constricting, (2) crushing, (3) oppressing, or (4) compressing. In addition, the patient often complains of something sitting

Fig. 34.3 Electrocardiograms from a patient with an acute myocardial infarction. The sequence is (A) normal; (B) hours after infarction, the ST segment becomes elevated; (C) hours to days later, the T wave inverts and the Q wave becomes larger; (D) days to weeks later, the ST segment returns to near normal; and (E) weeks to months later, the T wave becomes upright again, but the large Q wave may remain.

on or squeezing the chest. The pain is usually felt behind the sternum (retrosternal), spreading frequently to both sides of the chest, favoring the left side. Often the pain radiates down the left arm. In some instances, the pain of AMI may begin in the upper abdomen (epigastrium) and simulate a variety of abdominal disorders, which may lead to a misdiagnosis of indigestion. In other patients, the discomfort of AMI radiates to the (1) shoulders, (2) upper extremities, (3) neck, and (4) jaw, again usually favoring the left side. In patients with preexisting angina, the pain of infarction usually resembles that of angina with respect to features and location, but it is generally (1) much more severe, (2) lasts longer (more than 30 minutes), and/or (3) is not relieved by rest and nitroglycerin. Older individuals, diabetics, and women are more likely to present atypically, without pain or with nonspecific symptoms. Sometimes, the pain of AMI may have disappeared by the time a physician first encounters the patient, or it may persist for a few hours.

Role of Cardiac Biomarkers in Acute Coronary Syndrome

A **cardiac biomarker** measurement is useful in detecting cardiac injury (irreversible structural damage), most commonly for detecting myocardial injury, including AMI. In the latter setting, they are most useful when patients have nondiagnostic ECGs. For a biomarker to be clinically useful in detecting AMI, it must be released rapidly from the heart into the circulation and provide clinically sensitive and specific diagnostic (rule-out and rule-in) information. The analytical assays must be rapid and able to measure low concentrations of the biomarker in serum, plasma, or whole blood samples. Also, the ideal biomarker (cTn) of myocardial injury would persist in the circulation for several days to provide a late diagnostic time window for patients who arrive late after the event (for example, those with minimal pain). Understanding the kinetic rise and fall of a biomarker after an acute or chronic injury is important for clinical interpretation.

Diagnosis of Acute Myocardial Infarction

Historically, the use of cardiac biomarkers in the diagnosis of AMI began in the 1950s; with the measurement of serum (1) aspartate aminotransferase (AST), (2) lactate dehydrogenase (LD), (3) total creatine kinase (CK), and (4) α -hydroxybutyrate. In 1986 the World Health Organization (WHO) produced criteria for the diagnosis of AMI. These criteria required that at least two of the following be met for diagnosing AMI: (1) a history of chest pain, (2) evolutionary changes on the ECG, and/or (3) elevations of serial cardiac biomarkers to a level two times the normal value. Superseding these criteria are the 2000 European Society of Cardiology/American College of Cardiology (ESC/ACC) consensus conference updated in 2007 and 2012 (Global Task Force; pending the Fourth Universal Definition update in 2018) codified the role of cardiac biomarkers by advocating that diagnosis should be based on biomarkers of cardiac damage in the appropriate clinical situation (**Box 34.1**). The recommendations of the Biochemistry Panel of the ESC/ACC Committee for the use of biomarkers in the diagnosis of an established AMI are listed in **Box 34.2**.

Congestive Heart Failure

CHF is a syndrome characterized by ineffective pumping of the heart, often leading to an accumulation of fluid in the lungs. At least half of such cases are a result of the loss of cardiac tissue function and are called heart failure with reduced ejection fraction (HFREF). The other half are due to increased stiffness of the cardiac muscle. This type of HF is referred to as heart failure with preserved ejection fraction, or HFPEF.

BOX 34.1 Criteria for the Definition of Acute Myocardial Infarction

1. Detection of rise and/or fall of cardiac biomarkers (preferably troponin) above the 99th percentile of the upper reference limit, together with evidence of ischemia with at least one of the following:
 - a. Ischemic symptoms
 - b. Electrocardiogram changes of new ischemia (new ST-T changes or new left bundle branch block)
 - c. Development of pathologic Q waves on the electrocardiogram
 - d. Imaging evidence of new loss of viable myocardium or new regional wall motion abnormality
 - e. Identification of an intracoronary thrombus by angiography or autopsy

From Thygesen, K., Alpert, J. S., Jaffe, A. S., et al., the Writing Group on behalf of the Joint ESC/ACCF/AHA/WHF Task Force for the Universal Definition of Myocardial Infarction. (2012). Third universal definition of myocardial infarction. ESC/ACCF/AHA/WHF expert consensus document. *Circulation*, 126, 2020–2035.

BOX 34.2 European Society of Cardiology/American College of Cardiology Recommendations for Use of Cardiac Biomarkers for Detection of Myocardial Injury and Myocardial Infarction

- Increases in biomarkers of cardiac injury are indicative of injury to the myocardium, but not an ischemic mechanism of injury.
- cTn (I or T) is a preferred biomarker for diagnosis of myocardial injury.
- Increases in cardiac biomarker proteins reflect irreversible injury.
- Improved quality control of cTn assays is essential, especially at the 99th percentile for the hs-cTn assays.
- Myocardial infarction is present when there is cardiac damage, as detected by an increase of cTn above the 99th percentile URL in a clinical setting consistent with myocardial ischemia.
- For patients with an ischemic mechanism of injury, prognosis is related to the extent of cTn increases.
- If an ischemic mechanism is unlikely, other causes of cardiac injury should be pursued.
- Samples must be obtained at least at 0–3 h for hs-cTn assays and at 6–9 h for contemporary assays after the symptoms begin.

cTn, Cardiac troponin; hs, high sensitivity; URL, upper reference limit.

Other forms include those related to valvular heart disease and so-called high-output HF. The condition is one in which there is an abnormality of cardiac function such that the heart cannot pump sufficient blood to satisfy the requirements of metabolizing tissues, which are abnormally high. With too little blood being delivered, the organs and other tissues do not receive enough oxygen and nutrients to function properly.

To functionally stage CHF patients, the New York Heart Association (NYHA) classification system is often used (Table 34.1). In this system, Class I patients are generally considered asymptomatic with no restrictions on physical activity. In the highest class (IV), patients are often symptomatic at rest with severe limitations on physical activity. The clinical manifestations of heart failure vary considerably and many are nonspecific. The findings depend on many factors, including (1) the clinical characteristics of the patient, (2) the extent and rate at which the heart's performance becomes abnormal, (3) the cause of the heart disease, (4) concomitant comorbidities, and (5) the part of the heart that is affected by abnormal functioning. The severity of impairment ranges from mild, manifested clinically only during stress, to advanced, in which cardiac pump function is unable to sustain life without external support.

Because the symptoms and signs of heart failure are nonspecific, an objective biomarker test for heart failure (such as natriuretic peptide [NP] do increase progressively with increasing severity of disease, but should not increase or decrease in conditions that mimic CHF.

CARDIAC BIOMARKERS

Numerous biomarkers have been monitored to assess myocardial injury and dysfunction (Fig. 34.4, Tables 34.2 and 34.3). Most are myocardial proteins and differ in their (1) location within the myocyte, (2) release kinetics after damage, and (3) clearance from the circulation. In this section, cTns (used as biomarkers of myocardial injury and in diagnosis of AMI) and NPs (used in CHF) are described.

TABLE 34.1 New York Heart Association Functional Classification Used to Classify the Extent of Heart Failure

NYHA Class	Symptoms
I	Cardiac disease, but no symptoms and no limitation in ordinary physical activity (e.g., shortness of breath when walking, climbing stairs, etc.)
II	Mild symptoms (mild shortness of breath and/or angina) and slight limitation during ordinary activity
III	Marked limitation in activity due to symptoms, even during less-than-ordinary activity (e.g., walking short distances [20–100 m]). Comfortable only at rest
IV	Severe limitations; experiences symptoms even while <i>at rest</i> (mostly bedbound patients)

NYHA, New York Heart Association.

TABLE 34.2 Biomarkers in Heart Failure Divided by Pathophysiologic Pathway

Myocardial Stretch	
ANP, BNP, NT-proBNP, MR-proBNP	Neuregulin
GDF-15	sST2
Extracellular Matrix Remodeling	
MMPs (2, 3, 4, 8, and 9)	Myostatin
TIMP1	Syndecan-4
IL-6	Galectin-3
Collagen propeptides	sST2
N-terminal collagen type III peptide	Osteopontin
Myocyte Injury	
TnT, TnI, hsTn	Heart shock protein 60
CK-MB	sTRAIL
Myosin light-chain kinase I	Pentraxin 3
Heart-type fatty acid-binding protein	sFAS
Oxidative Stress	
MPO	Urinary and plasma isoprostanes
Oxidized LDLs	Urinary 8-hydroxy-2'-deoxyguanosine
Urinary biopyrrins	Plasma malondialdehyde
Inflammation	
CRP	Leucine-rich 2-glycoprotein
TNF- α	Cytokines
LP-PLA2	Prolactin
TWEAK	Adiponectin
IL-6 (1, 10, 18)	Soluble endoglin
Adipokines	Serine protease PR3
FAS (APO-1)	S100A8/A9 complex
Osteoprotegerin	CA-125
Soluble TNF receptors 1 and 2	Pentraxin-3
YKL-40	Midkine
IL-1 receptor antagonist	
Neurohumoral Activation	
Norepinephrine	Adrenomedullin
Renin	MR-proADM
Angiotensin II	Chromogranin A and B
Aldosterone	Urocortin
Arginine vasopressin	Endothelin
Copeptin	
Renal Dysfunction	
Neutral gelatinase-associated lipocalin	FGF-23
NAG	Cystatin C
Kidney injury molecule-1	B-trace protein
Quiescin Q6	
Other	
RDW	MicroRNA
β 2-microglobulin	Neprilysin
Triiodothyronine	Urinary albumin-to-creatinine ratio

ANP, Atrial natriuretic peptide; BNP, B-type natriuretic peptide; CRP, C-reactive protein; NT-proBNP, N-terminal portion of proBNP; RDW, red cell distribution width; TNF- α , tumor necrosis factor; TWEAK, tumor necrosis factor–like weak inducer of apoptosis.

Multiple molecular forms of circulating cardiac troponin: analytical and clinical significance. *Ann Clin Biochem*, 45:349–359. Figure courtesy of Paul Collinson.)

Cardiac Troponins I and T

cTnI and cTnT are proteins found in cardiac muscle and are measured in the diagnosis of MI. cTnI is 100% cardiac tissue specific, while cTnT has been reported, although infrequently, to be expressed in skeletal muscle in several neuromuscular diseases.

Biochemistry

Three troponin subunits form a complex that regulates the interaction of actin and myosin and thus regulates cardiac contraction (Fig. 34.5). The three troponins are (1) troponin T (the tropomyosin-binding component), (2) troponin I (the inhibitory component), and (3) troponin C (the

calcium-binding component). Troponins are localized primarily in the myofibrils (94% to 97%) with a smaller cytoplasmic fraction (3% to 6%); although some research does challenge that the cytoplasm fraction is experimentally induced. cTnI and cTnT have different amino acid sequences encoded by different genes, and are different from the predominant cTns found in other muscle such as skeletal muscle. Human cTnI has an additional posttranslational 31-amino acid residue on the amino terminal end compared with skeletal muscle TnI, giving it cardiac specificity. Only one isoform of cTnI has been identified. cTnI is not expressed in normal, regenerating, or diseased human or animal skeletal muscle. cTnT is also encoded by a different gene than the one that encodes skeletal muscle isoforms. An 11-amino acid amino terminal residue gives this biomarker cardiac specificity. However, during human fetal development and in some diseased human skeletal muscle, small amounts of cTnT are expressed as one of four identified isoforms in skeletal muscle. In humans, cTnT isoform expression has been reported in skeletal muscle specimens obtained from patients with (1) muscular dystrophy, (2) polymyositis, (3) dermatomyositis, and (4) end-stage renal disease; there is some evidence that diseased skeletal muscle increases circulating cTnT immunoreactivity measured by the current hs-cTnT (US Food and Drug Administration [FDA]-cleared Gen 5) immunoassay. The other troponin, troponin C, is not useful as a cardiac biomarker as the troponin C expressed in the heart is not specific for the heart. Following myocardial injury, multiple forms of troponin appear both in tissue and in blood. These include (1) the complexes of cardiac troponins T, I, and C (T-I-C, or ternary complex); (2) complexes of I and C (I-C binary complex); and (3) free I. Also, multiple modifications of these three forms exist resulting from biochemical processes involving (1) oxidation, (2) reduction, (3) phosphorylation, (4) dephosphorylation, and (5) removal of the amino acids at the ends (C or N) of the molecules.

Analytical Considerations

Many manufacturers have developed assays to measure cTnI, with only one assay for cTnT. These assays are not standardized, and result in different 99th percentile URLs for each assay. A comprehensive listing updated in 2017 by manufacturers can be found on the International Federation of Clinical Chemistry (IFCC) website (<http://www.ifcc.org/executive-board-and-council/eb-task-forces/task-force-on-clinical-applications-of-cardiac-bio-markers-tf-cb/>).

Assays. Cummins and coworkers were the first to develop a cTn radioimmunoassay (RIA) using (polyclonal) anti-cTnI antisera, followed by an enzyme-linked immunosorbent cTnI assay, which eliminated the need for radioactivity and achieved high specificity by use of monoclonal antibodies.

Numerous manufacturers have since developed monoclonal antibody-based diagnostic immunoassays for the measurement of cTnI in serum, plasma, or whole blood, and most have been cleared by the FDA for patient testing

within the United States. Typically, contemporary or point-of-care (POC) assays have limits of detection (LoD) in the range of 0.01 to 0.10 $\mu\text{g/L}$ compared to high-sensitivity (hs)-cTn assays with LoDs of less than 1 ng/L. Analytically insensitive, qualitative assays of cTnI have also been commercialized but are not recommended for clinical care. hs-cTnI and hs-cTnT results are reported in ng/L, whereas contemporary/POC assay results are reported in $\mu\text{g/L}$. Circumstances that limit the ease of switching from one cTn assay to another in clinical practice or research include: (1) no primary reference cTnI material is currently available for manufacturers to use in standardizing cTnI assays, and (2) cTnI circulates in various forms and the “different antibodies” used in assays recognize different epitopes of cTnI.

For POC immunoassays, the National Academy of Clinical Biochemistry (NACB; now renamed the American Association of Clinical Chemistry [AACC]) has developed Laboratory Medicine Practice Guidelines for use in ACS. These guidelines address (1) administrative issues, (2) cost-effective utilization, and (3) clinical and technical performance of cardiac biomarkers in the emergency medicine department. Proposed elements of the guidelines include:

1. Members of emergency medicine departments, primary care physicians, cardiologists, hospital administrators, and clinical laboratory staff should work collectively to develop an accelerated protocol for the use of biomarkers in the evaluation of patients with possible ACS.
2. Quality assurance measures should be used with monitoring to reduce medical errors and improve patient treatment.
3. The laboratory should perform biomarker testing with a maximum turnaround time (TAT) of 1 hour, optimally 30 minutes. The TAT is defined as the time from blood collection (0 hour) to reporting of results to the provider. Institutions that cannot consistently provide a 1-hour TAT should consider implementing POC assays. Performance specifications and characteristics for central laboratory and POC assays should not differ. POC assays should provide quantitative results.

Specimen requirements. For both central laboratory and POC testing, and for practical considerations, the optimal specimens for rapid processing and testing appear to be anticoagulated whole blood or plasma. This eliminates the extra time needed for clotting and additional sample handling. However, differences have been described among plasma, whole blood, and serum specimens for cTnI concentrations measurement by an individual assay. Some anticoagulants, as well as other factors, are known to interfere with cTnI and cTnT antibody-binding affinity, and produce matrix effects (Fig. 34.6). In addition, it is recommended that different sample types not be used during an individual's workup when serial, timed samples are being drawn to rule in or out a MI. It should be noted that at present, results obtained from all FDA-cleared POC assays are substantially less sensitive than

Fig. 34.6 Factors that can influence precise measurement of cTnI circulating in human blood. (With permission from HyTest Ltd.)

central laboratory-based contemporary and hs-assays, and that should be acknowledged by both laboratorians and clinicians when such assays are used. The higher limit of quantification (LoQ; defined at the lowest concentration with a 20% coefficient of variation [CV]) means that small increases of cTn at early time points after AMI will not be detected with these assays. This fact works against the goal of early detection of AMI.

Standardization/harmonization. Standardization of cTn assays remains elusive. The cTnI Standardization Subcommittee of the AACC in collaboration with the National Institute of Standards and Technology (NIST) have produced a cTnI standard reference material (SRM #2921) that is a TnC-cTnI-cTnT complex purified from human heart under non-denaturing conditions. Because this material was found to be commutable with only 50% of current cTnI assays, it is of limited value for assay harmonization of current assays and is not useful as a common calibrator. It does, however, allow for traceability to a common reference material. Currently an IFCC Working Group is working toward developing a secondary serum-based reference material, but it will unlikely provide standardization.

New clinical laboratory practice recommendations for the use of cTn assays in ACS were proposed in 2017 as an expert opinion from the AACC Academy and the IFCC Task Force-Cardiac Biomarkers (TF-CB). This document focuses on the following 10 topics: (1) quality control (QC) utilization, (2) assay limits validating the lower reportable analytical limits, (3) units to be used in reporting measurable concentrations for patients and QC materials, (4) 99th percentile sex-specific URLs to define normality, (5) criteria required to define hs-cTn assays, (6) communication with clinicians and the role laboratories play in educating clinicians on the influence of preanalytical and analytical problems that confound assay results, (7) studies on hs-cTn assays and how authors need to document preanalytical and analytical variables, (8) harmonizing and standardizing assay results and the role of commutable materials, (9) time to reporting of results from sample receipt and sample collection, and (10) changes in hs-cTn concentrations over

time and the role of both analytical and biological variabilities in results of serial blood collections. Highlights of this document are shown in [Box 34.3](#).

Defining Healthy Reference Populations for Determining 99th Percentile

Representative 99th percentiles for contemporary, POC, and hs-assays are shown in [Table 34.4](#). There is poor consistency in the composition or numbers of individuals enrolled for determining the 99th percentile. Defining what constitutes a healthy reference individual is a topic of debate. Should individuals be apparently healthy, young individuals, or should they be age-matched patients hospitalized without known cardiovascular disease, similar to the demographics of patients who rule in for an AMI, with ages of 30 to 90 years? How does one determine who is healthy? Should individuals be selected: (1) via personal interview with questions addressing known cardiac medications, such as statins; (2) after obtaining information about known diseases associated with cardiovascular disease, such as renal disease or diabetes; or (3) via definitive physician evaluation of an individual after taking a history and physical examination, including an ECG, echocardiogram or imaging? Both younger (<30 years) and older (>30 years, with median age of 60 to 65 years to be representative of cardiac patients), apparently healthy reference groups should be recruited. Inclusion criteria should be based on data obtained from a history of medications (not on cardiac drugs, i.e., statins), known underlying diseases, and blood surrogate biomarker measurements: NP concentration for ruling out underlying myocardial dysfunction, an estimated glomerular filtration rate (eGFR) for defining underlying renal insufficiency, and HbA1C for underdiagnosed diabetes.

At present, no definitive, multidiscipline, peer-reviewed surrogate biomarker recommendations have been published. Men and women should be equally represented, with a diverse racial and ethnic mix. The number of individuals for determining a 99th percentile has been defined by the IFCC TF-CB to be a minimum of 300 for men and 300 for women

BOX 34.3 Clinical Laboratory Practice Recommendations of the AACC Academy and IFCC Task Force Task on Clinical Applications of Cardiac Bio-Markers for the Use of Cardiac Troponin in Acute Coronary Syndromes

- For hs-cTn assays, laboratories should measure at least three different concentrations of quality control materials at least once per day.
- During initiation of hs-cTn testing, clinical laboratories should validate the limit of blank, limit of detection, or limit of quantification as applicable.
- Report hs-cTn assays in whole numbers using ng/L without decimal points, and report quality control values to one decimal point.
- Use a defined reference population to report 99th percentiles according to sex-specific cutoffs for hs-cTn assays.
- Assays unable to detect cTn at concentrations at or above the limits of detection in at least 50% of healthy men and women, individually, should be labeled as contemporary and not hs-cTn assays.
- For hospitals using two or more cTn assays, differences in the sensitivity of the various cTn assays should be explained to clinicians so they can better understand discrepancies when patients are transferred between facilities.
- Cardiac troponin results should be reported within 60 mins of a sample being received, with the first sample labeled 0 h.
- Determining the degree of serial changes for cTn values assists in differentiating between patients who have acute cardiac injury, including acute myocardial infarction, and those who have more chronic elevations, many of which may be related to structural heart disease.

cTn, Cardiac troponin; hs, high sensitivity.

From Apple, F. S., Jaffe, A. S., Collinson, P., et al., on behalf of the IFCC Task Force on Clinical Applications of Cardiac Bio-Markers. (2015). IFCC educational materials on selected analytical and clinical applications of high-sensitivity cardiac troponin assays. *Clin Biochem* 48, 201–203; Wu, A. H. B., Christenson, R. H., Greene, D. N., Jaffe, A. S., Kavsak, P. A., Ordóñez-Llanos, J., et al. (2018). Clinical laboratory practice recommendations for the use of cardiac troponin in acute coronary syndrome: expert opinion from the Academy of the American Association for Clinical Chemistry and the Task Force on Clinical Applications of Cardiac Bio-Markers of the International Federation of Clinical Chemistry. *Clin Chem*, 64, 645–655.

(based on 90% confidence intervals). No study has clinically compared all contemporary sensitive assays and/or hs-assays within the same reference or disease population. However, one study has compared multiple assays ($n = 19$) with the same reference group demonstrating substantial differences for both 99th percentiles and ability to measure concentrations above an LoD, as shown in Fig. 34.7.

Because most laboratories do not have (1) the resources to perform adequately powered 99th percentile reference studies, nor (2) the ability to carry out Clinical and Laboratory Standards Institute (CLSI) protocols to establish total imprecision criteria, these clinical laboratories must rely on the peer-reviewed published literature to assist in establishing both local reference limits and imprecision characteristics. Caution

must be taken when comparing the findings reported in the manufacturers' package inserts with the findings reported in the literature because of differences in (1) total sample size, (2) distributions by sex and ethnicity, (3) age ranges, and (4) statistical methods used to calculate the 99th percentile. The IFCC TF-CB website offers the most up-to-date list of cTn assays and 99th percentiles.

Guidelines and acute myocardial infarction. Guidelines have been developed by the (1) Global Task Force for the Fourth Universal Definition of Myocardial Infarction, (2) the joint AACC Academy and IFCC TF-CB document, (3) the ESC/ACC, (4) the American Heart Association (AHA)/ACC, and (5) the Acute Decompensated Heart Failure National Registry (ADHERE) Scientific Advisory Committee. Desirable imprecision of each cTn assay has been defined as less than 10% CV at the 99th percentile reference limit, and is required for an hs-assay. A percentage of CVs up to 20% are acceptable for clinical practice, with assays having greater than 20% CV at the 99th percentile used with caution if no other choice is available.

Clinical utility. Measurement of cTn has become the cornerstone of MI diagnosis (see Box 34.1), with Fig. 34.8 showing the kinetics of the rise and fall of cTn for an hs-cTnI assay for type 1 MI, type 2 MI, chronic myocardial injury, and a nonmyocardial injury patient. High-sensitivity cTn assays also play a substantial role in shortening the time for monitoring cTn to 3 hours, compared to 6 hours with contemporary assays, as shown in Fig. 34.9. Further, in the appropriate low-risk clinical setting, hs-cTn assays now allow for a very early rule-out of MI. Numerous studies have documented that 20% to 50% of patients presenting to emergency departments can be safely discharged predicated on a baseline (single) hs-cTn concentration of less than the LoD, with greater than 99.5% negative predictive value and clinical sensitivity.

B-Type Natriuretic Peptide

In 1981, the Canadian physiologist Adolfo de Bold and his colleagues reported that infusion of atrial tissue extracts produced (1) an increase in the renal excretion of sodium and water, (2) a rapid decrease in BP, and (3) an increase in blood hematocrit. The responsible substance was identified as a peptide comprising 28-amino acid residues and eventually named atrial natriuretic peptide (ANP). Later, brain natriuretic peptide (BNP) and C-type natriuretic peptide (CNP), two structurally related peptides, were isolated and identified in the porcine brain. However, because BNP is mainly expressed in the heart, it was later renamed B-type natriuretic peptide (BNP).

Biochemistry

BNP is a hormone that is mainly released from the myocardial ventricles. Fig. 34.10 illustrates the synthesis of the prohormone and subsequent secretion of NP proteins from the cardiac myocytes. It is not known whether proBNP is split in the myocyte or later in the plasma. The major circulating forms are NT-proBNP, which has an unknown function;

From Apple, F. S., Sandoval, Y., Jaffe, A. S., Ordóñez-Llanos J, for the IFCC Task Force on Clinical Applications of Cardiac Bio-Markers. (2017). Cardiac troponin assays: guide to understanding analytical characteristics and their impact on clinical care. *Clin Chem*, 63, 73–81.

proBNP, for which the function is also unknown; and BNP, the physiologically active hormone, which is the C-terminal part of pro-BNP. BNP is cleared via degradation by endopeptidases, by receptor-mediated clearance, and perhaps via the kidneys, which also secretes BNP. The NT-proBNP fragment is not cleared via receptor-mediated mechanisms, but is thought to be cleared predominantly by the kidneys. Therefore, it is more sensitive to changes in renal function. The majority of research on NPs in CHF has focused on BNP and NT-proBNP. However, investigations have now described substantial amounts of circulating proBNP, which cross-reacts in BNP and NT-proBNP assays.

Analytical Considerations

A number of immunoassays are available to measure BNP and NT-proBNP that use antibodies directed to different epitopes located on the antigen molecules (Fig. 34.11). Degradation of BNP is known to occur by cleavage at serine and proline residues in vivo and in vitro (Fig. 34.12); cleavage is mediated by proteases, which make the concentration of BNP unstable in collected blood. An improved understanding of potential cross-reactivity with split products of the N-terminal portion of NT-proBNP and proBNP itself is needed. For BNP, ethylenediaminetetraacetic acid (EDTA)-anticoagulated whole blood or plasma appears to be the only

acceptable specimen choices. For NT-proBNP, serum, heparin plasma, and EDTA plasma appear acceptable, although results trend slightly lower with the latter. Plastic blood collection tubes are necessary for BNP, whereas for NT-proBNP, either glass or plastic is acceptable. Recent studies have shown that (1) BNP (Fig. 34.13A) and NT-proBNP (see Fig. 34.13B) assays demonstrated substantial cross-reactivity

with proBNP peptides, (2) NT-proBNP assays do not detect glycosylated forms of NT-proBNP or proBNP, and (3) proBNP assays preferentially detect the BNP 1–32 peptide and have minimal cross-reactivity with BNP peptides and glycosylated proBNP. Thus, BNP or NT-proBNP results are not transferable among current immunoassays due to their differences in cross-reactivity and ability to detect

Fig. 34.7 Comparison of both 99th percentile values (circles) and percent measurable concentrations (boxes) in a presumably healthy population for 19 cardiac troponin assays designated as high-sensitivity (hs) (left), contemporary (middle), and POC (right). (From Apple, F. S., Ler, R., & Murakami, M. M. [2012]. Determination of 19 cardiac troponin I and T assay 99th percentile values from a common presumably healthy population. *Clin Chem*, 58, 1574–1581.)

various glycosylated forms of proBNP-derived fragments. It is interesting that, despite a lack of standardized NP assays, clinical cardiovascular and heart failure guidelines recommend uniform cut points for BNP and NT-proBNP assays.

Fig. 34.9 Cardiac troponin kinetics comparing high-sensitivity and contemporary assays in a patient presenting within 30 minutes of acute myocardial infarction. Fig. 34.10 The biotransformation and release of BNP and NT-proBNP from the myocyte into the circulation. aa, Amino acid; LV, left ventricular.

Opportunities to improve standardization and harmonization efforts for NP assays and ultimately to improve clinical care for heart failure patients, particularly with the advent of new pharmacologic agents, still exist.

Guidelines. In 2005, the IFCC established recommended analytical and preanalytical quality specifications for NP assays. These specifications were intended for use by the manufacturers of commercial assays and by clinical laboratories that use NP assays. Subsequently, the NACB and the IFCC committee developed guidelines pertaining to analytical issues for biomarkers of heart failure.

Recommendations from these guidelines include:

1. Reference limits (95th or 97.5th percentile) should be established independently for both BNP and NT-proBNP based on age (by decade) and by sex. Each commercial assay should be validated separately. The effects of ethnicity and renal function need to be evaluated as possible independent variables.
2. Receiver operating characteristic (ROC) curves (Fig. 34.14) should be established to evaluate clinical effectiveness and to establish optimal medical decision cutoffs for BNP and NT-proBNP assays for diagnostic usefulness.
3. Assays for BNP and NT-proBNP should have total imprecision (%CV) of less than or equal to 15% at their age- and sex-defined URLs, and at the NYHA-defined medical decision concentrations.

Before introduction into clinical practice, BNP and NT-proBNP assays must be characterized with respect to the following preanalytical and analytical issues:

1. Preanalytical:
 - a. Effects of storage time and temperature
 - b. Influence of different anticoagulants
 - c. Influence of gel separator tubes
 - d. Need for plastic blood collection tubes for BNP; for NT-proBNP, either glass or plastic is acceptable

Fig. 34.11 Epitope locations on BNP and NT-proBNP used by commercially available assays. (From Vasile, V. C., & Jaffe, A. S. [2017]. Natriuretic peptides and analytical barriers. *Clin Chem*, 63, 50–58.)

Fig. 34.12 Schematic of possible proBNP-derived peptide products. Note that most peptides are not chemically identified, but are instead suggested by biochemical methods that rely on antibody recognition. Carbohydrate is indicated by the shaded hexagons. (From Rifai, N. [2018]. *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics* [6th ed.]. St. Louis: Elsevier.)

2. Analytical:
 - a. Identification of the epitopes in the NP that are recognized by the reagent antibodies
 - b. Cross-reactivity characteristics with related NPs, including NT-proANP, ANP, CNP, BNP, and glycosylated and nonglycosylated NT-proBNP and proBNP
 - c. Identification of interference from heterophile antibodies, rheumatoid factors, and human antimouse antibodies
 - d. Description of calibration material used, how the material was defined, and the concentration value assigned
 - e. Clarification of dilution response
3. For both BNP and NT-proBNP, measurements should be reported in ng/L, not in pmol/L; and patient specimen comparisons and regression analysis should be performed, in accordance with CLSI guidelines, to establish the degree or lack of harmonization across the dynamic range of each assay. Specifically, harmonization around the current presumed optimal diagnostic medical decision cutoff of 100 ng/L for BNP should be validated.
4. For both BNP and NT-proBNP, biological variability has been determined to be at least 50%. Therefore, caution should be exercised in interpreting concentration changes of less than 50% to 80% as reflective of medical therapy. However, consistent trends should be followed as clinically important.

Reference intervals. At present, multiple companies have FDA-cleared BNP and NT-proBNP assays. A

comprehensive listing assays, updated in 2017 by manufacturers, can be found on the IFCC website (<http://www.ifcc.org/executive-board-and-council/eb-task-forces/task-force-on-clinical-applications-of-cardiac-bio-markers-tf-cb/>). Both laboratory-based assays and POC assays based on the use of whole blood are available. Research assays for proBNP and a novel assay that is capable of distinguishing BNP 1–32 from proBNP have been described. There is also a midregional proatrial natriuretic peptide (MR-proANP) that is equivalent to BNP as a biomarker to rule out and confirm HF. As the number of assays for all four NP biomarkers grows, it is even more essential that appropriate clinical and analytical assay criteria are uniformly adapted.

There are several practical issues regarding the use of serum/plasma/whole blood monitoring of NPs. First, reference intervals vary depending on the assay and the reference population used. Second, a number of biological factors affect the BNP and NT-proBNP concentrations, most importantly (1) age, (2) sex, (3) obesity, and (4) renal function. Significant differences are observed between men and women (higher), and concentrations increase with age, as shown in Fig. 34.15 for BNP (A) and NT-proBNP (B). For both BNP and NT-proBNP, there is an inverse relationship between concentrations and body mass index. For NT-proBNP, review of both the FDA-approved US package insert and the European assay package insert reveals substantial differences in the concentrations that are considered as reference intervals by age and sex.

For BNP, a single cutoff at 100 pg/mL (ng/L) has been designated, likely driven by the FDA clearance at this

Fig. 34.13 Cross-reactivity profiles for (A) BNP assays and (B) NT-proBNP assays with BNP and NT-proBNP peptides, respectively. (From Saenger, A. K., Rodriguez-Fraga, O., et al. [2017]. Specificity of B-type natriuretic peptide assays: cross-reactivity with different BNP, NT-proBNP, and proBNP peptides. *Clin Chem*, 63, 351–358.)

value as the ROC curve value optimized for diagnostic accuracy based on the Breathing Not Properly trial. For NT-proBNP, the FDA-cleared assays had cutoffs that are age based: 125 ng/L for patients younger than 75 years and 450 ng/L for patients older than 75 years. These cutoffs appear to misclassify many normal subjects. Clinical studies (proBNP Investigation of Dyspnea in the Emergency [PRIDE]) and the International Collaborative on NT-proBNP [ICON]) have more appropriately defined age-derived and renal function-derived cutoffs as shown in Fig. 34.15B, designated by 50 years of age and eGFR at 60 mL/min per 1.73 m², with an optimal negative predictive value of less than 300 ng/L that is age, gender, and eGFR independent. Obesity also has been shown to have

an association with BNP and NT-proBNP concentrations, with an inverse relationship between body mass index and BNP in CHF patients. Finally, a lack of understanding of the physiological and biological variability of BNP and NT-proBNP in HF patients may cause clinicians to misinterpret changing (increasing or decreasing) BNP and NT-proBNP concentrations in the context of establishing the success or failure of therapy. It has been shown that both BNP and NT-proBNP exhibit a within-subject biological variability of 35% to 45%. Thus, when considering what is clinically, significantly different between serial BNP and NT-proBNP values, a reference change value of 80% is necessary. This is what has been documented in patients with chronic HF.

Fig. 34.14 Receiver operating characteristic (ROC) analysis for brain natriuretic peptide (BNP) and N-terminal pro B-type natriuretic peptide (NT-proBNP) for the diagnosis of acute heart failure. (From Rifai, N. [2018]. *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics* [6th ed.]. St. Louis: Elsevier.)

Fig. 34.15 Representative (A) BNP and (B) NT-proBNP concentration distributions in normal males and females by decade (years) with indication of cutoff values by assay. (From Rifai, N. [2018]. *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics* [6th ed.]. St. Louis: Elsevier.)

Clinical Utility

BNP has a multiplicity of cardiac functions and is released as a counterregulatory hormone in response to a variety of cardiac stresses, but most particularly cardiac stretch. It is significantly affected by changes in volume and in cardiac performance, and among its effects are fluid-volume reduction and vasodilation. BNP and NT-proBNP depend on age and sex, are increased in CHF, and are correlated with its severity. NP measurements are useful (1) in identifying patients with moderate to severe CHF and (2) **risk stratification** of CHF patients and of patients who present with ACS. Higher NP values are in general associated with a more adverse prognosis (Fig. 34.16) in both the acute and chronic situations.

Perhaps the most interesting use of NPs is in the patient with HF with the hope of finding the ability to titrate therapy more efficaciously. BNP and NT-proBNP provide information that is synergistic with the measurement of cTn in these settings and is especially useful for risk stratification when cTn concentrations are within the reference intervals.

Cardiac Biomarkers With Potential and Limited Utilization in Clinical Practice

Several biomarkers that have been used in a limited fashion in clinical practice, but not globally endorsed, are as follows. First, copeptin, a 30–amino acid glycoprotein that constitutes the C-terminal portion of arginine vasopressin,

Covariates for adjustment: age, gender, NYHA class, ischemic etiology, LVEF, LVIDd, serum creatinine and bilirubin, randomized treatment, prescription of β -blockers, digitalis and diuretics, presence of AF or diabetes at study entry.

Fig. 34.16 Relationships of BNP and NT-proBNP values and outcomes. (From Rifai, N. [2018]. *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics* [6th ed.]. St. Louis: Elsevier.)

has been described as a rapid and early rule-out biomarker for AMI at presentation in patients with symptoms suggestive of ACS with a normal cTn value. Second, galectin-3—a protein that is a member of the lectin family and that contains a carbohydrate-recognition-binding domain (CRD) of about 130 amino acids that enable the specific binding of β -galactosides—has been shown to be involved in several biological processes. Clinically, galectin-3 has been found to be involved in (1) cancer, (2) inflammation, (3) fibrosis, (4) stroke, and (5) heart disease. It has also been shown that the expression of galectin-3 is implicated in a variety of processes associated with (1) heart failure, (2) myofibroblast proliferation, (3) fibrogenesis, (4) tissue repair, (5) inflammation, and (6) remodeling of ventricles. Third, ST2, a member of the IL-1 receptor protein family and a biomarker of cardiac stress, has predicted the presence and severity of adverse cardiac

remodeling and tissue fibrosis, which occurs in response to (1) MI, (2) ACS, or (3) heart failure. Fourth, N- and C-terminal fragments of IGF-binding protein-4 (NT- and CT-IGFBP-4), which are released from vulnerable atherosclerotic plaques, are the most recent biomarker being explored for major adverse cardiac events (MACE) prediction in patients with suspected myocardial ischemia.

Several biomarkers that were once used in clinical practice are no longer recommended for routine patient care in the evaluation of ACS and heart failure, because they lack tissue specificity or provide no added value to cTn or NP for diagnosis or risk assessment. These biomarkers include: CK, CK-MB, the isoforms of CK-MB, C-reactive protein (CRP), and myoglobin. Numerous other investigational biomarkers, which reflect different pathophysiologic mechanisms of ACS and heart failure, are shown in Fig. 34.4.

AT A GLANCE

Strategies for ruling in and ruling out acute MI with contemporary and high-sensitivity cTn assays.

REVIEW QUESTIONS

- The technique of choice for measuring cTns is a(n):
 - photometric assay.
 - immunoassay.
 - potentiometric assay.
 - amperometric assay.
- What are the names of the contractile proteins that are located in the striated muscle fibers of the heart?
 - Natriuretic peptides
 - Modified albumins
 - Cardiac troponins
 - Actin and myosin
- Which one of the following cardiac biomarkers is important in detecting moderate to severe CHF?
 - B-type natriuretic peptide
 - Cardiac troponin
 - Nourin
 - ST2
- High-sensitivity cardiac troponin assays are characterized by the following except
 - Ability to measure >50% of normal subjects
 - Maximum acceptable %CV at the 99th percentile is 20%
 - Concentrations units express as whole numbers by ng/L
 - Sex-specific 99th percentiles are used
- A protein that is involved in a number of disease processes including cancer, inflammation, and heart disease and that is expressed in the process of cardiac ventricular remodeling is:
 - isoprostane.
 - phospholipase A₂.
 - galectin-3.
 - MPO.
- The most common cause of ACS is:
 - myocardial ischemia due to incomplete occlusion of a coronary artery.
 - atherosclerosis in coronary arteries.
 - reduced outflow of blood from the left side of the heart.
 - decreased output of the right side of the heart due to cardiac valve destruction.

7. Which one of the following is not a requirement for an ideal cardiac biomarker?
 - a. Specificity
 - b. Rapid release from the heart into circulation
 - c. Rapid removal from circulation
 - d. Sensitivity
8. Loss of oxygen in the form of arterial blood supply to an area of cardiac tissue is referred to as:
 - a. ischemia.
 - b. infarct.
 - c. necrosis.
 - d. atherosclerosis.
9. The condition resulting from ineffective pumping of blood to the body's tissues is referred to as:
 - a. coronary artery syndrome.
 - b. AMI.
 - c. stable angina.
 - d. CHF.

Kidney Disease

*Michael P. Delaney, Edmund J. Lamb**

OBJECTIVES

1. Define the following:
 - Bence-Jones protein
 - Clearance
 - Cystatin-C
 - Diabetes insipidus (DI)
 - Diabetic nephropathy
 - Dialysis
 - Diuretic
 - Glomerulus
 - Glomerular filtration rate (GFR)
 - Juxtaglomerular apparatus
 - Micturition
 - Nephrolithiasis
 - Nephron
 - Pyelonephritis
 - Renal pelvis
 - Renal replacement therapy (RRT)
 - Ureter
 - Urine
2. Describe the following components of the renal system, including structure, function, contribution to urine formation, and clinical significance:
 - Bladder
 - Bowman capsule
 - Collecting tubules
 - Distal convoluted tubule
 - Glomerulus
 - Juxtaglomerular apparatus
 - Kidneys
 - Loop of Henle
 - Nephron
 - Proximal convoluted tubule
3. State the significance of the kidneys' blood supply in the formation of urine within the structure of the glomerulus; list the arteries that form the glomerular capillary bed.
4. List and describe the three major functions of the kidneys, including processes involved, laboratory analytes affected in each process, and how each function is controlled.
5. Describe the glomerular filtration rate (GFR) and clearance in terms of clinical usefulness and effects of renal disease and age on each process.
6. Describe the renal handling of electrolytes and water, including normal physiology, hormones involved, and effect of disease on each function.
7. Discuss the following conditions including the causes (such as, drugs and toxins), symptoms, acid-base disturbances (if any), laboratory methods used to assess, and pertinent laboratory results obtained:
 - Acute kidney injury (AKI)
 - Acute nephritic syndrome
 - Acute tubular necrosis (ATN)
 - Chronic kidney disease (CKD)
 - Diabetes insipidus (DI)
 - End-stage renal disease (ESRD) (including uremic syndrome)
 - Glomerular disease
 - Interstitial nephritis
 - Nephrotic syndrome
 - Pyelonephritis
 - Renal tubular acidoses (RTAs)
 - Uremic syndrome
 - Urinary tract obstruction
8. Describe two options for renal replacement therapy (RRT), including the clinical need for the therapy and laboratory assessment of each therapy.
9. Evaluate and analyze case studies related to renal disease and laboratory analysis of renal disease.

*We are grateful for the data supplied by the US Renal Data System (USRDS). The interpretation and reporting of these data are the responsibility of the authors and in no way should be seen as an official policy or interpretation of the US government. We are also grateful for data supplied by the UK Renal Registry. The interpretation and reporting of these data are the responsibility of the authors and in no way should be seen as an official policy or interpretation of the UK Renal Registry. We also acknowledge the input of Professor Christopher Price to previous editions of this chapter.

KEY WORDS AND DEFINITIONS

Acidosis Accumulation of acid and hydrogen ions or depletion of the alkaline reserve (bicarbonate content) in the blood and body tissues.

Acute kidney injury (AKI) A rapid decline in kidney function that occurs over hours and days.

Acute nephritic syndrome The sudden onset of hematuria, proteinuria, diminished urine production, azotemia, hypertension, and edema.

Acute tubular necrosis (ATN) Acute renal failure with mild to severe damage or necrosis of tubule cells.

Antidiuretic hormone (ADH; vasopressin) A nonapeptide hormone formed by the neuronal cells of the hypothalamic nuclei and stored in the posterior lobe of the pituitary gland (neurohypophysis). It has both antidiuretic and vasopressor actions.

Azotemia An excess of urea or other nitrogenous compounds in the blood.

Bartter syndrome Hypertrophy and hyperplasia of the juxtaglomerular cells, producing hypokalemic alkalosis and hyperaldosteronism.

Bence-Jones protein An abnormal plasma or urinary protein consisting of monoclonal immunoglobulin light chains, which is excreted in some neoplastic diseases. It is a characteristic protein found in the urine of most patients with multiple myeloma.

Bowman capsule The double-walled globular kidney structure that forms the beginning of a renal tubule and surrounds the glomerulus.

Chronic kidney disease (CKD) Abnormalities of kidney structure or function, present for greater than 3 months, with implications for health.

Clearance The volume of plasma from which a given substance is completely cleared by the kidneys per unit of time.

Diabetes insipidus (DI) A diabetic (defined as the excessive production of urine) disorder due either to insufficient synthesis of antidiuretic hormone (ADH), defective ADH receptors, or end-organ resistance to its action. This results in failure of tubular reabsorption of water in the kidney.

Diabetic nephropathy The nephropathy that commonly accompanies later stages of diabetes mellitus; it begins with hyperfiltration, renal hypertrophy, albuminuria, and hypertension.

Dialysis The removal—for example, by means of a hemodialysis (HD) machine or filter—of certain elements from the blood by virtue of differences in the rates of their diffusion through a semipermeable membrane.

End-stage renal disease (ESRD) A condition where renal function is no longer adequate to support life.

Erythropoietin A glycoprotein hormone secreted chiefly by the kidney in the adult; it increases the production of red blood cells.

Fanconi syndrome A rare recessive disorder with a poor prognosis, characterized by pancytopenia, bone marrow hypoplasia, and patchy brown skin as well as multiple congenital anomalies of the musculoskeletal and genitourinary systems.

Gitelman syndrome A syndrome of hypertrophy of juxtaglomerular cells similar to Bartter syndrome but with hypocalciuria and hypomagnesemia.

Glomerular filtration rate (GFR) The rate in milliliters per minute at which small molecules are filtered through the kidney's glomeruli. It is a measure of the number of functioning nephrons.

Glomerulonephritis Nephritis accompanied by inflammation of the capillary loops of the glomeruli of the kidney. It occurs in acute, subacute, and chronic forms.

Glomerulus A tuft of blood vessels found in each nephron of the kidney that is involved in the filtration of blood.

Hematuria Blood in the urine.

Hemodiafiltration A type of hemofiltration with a dialytic component added. With it, blood flow is accelerated to twice that of conventional dialysis.

Hypertension A medical condition characterized by high arterial blood pressure.

IgA nephropathy A common, chronic form of glomerulonephritis marked by hematuria and proteinuria and by deposits of immunoglobulin A in the mesangial areas of the renal glomeruli.

Interstitial nephritis Primary or secondary disease of the renal interstitial tissue.

Juxtaglomerular apparatus (JGA) A complex in the kidney whose function is the autoregulation of the glomerular filtration rate.

Liddle syndrome A rare autosomal dominant syndrome resulting from mutations affecting the epithelial sodium channel leading to abnormally increased channel function.

Lithotripsy The crushing of a calculus within the urinary system, followed at once by the washing out of the fragments; it is done either surgically or by several different noninvasive methods.

Loop of Henle The U-shaped part of the renal tubule, extending through the medulla from the end of the proximal convoluted tubule to the beginning of the distal convoluted tubule.

Metabolic acidosis Any of the various kinds of acidosis in which the acid-base status of the body shifts toward the acid side because of loss of base or retention of acids other than carbonic acid.

Nephritis Inflammation of the kidney with focal or diffuse proliferation or destructive processes that may involve the glomerulus, tubule, or interstitial renal tissue.

Nephrolithiasis A condition marked by the presence of renal calculi (stones).

Nephron The anatomic and functional unit of the kidney, consisting of the (1) renal corpuscle, (2) proximal convoluted tubule, (3) descending and ascending limbs of loop of Henle, (4) distal convoluted tubule, and (5) collecting tubule.

Nephrotic syndrome General name for a group of diseases involving defective kidney glomeruli, characterized by massive proteinuria and lipiduria with varying degrees of edema, hypoalbuminemia, and hyperlipidemia.

Obstructive uropathy Uropathy resulting from an obstruction in the urinary tract.

Oliguria Diminished urine production and excretion.

Peritoneal dialysis (PD) Diffusion of solutes and convection of fluid through the peritoneal membrane. The dialyzing solution is introduced into and removed from the peritoneal cavity as either a continuous or intermittent procedure.

Polycystic kidney disease The most common renal cystic condition, with concomitant deterioration of renal function.

Polyuria The passage of a large volume of urine in a given period.

Proteinuria Excessive serum proteins in the urine, as in renal disease, after strenuous exercise, and with dehydration.

Pseudohypoaldosteronism type 1 A hereditary disorder of infancy characterized by severe salt wasting, failure to thrive, and other signs of aldosterone deficiency.

Pyelonephritis An inflammation of the kidney and its pelvis as a result of infection.

Rapidly progressive glomerulonephritis (RPGN) Acute glomerulonephritis marked by a rapid progression to end-stage renal disease.

Renal replacement therapy (RRT) Any treatment that replaces kidney function, including dialysis and transplantation.

Renal tubular acidosis (RTA) A variety of metabolic acidosis resulting from the impairment of renal function.

Renin An enzyme of the hydrolase class that catalyzes cleavage of the leucine-leucine bond in angiotensinogen to generate angiotensin I.

Toxic nephropathy Kidney damage caused by the effects of a nephrotoxin.

Uremia An excess in the blood of urea, creatinine, and other nitrogenous end products of protein and amino acid metabolism; also referred to as azotemia.

Uremic syndrome The spectrum of symptoms accompanying uremia.

The kidneys play a central role in homeostasis, and reduced renal function strongly correlates with increasing morbidity and mortality. The basic anatomy and physiology of the kidneys are described as a foundation for understanding the pathophysiology of disease and the rationale for diagnostic and management strategies in kidney disease. Key analytic methods employed during the investigation of kidney disease are dealt with in Chapter 21.

ANATOMY

The kidneys are a paired organ system located in the lumbar region. Their function is to (1) filter the blood and excrete the end products of body metabolism in the form of urine; (2) regulate the concentrations of (a) hydrogen, (b) sodium, (c) potassium, (d) phosphate, and (e) other ions in the extracellular fluid; and (3) produce hormones. In an adult, each kidney is about 12 cm long and weighs about 150 g in men and 135 g in women. Through the characteristically bean-shaped kidney pass the vessels, nerves, and ureter (Fig. 35.1).

Nephron

The functional unit of the kidney is the **nephron**. Each kidney may contain up to 1.5 million nephrons. The nephron consists of a (1) glomerulus, (2) proximal tubule, (3) loop of Henle, (4) distal tubule, and (5) collecting duct (Fig. 35.2). The collecting ducts ultimately combine to develop into the renal calyces, where the urine collects before passing along the ureter and into the bladder. The kidney is divided into

Fig. 35.1 Vascular and anatomic relationships of the kidneys in the human. (From Leaf, A., & Cotran, R. S. [1985]. *Renal pathophysiology* [3rd ed.]. Oxford: Oxford University Press. Reproduced by permission of Oxford University Press.)

Fig. 35.2 Diagrammatic representation of the nephron, the functional unit of the kidney, illustrating the anatomic and vascular arrangements. (From Pitts, R. F. [1974]. *Physiology of the kidney and body fluids* [3rd ed., p. 8]. Chicago: Year Book Medical Publishers.)

several lobes. The outer, darker region of each lobe—the cortex—consists of the glomeruli and the proximal and distal tubules. The cortex surrounds a paler inner region—the medulla—which is further divided into a number of conical areas known as the renal pyramids, the apex of which extends toward the renal pelvis, forming papillae. Medullary rays are visible striations in the renal pyramids that connect the kidney cortex with the medulla. They are composed of (1) descending (straight proximal) and (2) ascending (straight distal) thick limbs of Henle and (3) collecting ducts and associated blood vessels (the vasa recta). The central hilus is where blood vessels, lymphatics, and the renal pelvis (containing the ureter) join the kidney.

The **glomerulus** is formed from a specialized capillary network. Each capillary develops into approximately 40 glomerular loops around 200 μm in size and consisting of a variety of different cell types supported on a specialized basement membrane. Some endothelial and epithelial cells act in concert with the specialized glomerular basement membrane (GBM) to form the glomerular filtration barrier. The glomerular capillaries are supported by a network of

mesangial cells and a mesangial matrix that act as connective tissue for the glomerular apparatus. The basement membrane forms the main size-discriminant barrier to protein passage into the tubular lumen.

The **Bowman capsule** forms the beginning of the tightly coiled proximal convoluted tubule (*pars convoluta*), which as it progresses toward the renal medulla becomes straightened and is then called the *pars recta*. The proximal tubule is about 15 mm long. It is the most metabolically active part of the nephron, facilitating the reabsorption of 60% to 80% of the glomerular filtrate volume—including 70% of the filtered load of (1) sodium and (2) chloride, most of the (3) potassium, (4) glucose, (5) bicarbonate, (6) phosphate, and (7) sulfate—and secreting 90% of the hydrogen ion excreted by the kidney.

The *pars recta* drains into the descending thin **loop of Henle**, which, after passing through a hairpin loop, becomes first the ascending thin limb and then the thick ascending loop. At the end of the thick ascending limb is a cluster of cells known as the *macula densa* (Fig. 35.3). The main role of the loop of Henle is to provide the ability to generate a concentrated urine that is hypertonic with respect to plasma.

Fig. 35.3 The juxtaglomerular apparatus. The beginning of the distal tubule (i.e., where the loop of Henle reenters the cortex) lies very close to the afferent and efferent arterioles, and the cells of both the afferent arteriole and the tubule show specialization. The cells of the afferent arteriole are thickened, granular (juxtaglomerular) cells innervated by sympathetic nerve fibers. The mesangial cells are irregularly shaped and contain filaments of contractile proteins. Identical cells are found just outside the glomerulus and are termed *extraglomerular mesangial cells* or *Goormaghtigh cells*. (From Lote, C. J. [2000]. *Principles of renal physiology* [4th ed., Chapter 2]. London: Kluwer Academic Publishers.)

The cells forming the distal tubule of the nephron start at the macula densa and extend to the first fusion with other tubules to form the collecting ducts. Sodium chloride reabsorption and some potassium and hydrogen ion excretion occur at this site.

The collecting ducts are formed from approximately six distal tubules. These are successively joined by other tubules to form ducts of Bellini, which ultimately drain into a renal calyx.

Juxtaglomerular Apparatus

Where the thick ascending limb of the loop of Henle passes very close to the glomerulus of its own nephron, the cells of the tubule and the afferent arteriole show regional specialization (see Fig. 35.3). The tubule forms the macula densa; the arteriolar cells are filled with granules (containing renin or its inactive precursor, prorenin) and are innervated with sympathetic nerve fibers. This area is called the **juxtaglomerular apparatus (JGA)**. The JGA plays an important part in maintaining systemic blood pressure through regulation of the circulating intravascular blood volume and sodium concentration. The proteolytic enzyme renin is released primarily in response to decreased afferent arteriolar pressure and decreased intraluminal sodium delivery to the macula densa. Renin release from the macula densa is also influenced by nitric oxide, renal cortical prostaglandins (predominantly PGI_2), and the sympathetic nervous system. The released renin then acts on the plasma protein angiotensinogen to generate angiotensin I. This is converted in the lungs by angiotensin converting enzyme (ACE) to the potent vasoconstrictor and stimulator of aldosterone release, angiotensin II (AII). The vasoconstriction and aldosterone release (with

increased distal tubular sodium retention) act in concert with the other action of AII, to increase the release of **antidiuretic hormone (ADH; vasopressin)** and to increase proximal tubular sodium reabsorption, intravascular volume, and pressure. AII also has an inhibitory effect on renin release as part of a negative feedback loop.

Blood Supply

The renal artery divides into posterior and anterior elements, which then divide into the interlobar, arcuate, interlobular, and ultimately afferent arterioles, which expand into the capillary bed that forms the glomerulus (see Fig. 35.2). These capillaries then rejoin to form the efferent arteriole, which then forms the capillary plexuses as well as the elongated vessels (the *vasa recta*) that pass around the remaining parts of the (1) nephron, (2) proximal and distal tubules, (3) loop of Henle, and (4) collecting duct, providing oxygen and nutrients and removing ions, molecules, and water, which are reabsorbed by the nephron. The efferent arteriole then merges with renal venules to form the renal veins, which emerge into the inferior vena cava. The complex architecture of the intrarenal vascular tree is ordered in three dimensions in a characteristic arrangement that probably serves to distribute the blood pressure and flow appropriately to the glomeruli.

In the adult, the kidneys receive approximately 25% of the cardiac output; however, in the newborn infant it is 5%, reaching adult proportions only by the end of the first year of life. About 90% of this blood flow supplies the renal cortex, maintaining the highly active tubular cells. The maintenance of renal blood flow is essential to renal function, and there is a complex array of intrarenal regulatory mechanisms ensuring that it is maintained across a wide range of systemic blood

pressures. The renal glomerular perfusion pressure is independent of the systemic pressure between 90 and 200 mm Hg, being maintained at a constant 45 mm Hg.

KIDNEY FUNCTION

The main biologic functions of the kidneys are (1) excretion, (2) homeostatic regulation, and (3) endocrine function. The kidneys integrate these functions to maintain homeostasis and regulate the internal milieu.

Excretory Function

Urine is (1) excreted by the kidneys, (2) passed through the ureters, (3) stored in the bladder, and (4) discharged through the urethra. In health, it (1) is sterile and clear, (2) is of yellow or amber color, (3) has a slightly acid pH (5.0 to 6.0), and (4) has a characteristic odor. Its specific gravity is about 1.024. In addition to dissolved compounds, it contains a number of cells, proteinaceous casts, and crystals (formed elements). Changes in these formed elements are studied using urine microscopy.

Urination, also termed *micturition*, is the discharge of urine. In normal adults, adequate homeostasis is maintained with a urine output of about 500 mL/day. Alterations in urinary output are described as *anuria* (<100 mL/day), *oliguria* (<400 mL/day), or *polyuria* (>3 L/day or 50 mL/kg body weight per day). The most common disorder of urination is altered frequency, which may be associated with increased urinary volume or partial urinary tract obstruction (e.g., in prostatic hypertrophy).

The first step in urine formation is filtration of plasma water at the glomeruli. A net filtration pressure of about 17 mm Hg in the capillary bed of the tuft drives the filtrate through the glomerular membrane. The filtrate is called an ultrafiltrate because its composition is essentially the same as that of plasma, but with a notable reduction in molecules of molecular weight exceeding 15 kDa. Each nephron produces about 100 μ L of ultrafiltrate per day. Overall, approximately 170 to 200 L of ultrafiltrate passes through the glomeruli in 24 hours. In the passage of ultrafiltrate through the tubules, reabsorption of solutes and water in various regions of the tubules reduces the total urine volume, which typically ranges between 0.4 and 2 L/day.

Transport of solutes and water occurs both across and between the epithelial cells that line the renal tubules. Transport is both active (energy-requiring) and passive, but many of the so-called passive transport processes are dependent on or secondary to active transport processes, particularly those involving sodium transport. All known transport processes involve receptor or mediator molecules, many of which have now been identified and characterized using molecular biology techniques. The activity of many of these molecules is regulated by phosphorylation facilitated by protein kinase C or A. Their renal distribution has been shown to correlate with the known regional functional activities. There are inherited disorders of specific tubular transporters and a well-known generalized disorder affecting all of the transport processes, causing **Fanconi syndrome**.

Direct coupling of adenosine triphosphate (ATP) hydrolysis is an example of an active transport process. The most important of these in the nephron is Na^+, K^+ -ATPase, which is located on the basolateral membranes of the tubuloe epithelial cells. This enzymatic transporter accounts for much of renal oxygen consumption and drives more than 99% of renal sodium reabsorption.

Renal epithelial cell membranes also contain proteins that act as ion channels. For example, there is one for sodium that is closed by amiloride and modulated by hormones such as atrial natriuretic peptide (ANP). Ion channels enable much faster rates of transport than ATPases, but are relatively fewer in number—approximately 100 sodium and chloride channels as against 10^7 Na^+, K^+ -ATPase molecules per cell.

In the tubules, the solute composition of the ultrafiltrate is altered by the processes of reabsorption and secretion, so that the urine excreted may have a very different composition from that of the original filtrate. Different regions of the tubule have been shown to specialize in certain functions. In the proximal tubule, 60% to 80% of the ultrafiltrate is reabsorbed in an obligatory fashion, along with (1) sodium, (2) chloride, (3) bicarbonate, (4) calcium, (5) phosphate, (6) sulfate, and (7) other ions. Glucose is virtually completely reabsorbed, predominantly in the proximal tubule by a passive but sodium-dependent process that is saturated at a blood glucose concentration of about 180 mg/dL (10 mmol/L). Uric acid is also reabsorbed in the proximal tubule by a passive sodium-dependent mechanism, but there is also an active secretory mechanism.

In the loops of Henle, chloride and more sodium without water are reabsorbed, generating dilute urine. Water reabsorption in the more distal tubules and collecting ducts is then regulated by ADH. In the distal tubule, secretion is the prominent activity; organic ions, potassium ions, and hydrogen ions are transported from the blood in the efferent arteriole into the tubular fluid. It is also this region that secretes hydrogen ions and reabsorbs sodium and bicarbonate to aid in acid-base regulation. Paracellular (between cell) movement is driven predominantly by concentration, osmotic, or electrical gradients.

Regulatory Function

The *regulatory function* of the kidneys has a major role in homeostasis. The mechanisms of differential reabsorption and secretion, located in the tubule of a nephron, are the effectors of regulation. These mechanisms operate under a complex system of control in which both extrarenal and intrarenal humoral factors participate.

Electrolyte Homeostasis

The proximal convoluted tubule is predominantly concerned with reabsorption (Fig. 35.4). Water reabsorption in the proximal convoluted tubule is termed “obligatory” because its volume is related to the heavy load of solutes being returned to the blood in the efferent arteriole. The amount of bicarbonate reabsorption is related to the **glomerular filtration rate (GFR)** and the hydrogen ion secretory rate. The amount of phosphate reabsorption is controlled in part by plasma

Fig. 35.4 Countercurrent multiplication mechanism: schematic representation of the principal processes of transport in the nephron. In the convoluted portion of the proximal tubule (1), salts and water are reabsorbed at high rates in isotonic proportions. Bulk reabsorption of most of the filtrate (65% to 70%) and virtually complete reabsorption of glucose, amino acids, and bicarbonate take place in this segment. In the pars recta (2), organic acids are secreted and continuous reabsorption of sodium chloride takes place. The loop of Henle comprises three segments: the thin descending (3) and ascending (4) limbs and the thick ascending limb (5). The fluid becomes hyperosmotic because of water abstraction as it flows toward the bend of the loop, and it becomes hyposmotic because of sodium chloride reabsorption as it flows toward the distal convoluted tubule (6). Active sodium reabsorption occurs in the distal convoluted tubule and in the cortical collecting tubule (7). This last segment is water-impermeable in the absence of vasopressin (antidiuretic hormone), and the reabsorption of sodium in this segment is increased by aldosterone. The collecting duct (8) allows equilibration of water with the hyperosmotic interstitium when vasopressin is present. For additional details, see text. (From Burg, M. B. [1978]. The nephron in transport of sodium, amino acids, and glucose. *Hospital Practice*, 13, 100. Modified from a drawing by A. Iselin.)

calcium concentration and in part by the effect of parathyroid hormone (PTH) on the tubular cells. Normally the high-threshold substances—glucose and, to a great extent, amino acids—are reabsorbed here by means of specific intracellular active transport systems. Uric acid may be either reabsorbed or secreted in the proximal convoluted tubule by a two-way carrier-mediated process.

In the ascending loop of Henle, 20% to 25% of filtered sodium is reabsorbed without concomitant reabsorption of water. This process generates dilute urine with an osmolality of 100 to 150 mOsm/kg of water and helps establish the corticomedullary osmotic gradient. The resulting hypertonicity of the interstitium is important in the pathogenesis of renal infections because the hypertonic environment interferes with leukocyte function. Subsequent water reabsorption is regulated by ADH. Although the reabsorption of Na^+ in the loop of Henle is complex and incompletely understood, at least one mechanism consists of an active Cl^- pump with subsequent reabsorption of Na^+ along an electrochemical gradient. This mechanism is inhibited by loop diuretics.

The distal tubule is functionally the most active region of the nephron for the homeostatic regulation of plasma electrolytes and plasma acid-base concentrations. Here a combination of secretion and reabsorption takes place between Na^+ , K^+ , and H^+ . Although excess plasma hydrogen ions are secreted all along the tubule, it is in the distal tubule that exchange of H^+ for Na^+ (which is reabsorbed) fine tunes the balance between H^+ loss and retention (see Chapter 36).

Potassium ions are also secreted in the distal tubule. Aldosterone is a potent modulator of Na^+ reabsorption in the distal tubule, particularly when the need arises to conserve Na^+ . Production of aldosterone in the adrenal cortex is stimulated by the renin-angiotensin system and by high plasma potassium concentration. Renal secretion of renin is complex but is at least partly regulated by renal perfusion and plasma sodium concentration. Both inadequate perfusion and a low concentration of plasma sodium stimulate renin secretion. Organic anions, such as acetoacetate and β -hydroxybutyrate, also consume H^+ as they are eliminated in part in their nondissociated acid form. When H^+ must be conserved to maintain blood pH, distal tubule cells reduce the secretion of H^+ , reduce NH_4^+ generation, reduce Na^+ - H^+ exchange, and increase bicarbonate excretion. The net effect is a reduction in plasma bicarbonate and restoration of normal blood pH.

Water Homeostasis

The production of glomerular filtrate normally amounts to about 180 L/day. The unique physiology of the kidney enables approximately 99% of this to be reabsorbed in the production of urine with variable osmolality: between 50 and 1400 mOsm/kg H_2O at extremes of water intake. Different segments of the nephron show differing permeability to water, enabling the body to both retain water and produce urine of variable concentration. Approximately 70% of the water content of the tubular fluid is reabsorbed in the proximal tubule, 5% in the loop of Henle, 10% in the distal tubule, and the remainder in the collecting ducts.

Water reabsorption occurs both isosmotically, in association with electrolyte reabsorption in the proximal tubule, and differentially, in the loop of Henle, distal tubule, and collecting duct in response to the action of the nonapeptide ADH. Absorption of water depends on the driving force for water reabsorption (predominantly active sodium transport) and the osmotic equilibration of water across the tubular epithelium. The generation of concentrated urine depends upon medullary hyperosmolality, which in turn requires low water permeability in some kidney segments (ascending limb of the loop of Henle), whereas in other kidney segments there is a requirement for high water permeability: differing permeability and the enaction of hormonal control is largely caused by the differential expression along the nephron of a family of proteins known as the aquaporins (AQP), which act as water channels.

Urinary concentration is predominantly achieved by countercurrent multiplication in the loop of Henle (see Fig. 35.4). Although the descending thin limb is very permeable to water, the ascending limb and the collecting duct are not (the collecting ducts are also poorly permeable to urea). The fluid entering the loop of Henle is isotonic to plasma but is hypotonic on leaving it. The ascending limb has active sodium reabsorption driven by $\text{Na}^+\text{K}^+\text{-ATPase}$ with electroneutralizing transport of chloride, a combined process that can be inhibited by the so-called loop diuretics (e.g., furosemide). In this section of the nephron, sodium reabsorption is not accompanied by water, creating a hypertonic medullary interstitium and facilitating water reabsorption from the anatomically adjacent descending limb. The descending limb cells are permeable to sodium chloride, which is cycled from the descending limb back to the ascending limb. The continuous flow along the loop generates an osmotic gradient at the tip of the loop that can reach 1400 mOsmol/kg per H_2O . Approximately 5% of water is reabsorbed in the loop of Henle.

A further 10% of water reabsorption occurs in the distal tubule, with the remainder (more than 20 L/day) being reabsorbed in the collecting ducts. Entry of water into the collecting duct cells occurs via apical AQP2 channels under the influence of ADH. ADH also increases the permeability of collecting duct cells to urea, which is the major osmotically active component of the luminal fluid in the distal tubule. Fluid of high urea concentration therefore enters the deepest layers of the medullary interstitium, passing down its concentration gradient, contributing to medullary hyperosmolality. The regulation of ADH excretion is of vital importance to fluid homeostasis. The normal plasma osmolality is maintained very tightly between 280 and 290 mOsmol/kg H_2O and is regulated by means of specific osmoreceptors found in the anterior hypothalamus. These receptors modulate the release of ADH and also affect thirst. ADH release may also be stimulated by hypotension, hypovolemia, and vomiting independently of osmoregulation.

Endocrine Function

The *endocrine functions* of the kidneys may be regarded as (1) primary, because the kidneys are endocrine organs producing hormones, or (2) secondary, because the kidneys are a site

of action for hormones produced or activated elsewhere. In addition, the kidneys are a site of degradation for hormones such as insulin and aldosterone. In their primary endocrine function, the kidneys produce (1) erythropoietin, (2) prostaglandins and thromboxanes, (3) renin, and (4) 1,25(OH_2) vitamin D_3 .

Erythropoietin

Erythropoietin (EPO) is a glycoprotein hormone secreted chiefly by the kidney in the adult and by the liver in the fetus that acts on the bone marrow cells to stimulate erythropoiesis. It is an α -globulin having a molecular weight of 38 kDa. Physiologically the kidneys sense a reduction in O_2 delivery to tissue by blood and release EPO, thereby stimulating the bone marrow to make more red blood cells (RBCs). Conversely, with a surplus of O_2 in blood traversing the kidneys, as in some forms of polycythemia, the release of EPO into blood is diminished. The use of recombinant human EPO (rhEPO, Epoetin) in the management of anemia of kidney disease is discussed further on.

Prostaglandins and Thromboxanes

Prostaglandins and thromboxanes are synthesized from arachidonic acid by the cyclooxygenase (COX) enzyme system (see Chapter 23). This system is present in many parts of the kidneys. The predominant metabolite of its vascular endothelial activity is prostacyclin (PGI_2). Prostaglandin E_2 (PGE_2) appears to be the major metabolite of mesangial and tubular cells. The production and activity of these biologically active compounds have an important role in regulating the physiological action of other hormones on renal vascular tone, mesangial contractility, and tubular processing of salt and water.

Renin

Renin is produced within juxtaglomerular cells after the processing and cleavage of prorenin, which is produced in the liver. Increased production of renin results in formation of Angiotensin II (Ang II) in the lungs, which is a powerful intrarenal vasoconstrictor and also a key stimulus of aldosterone release from zona glomerulosa cells in the adrenal glands. The net effect is (1) systemic vasoconstriction, (2) intrarenal vasoconstriction, and (3) increased aldosterone release. Aldosterone controls salt and water balance in the kidney. Its effect is predominantly on the distal tubular network, affecting an increase in sodium reabsorption in exchange for potassium.

1,25(OH_2) Vitamin D_3

The kidneys are primarily responsible for producing 1,25(OH_2) vitamin D_3 from 25-hydroxycholecalciferol as a result of the action of the enzyme 25-hydroxycholecalciferol 1 α -hydroxylase found in proximal tubular epithelial cells. The regulation of this system is discussed in Chapter 39.

KIDNEY PHYSIOLOGY

The (1) GFR, (2) renal blood flow, and (3) glomerular permeability are important physiologic components of renal function.

Glomerular Filtration Rate

The GFR is considered to be the most reliable measure of the functional capacity of the kidneys and is often thought of as indicative of the number of functioning nephrons. As a physiologic measurement, it has proved to be a useful marker of changes in overall renal function.

The rate of formation of glomerular filtrate depends on the balance between hydrostatic and oncotic forces along the afferent arteriole and across the glomerular filter. The net pressure difference must be sufficient not only to drive filtration across the glomerular filtration barrier but also to drive the ultrafiltrate along the tubules against their inherent resistance to flow. In the absence of sufficient pressure, the lumina of the tubules will collapse.

A decrease in GFR precedes kidney failure in all forms of progressive disease. Different pathologic kidney conditions have been known to progress to end-stage renal disease (ESRD) and dialysis dependency at rates varying from weeks to several decades. The symptoms accompanying progressive kidney disease and their correlation with falling GFR will be influenced by this rate of progression. Measuring GFR in established disease is useful in (1) targeting treatment, (2) monitoring progression, and (3) predicting when **renal replacement therapy (RRT)** will be required. It is also used as a guide to dosage of drugs excreted by the kidneys to prevent potential drug toxicity (see Chapter 30). Measurement of GFR is discussed in Chapter 21.

Glomerular Filtration Rate and Age

Kidney function is not constant throughout life. In utero, urine is produced by the developing fetus from about the ninth week of gestation. The GFR at birth is approximately 30 mL/min per 1.73 m². It increases rapidly during the first weeks of life to reach approximately 70 mL/min per 1.73 m² by age 16 days, with adult values of body surface area (BSA)-corrected GFR being achieved by 2 years of age. On average, GFR declines with age by approximately 1 mL/min per 1.73 m² per year over the age of 40 years, and the rate of decline in GFR accelerates after age 65.

Glomerular Permeability, Filtration, and Protein Loss

The glomerular permeability and filtration capabilities of the kidney control the amount of protein lost in the urine.

Glomerular Permeability and Filtration

The glomerulus acts as a selective filter of the blood passing through its capillaries. The combination of (1) the fenestrated endothelial layer, (2) a basement membrane rich in negatively charged proteoglycans, and (3) a highly specialized terminally differentiated epithelial cell barrier produces a filter that restricts the passage of macromolecules in a (1) size-, (2) charge-, and (3) shape-dependent manner. The epithelial cells (podocytes) have foot processes that are connected to the GBM and form the final barrier to filtration via interdigitating with neighboring cell foot processes connected by a slit diaphragm. Examples of the relationships between size, charge, and mass of the major urinary proteins and their glomerular handling are listed in Table 21.1. In general, proteins of molecular weight

greater than that of albumin (66 kDa, diameter 3.5 nm) are retained by the healthy glomerulus and termed high-molecular-weight proteins. However, lower-molecular-weight proteins are also retained to a significant extent.

Urinary Protein Loss

Increased urinary protein loss (**proteinuria**) results from (1) any increase in the filtered load, (2) an increased circulating concentration of low-molecular-weight proteins, or (3) a decrease in reabsorptive capacity. Historically, the pattern of urinary protein loss has been used to identify the cause and classify the proteinuria, of which there are three main types: (1) glomerular, (2) overflow, and (3) tubular proteinuria.

The normal urinary total protein loss is less than 150 mg/day. The proteins lost are made up of mostly albumin (50% to 60%) and some smaller proteins together with proteins secreted by the tubules, of which Tamm-Horsfall glycoprotein (THG, uromodulin) is one. The normal concentrations of proteins found in urine are listed in Table 21.1. Investigation for increased urinary protein loss is mandatory in any patient with suspected kidney disease and is considered in Chapter 21.

Consequences of Proteinuria

Many physicians believe that proteinuria is not just a consequence of the progression of kidney disease but contributes directly to it. The accumulation of proteins in abnormal amounts in the tubular lumen may trigger an inflammatory reaction, which in turn may contribute to interstitial structural damage and expansion and thus to the progression of kidney disease. Evidence gathered from in vitro studies suggests that glomerular filtration of an abnormal amount or types of protein induces mesangial cell injury, leading to glomerulosclerosis, and that these same proteins also have adverse effects on the function of proximal tubular cells. Numerous studies have demonstrated that proteinuria is a potent risk marker for the progression of renal disease in both nondiabetic and diabetic kidney disease. Furthermore, the reduction of protein excretion slows the rate of progression of proteinuric kidney disease. This has been observed in clinical trials in patients treated with ACE inhibitors and angiotensin II receptor blockers (ARBs) either alone or in combination. These drugs reduce protein loss by reducing intraglomerular filtration pressure and possibly by stabilizing the glomerular epithelial cell slit diaphragm proteins. Consequently the reduction of proteinuria is an important therapeutic target.

PATHOPHYSIOLOGY OF KIDNEY DISEASE

Despite the diverse initial causes of injury to the kidney, the progression of kidney disease leading to loss of function and ultimately to kidney failure is a remarkably monotonous process characterized by (1) early inflammation, (2) accumulation and deposition of extracellular matrix, (3) tubulointerstitial fibrosis, (4) tubular atrophy, and (5) glomerulosclerosis (scarring). Proteinuria is thought to be one of

the most important risk factors for the progression of kidney diseases. The renin-angiotensin-aldosterone system (RAAS) plays a pivotal role in many of the pathophysiologic changes that cause kidney injury and is an important therapeutic target.

The kidneys have considerable ability to increase their functional capacity in response to injury. Thus a significant reduction in functioning renal mass (50% to 60%) may occur before the onset of any significant symptoms or even before any major biochemical alterations appear. The most sensitive and specific measure of functional change—the GFR—can be reduced to less than 60 mL/min per 1.73 m² before signs and symptoms of kidney failure will be observed. An increase in workload per nephron is thought to be an important cause of progressive renal injury.

Overview of Kidney Disease and Its Clinical Manifestations

Most often kidney disease is detected opportunistically by measurement of blood pressure and urine and blood testing in asymptomatic individuals. Such testing can occur in the primary care setting or for health clearance purposes for insurance. Typical findings include isolated **hematuria** and isolated proteinuria. Kidney disease may also present with macroscopic hematuria, swollen ankles, headaches, and visual disturbances due to severe **hypertension**, or as a manifestation of systemic disease. Symptoms suggestive of advanced kidney disease include fatigue, nausea, vomiting, poor appetite, shortness of breath, fluid retention, poor memory, loss of libido, and itching. Unfortunately many individuals present very late in their disease and may require urgent **dialysis** without having had any previous experience with the specialist nephrology service. These patients have a poor prognosis compared with patients who have been cared for in a multidisciplinary specialist environment for at least 1 year. Therefore early recognition of kidney disease is of paramount importance to outcome.

Effective management of the patient with kidney disease is dependent on establishing a definitive diagnosis. Initial management includes a (1) detailed clinical history, (2) clinical examination, and (3) urinalysis and assessment of the urinary sediment.

Terminology of Kidney Disease

The commonly used term *acute renal failure* (ARF) has been replaced by **acute kidney injury** (AKI). *Kidney failure* is defined as a GFR of less than 15 mL/min per 1.73 m². Not all patients with kidney failure require RRT (dialysis or transplantation) to sustain life. **End-stage renal disease** (ESRD) is a US government-defined term that indicates the need for long-term chronic RRT. Each patient with ESRD is registered through the Medical Evidence Form (2728) that all dialysis and transplant providers must submit. This now includes both Medicare and non-Medicare populations.

AT A GLANCE

Who Should be Tested for Chronic Kidney Disease (CKD)?^a

Offer testing for CKD using estimated GFR and a urinary albumin-to-creatinine ratio (ACR) to people with any of the following risk factors:

- Diabetes mellitus
- Hypertension
- Acute kidney injury
- Cardiovascular disease (ischemic heart disease, chronic heart failure, peripheral vascular disease, or cerebral vascular disease)
- Structural renal tract disease, recurrent renal calculi, or prostatic hypertrophy
- Multisystem diseases with potential kidney involvement—e.g., systemic lupus erythematosus
- Family history of kidney failure (GFR category G5) or hereditary kidney disease
- Opportunistic detection of hematuria

Do not use age, gender, or ethnicity as risk markers to test people for CKD. In the absence of metabolic syndrome, diabetes mellitus, or hypertension, do not use obesity alone as a risk marker to test people for CKD.

Monitor GFR at least annually in people taking drugs known to be nephrotoxic, such as calcineurin inhibitors (e.g., cyclosporin or tacrolimus), lithium, and nonsteroidal antiinflammatory drugs.

^aModified from National Institute for Health and Care Excellence. (2014). *Chronic kidney disease. Early identification and management of chronic kidney disease in adults in primary and secondary care.* <http://www.nice.org.uk/nicemedia/live/13712/66658/pdf>.

Classification of Chronic Kidney Disease

Chronic kidney disease is an important public health problem, emphasizing the need for earlier identification and treatment. Historically, data obtained from epidemiologic surveys were compromised by lack of consistent surrogate markers of kidney function to identify established disease. For example, serum creatinine, calculated creatinine **clearance** (C_{Cr}), and measured C_{Cr} were variously used. Landmark guidelines developed by the National Kidney Foundation–Kidney Disease Outcomes Quality Initiative (NKF-K/DOQI) were published in 2002 and were based on categories of GFR. They have subsequently been revised and updated by Kidney Disease: Improving Global Outcomes (KDIGO) and broadly adopted by other national organizations (**Table 35.1**). The KDIGO 2012 guideline added a second dimension to the classification system with three identified levels of albuminuria, acknowledging the powerful additional prognostic information imparted by the presence of proteinuria (see **Table 35.1**).

A high prevalence of CKD is identified with the classification system, with an estimated 1 in 7 adults affected within the United States. Most individuals with CKD do not progress to kidney failure, with prevalence rates of patients in GFR category G3 10 to 20 times higher than the prevalence rates of GFR categories G4 and G5. There is some concern that many individuals being identified with G3 CKD are not at increased risk; use of cystatin C to delineate risk in this population is being evaluated.

TABLE 35.1 Classification of Chronic Kidney Disease Indicating Prognosis and Secondary/Tertiary Care Referral Decision Making by Glomerular Filtration Rate and Albuminuria Categories

				PERSISTENT ALBUMINURIA CATEGORIES: DESCRIPTION AND RANGE		
				A1	A2	A3
				Normal to mildly increased <30 mg/g (<3 mg/mmol)	Moderately increased 30–300 mg/g (3–300 mg/mmol)	Severely increased >300 mg/g (>30 mg/mmol)
Glomerular filtration rate categories (mL/min/1.73 m ²): description and range	G1	Normal or high	>90	55.6	1.9 Monitor	0.4 Refer ^a
	G2	Mildly decreased	60–89	32.9	2.2 Monitor	0.3 Refer ^a
	G3a	Mildly to moderately decreased	45–59	3.6 Monitor	0.8 Monitor	0.2 Refer
	G3b	Moderately to severely decreased	30–44	1.0 Monitor	0.4 Monitor	0.2 Refer
	G4	Severely decreased	15–29	0.2 Refer ^a	0.1 Refer ^a	0.1 Refer
	G5	Kidney failure	<15	<0.1 Refer	<0.1 Refer	0.1 Refer

DARK BLUE, very high risk; **MIDDLE BLUE**, high risk; **BLUE**, moderately increased risk; **LIGHT BLUE**, low risk (if no other markers of kidney disease, no CKD).

^aReferring clinicians may wish to discuss with their local nephrology service, depending on local arrangements regarding referral and monitoring.

NOTE: Numbers in the cells show the proportion (in %) of the adult population in the United States.

Modified from Kidney Disease Improving Global Outcomes. (2013). Clinical practice guideline for the evaluation and management of chronic kidney disease. *Kidney International*, 3, 1–150.

The main causes of CKD leading to kidney failure in the United States are indicated in [Fig. 35.5](#). As shown, diabetes mellitus is the largest single cause of advanced CKD and accounts for almost 50% of new dialysis patients in the United States. Hypertension is the underlying diagnosis in around 28% of new dialysis patients and is particularly prevalent among African Americans. In addition, the rate of new ESRD in African Americans is 3.5 times higher than that among whites. The myriad of kidney diseases include (1) **glomerulonephritis**, (2) infection, (3) hereditary conditions, (4) systemic conditions, (5) interstitial conditions, (6) obstructive conditions, and (7) those of unknown origin.

AT A GLANCE

Defining and Classifying CKD^a

CKD is defined as abnormalities of kidney structure or function present for at least 3 months with implications for health.

Markers of reduced kidney function or damage include:

- Reduced glomerular filtration rate (GFR <60 mL/min per 1.73 m²)
- Albuminuria (≥30 mg/24 h; ACR ≥30 mg/g [≥3 mg/mmol])
- Urine sediment abnormalities
- Electrolyte and other abnormalities due to tubular disorders
- Abnormalities detected by histology
- Structural abnormalities detected by imaging
- History of kidney transplantation

Assign GFR and albuminuria categories as described in [Table 35.1](#).

^aModified from Kidney Disease Improving Global Outcomes. (2013). Clinical practice guideline for the evaluation and management of chronic kidney disease. *Kidney International*, 3, 1–150.

Management of Chronic Kidney Disease

Irrespective of the underlying cause, the rate of progression of CKD (i.e., the rate at which a patient approaches kidney failure) is dependent on both nonmodifiable factors, such as age, gender, race, and level of kidney function at diagnosis, and modifiable characteristics, including proteinuria, blood pressure control, and smoking.

Lowering blood pressure and reduction of proteinuria have been shown to decrease the progression of CKD. The Modification of Diet in Renal Disease (MDRD) study compared the rates of decline in GFR in patients with various causes of CKD assigned to either a “usual” or “low” blood pressure goal. Outcome data suggest that the low blood pressure goal had some beneficial effect in those patients with higher concentrations of proteins in their urine. In practice, medications that inhibit parts of the RAAS are typically preferred because these drugs have been demonstrated to reduce proteinuria and rate of progression of CKD.

Protein intake is restricted spontaneously to approximately 0.6 to 0.8 g/kg per day in uremic patients not receiving dietary advice. To prevent malnutrition, patients receive professional dietary advice with diets containing an increased proportion of first-class protein and increased calorie content of up to 35 kcal/kg per day. General health measures, including cessation of cigarette smoking, are encouraged. Complications of CKD that develop before the need for RRT are numerous and include (1) cardiovascular disease, (2) bone disease, and (3) anemia. Albuminuria and proteinuria have been shown to be associated with increased risk of cardiovascular disease, cardiovascular mortality, and all-cause mortality.

Fig. 35.5 Trends in (A) ESRD incident cases, in thousands, and (B) adjusted* ESRD incidence rate, per million/year, by *primary cause of ESRD*, in the US population, 1980–2012. (From US Renal Data System, 2014 USRDS Annual Data Report. [2014]. *An overview of the epidemiology of kidney disease in the United States*. Bethesda, MD: National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases.)

Cardiovascular Complications of Chronic Kidney Disease

The incidence of cardiovascular disease is seven- to ten-fold greater in patients with CKD than in non-CKD age- and sex-matched controls; by the time patients develop the need for RRT, the risk becomes approximately 17 times greater.

The spectrum of cardiovascular disease in CKD includes (1) angina, (2) congestive heart failure, (3) myocardial infarction, (4) peripheral vascular disease, (5) stroke, (6) sudden cardiac death, and (7) transient ischemic attack. Structural heart disease, such as left ventricular hypertrophy (LVH) and valvular heart disease, is very common. Up to 75% of patients commencing dialysis have echocardiographic evidence of LVH. Vascular calcification is highly prevalent in dialysis patients and is associated with reduced survival.

Dyslipidemia in Chronic Kidney Disease

The pattern of dyslipidemia (abnormal concentration of lipids in the blood) in CKD differs from that seen in non-CKD. Although total cholesterol concentration may be normal,

there is often a highly abnormal lipid subfraction profile with a predominance of atherogenic small, dense, low-density lipoprotein (LDL) particles. In addition, triglyceride concentrations are high. Low cholesterol is associated with increased mortality in dialysis patients, likely reflecting coincident inflammation and malnutrition (“reverse causality”). Although there are no data to suggest that statins are of benefit in patients receiving dialysis, the Study of Heart and Renal Protection (SHARP) evaluated the use of cholesterol lowering with simvastatin and ezetimibe in 9000 patients (including 3000 dialysis patients) and demonstrated significant reductions in stroke and arterial revascularization in the treated patients followed for a median of 4.9 years.

Disturbances in calcium and phosphorus metabolism and bone disease in chronic kidney disease. Bone disease as a consequence of CKD has long been recognized. As GFR declines, renal activation of vitamin D decreases and plasma phosphate concentration rises, resulting in reduced ionized calcium. Consequently the parathyroid glands increase the

production of PTH. This increased secretion of PTH stimulates resorption of calcium and phosphate from the bone, the body's major calcium reservoir. Problems develop early, typically once GFR has fallen to approximately 45 mL/min per 1.73 m². Secondary hyperparathyroidism classically causes (1) bone changes, (2) so-called high-turnover bone disease, and (3) increased risk of fracture.

"Adynamic," low-turnover bone disease is also highly prevalent in patients with CKD and is characterized by poor bone formation. It is more common in the elderly and those with diabetes mellitus and malnutrition. Adynamic bone is associated with (1) a low PTH concentration, (2) abnormal calcium balance, (3) hyperphosphatemia, (4) **acidosis**, and (5) the use of high doses of vitamin D analogues (e.g., alfacalcidol [1α -hydroxyvitamin D₃]). Vascular calcification is commonly associated with adynamic bone disease. The diagnosis of adynamic bone is ultimately made on bone biopsy, but patients are reluctant to undertake this procedure. Unfortunately PTH alone does not correlate with bone biopsy findings. Serum bone-specific alkaline phosphatase (ALP) measured using an immunoassay technique has good predictive value in separating high from low bone turnover, particularly in combination with PTH measurements. For example, low bone formation has been associated with bone-specific ALP concentrations below 20 μ g/L and PTH below 200 ng/L.

High concentrations of plasma phosphate are associated with increased mortality in hemodialysis (HD) patients. Strategies to reduce phosphate concentrations are employed routinely in the treatment of patients on dialysis. Phosphate is present in many foods and is linearly associated with protein ingestion. The recommended allowance of phosphate is reduced for patients on dialysis to around 800 mg/day. Treatment with vitamin D analogues increases gut absorption of phosphate from approximately 65% to almost 85%. The use of phosphate binders, taken with meals, is almost universal in dialysis patients, reducing phosphate absorption to 30% to 40%. It has been possible to normalize phosphate balance in patients treated by daily HD.

Anemia

The World Health Organization (WHO) defines anemia as a hemoglobin concentration of less than 13 g/dL in men and less than 12 g/dL in women. In the absence of treatment, anemia is inevitable as CKD progresses. Therapies are available to correct anemia; therefore it is mandatory to assess a patient with CKD for this condition. The NKF KDOQI guideline recommends that an estimated GFR of less than 60 mL/min per 1.73 m² should be the cutoff value for determining the presence or absence of anemia. Detection is important, since treatment may alleviate many of the symptoms of CKD and hopefully reduce risk of LVH. The pathology of anemia in CKD is multifactorial, but the predominant cause is loss of peritubular fibroblasts (specialized cells that produce collagen and other materials) within the renal cortex that synthesize EPO. Failure to produce EPO leads to decreased numbers of red cells and concomitant decreased concentrations of hemoglobin. Other causes of anemia include (1)

absolute or functional iron deficiency, (2) folic acid and vitamin B₁₂ deficiencies, and (3) chronic inflammation. Red cell survival may also be reduced. Treatment with recombinant erythropoiesis-stimulating agents is recommended to correct anemia. The gene for human EPO was cloned in 1985 and rhEPO-, epoetin-, or EPO-stimulating agents (ESAs) were introduced into clinical practice shortly thereafter. The most common side effect is hypertension therefore blood pressure should be well controlled before treatment is introduced. The majority of patients respond to treatment. However, failure to respond requires thorough investigation for many potential causes, such as (1) occult blood loss, (2) hyperparathyroidism, (3) iron deficiency, (4) vitamin B₁₂ deficiency, (5) folate deficiency, and (6) inadequate dialysis. Many clinical benefits are derived from correcting anemia with ESAs, including (1) improved exercise capacity, (2) improved cognitive function, (3) better quality of life, and (4) increased libido. Later studies have, however, highlighted the risks of high doses of ESAs in nondialysis CKD patients with associated increases in mortality and cardiovascular morbidity. These studies have been instructive in setting the current hemoglobin target of 10.0 to 12.0 g/dL and in recommending ESA dose adjustments when hemoglobin is less than 10.5 or greater than 11.5 g/dL to balance benefit versus safety to patients.

Treatment of anemia in CKD requires adequate iron stores. For example, in patients with CKD, a plasma ferritin less than 100 μ g/L is considered to suggest iron deficiency, and a plasma ferritin of 100 to 200 μ g/L in association with a transferrin saturation (TSAT) of less than 20% represents "functional" iron deficiency. Parenteral iron is the treatment of choice for absolute and functional iron deficiency, since oral iron has low efficacy in CKD.

Uremic Syndrome

Uremic syndrome comprises (1) symptoms, (2) physical signs, and (3) abnormal findings on diagnostic studies that result from the failure of the kidneys to maintain adequate (1) excretory, (2) regulatory, and (3) endocrine function. It is considered the terminal clinical manifestation of kidney failure. At least 90 organic compounds have been shown to be retained in uremia.

The classic signs of **uremia** (**azotemia**) include (1) progressive weakness and easy fatigue, (2) loss of appetite followed by (3) nausea and vomiting, (4) muscle wasting, (5) tremors, (6) abnormal mental function, (7) frequent but shallow respirations, and (8) **metabolic acidosis**. The syndrome evolves to produce (1) stupor, (2) coma, and (3) ultimately death unless support is provided by dialysis or successful kidney transplantation. The composition of plasma is abnormally labile in response to such factors as (1) diet, (2) state of hydration, (3) gastrointestinal bleeding, (4) vomiting, (5) diarrhea, and (6) intake of therapeutic drugs. Patients with kidney failure (GFR of ≤ 15 mL/min per m²) will generally exhibit signs and symptoms of uremia, or a need for RRT.

The most characteristic laboratory findings are increased concentrations of nitrogenous compounds in plasma, such as urea and creatinine, as a result of reduced GFR and decreased

tubular function. Retention of these compounds and of metabolic acids is followed by progressive (1) hyperphosphatemia, (2) hypocalcemia, and (3) potentially dangerous hyperkalemia. Although most patients eventually exhibit acidemia, respiratory compensation by the elimination of carbon dioxide is extremely important. In addition, reduced endocrine function is manifested by inadequate synthesis of EPO and calcitriol, with resulting anemia and osteomalacia. Disordered regulation of blood pressure generally leads to hypertension. Biochemical characteristics of the uremic syndrome are summarized in the following Points to Remember box.

In addition to the consequences of reduced (1) excretory, (2) regulatory, and (3) endocrine function of the kidneys, the uremic syndrome has several systemic manifestations, among which are (1) pericarditis, (2) pleuritis, (3) disordered platelet and granulocyte function, and (4) encephalopathy.

Many retained metabolites have been implicated in the systemic toxicity of the uremic syndrome. Although urea was the first of these metabolites to be identified as being increased in uremia, it does not appear to be responsible for the systemic manifestations of uremia. Urea is a 60-Da water-soluble compound (see Chapter 21) that has the highest concentration of presently known uremic retention solutes in uremic plasma. Although its removal by dialysis is directly related to patient survival, the effects of urea on biologic systems are not clear. Urea removal by dialysis is not necessarily representative of other molecules retained in the uremic syndrome, particularly protein-bound solutes or lower-molecular-weight proteins, such as PTH and cystatin C.

Acute Kidney Injury

The definition of AKI, endorsed by KDIGO during 2012, is the occurrence of any one of the following:

1. Increase of plasma creatinine by equal to or greater than 0.3 mg/dL ($\geq 26 \mu\text{mol/L}$) within 48 hours
2. Increase in plasma creatinine to equal to or greater than 1.5 times baseline, which is known or presumed to have occurred within the prior 7 days
3. Reduction in urine output (documented oliguria $<0.5 \text{ mL/kg}$ per hour for >6 hours)

In addition, AKI is staged from 1 to 3, depending on severity. In the United Kingdom, the National Confidential Enquiry into Patient Outcome and Death: Adding Insult to Injury (http://www.ncepod.org.uk/2009report1/Downloads/AKI_summary.pdf, accessed April 08, 2013) reported that failure (1) to identify intravascular volume depletion, (2) to withhold nephrotoxic drugs, and (3) of early diagnosis of causative conditions (such as, sepsis) directly contributed to in-hospital mortality associated with AKI. Approximately 20% of postadmission AKI episodes are predictable and avoidable. Therefore prompt administration of intravenous crystalloid solutions (such as, 0.9% sodium chloride) may prevent further deterioration of AKI in many cases. Patients at risk for AKI include (1) older persons, (2) those with preexisting CKD, (3) those with sepsis, (4) those with diabetes mellitus, (5) patients with heart disease, and (6) those receiving nephrotoxic drugs, particularly in the setting of hypovolemia. Hypokalemia or hyperkalemia
Hyperchloremia
Hypocalcemia
Hyperphosphatemia
Hypermagnesemia

Carbohydrate Intolerance

Insulin resistance (hypoglycemia may also occur)
Plasma insulin normal or increased
Delayed response to carbohydrate loading
Hyperglucagonemia

Abnormal Lipid Metabolism

Hypertriglyceridemia
Decreased high-density lipoprotein cholesterol
Hyperlipoproteinemia

Altered Endocrine Function

Secondary hyperparathyroidism
Osteomalacia (secondary to abnormal vitamin D metabolism)
Hyperreninemia and hyperaldosteronism
Hyporeninemia
Hypoaldosteronism
Decreased erythropoietin production
Altered thyroxine metabolism
Gonadal dysfunction (increased prolactin and luteinizing hormone, decreased testosterone)

AKI should consider whether the precipitant is (1) prerenal, (2) intrarenal (intrinsic), or (3) postrenal. As intrinsic AKI is caused by primary vascular, glomerular, or interstitial disorders, it is important that all patients presenting with AKI undergo urinalysis to test for (1) infection, (2) hematuria, and (3) proteinuria. In most cases, the kidney lesion seen on histology is referred to as **acute tubular necrosis (ATN)**. ATN is caused by ischemic or nephrotoxic injury to the kidney. In 50% of cases of hospital-acquired AKI, the cause is multifactorial. Urinary electrolyte measurements are seldom required or useful in the investigation of AKI. Laboratory testing of blood is crucial in the management of AKI. Blood tests also assist in establishing the underlying diagnosis, and specific investigations are requested if kidney function has not improved following volume correction. An acute renal screen should clearly focus on the most likely diagnoses and include the tests shown in [Table 35.2](#).

TABLE 35.2 Investigation of Acute Kidney Injury

Test	Indication/Comments
Urine Testing	
Urine reagent strip ("dipstick")	Hematuria and proteinuria may indicate glomerular origin
Red cell casts on microscopy	(Not available universally; may need bedside microscope)
Urine microscopy and culture	Identify urinary tract infection
Urine protein electrophoresis and immunofixation	
Blood Tests	
Baseline Studies	
Urea, electrolytes, and creatinine	Check previous laboratory reports: AKI or AKI with preexisting CKD
Calcium, phosphate, albumin	
Liver function tests	Suspected multiorgan involvement or abnormal coagulation
Acid-base studies	Arterial blood gas or venous plasma bicarbonate concentration
Full blood count	Anemia, hemolysis, thrombocytopenia
Coagulation studies	Evidence of intravascular coagulation; need to normalize if considering kidney biopsy and central line insertion
Selected Additional Investigations	
Blood culture	Any infection, but especially endocarditis, severe pneumonia, or urinary tract sepsis
Creatine kinase	Very high in cases of muscle inflammation and necrosis (rhabdomyolysis)
Lactate dehydrogenase	If high, suspect renal infarction and consider hemolysis
Antineutrophil cytoplasmic antibodies	Vasculitides
Antiglomerular basement membrane antibody	Antiglomerular basement membrane disease
Antinuclear antibodies	SLE
Anti-dsDNA antibodies, extractable nuclear antigens	SLE
Low C3 complement	SLE, MPGN, C3 glomerulopathies
Low C4 complement	Systemic lupus erythematosus, atheroembolism, cryoglobulinemia, MPGN (immune complex positive)
Cryoglobulin	Cryoglobulinemia
Urate	Urate nephropathy
Serum protein electrophoresis	Myeloma
Virology studies	Hepatitis serology, human immunodeficiency virus
Other serology	Antistreptolysin O titer
Imaging	
Chest x-ray	Pulmonary edema, pneumonia, effusions, malignancy, and granulomas
Abdominal x-ray (kidney, ureter, and bladder)	Renal stones
Renal tract ultrasound scan	Identify size and symmetry of kidneys Evidence of an obstructed system Small, shrunken kidneys in advanced CKD
Computed tomography scan	Anatomy and perfusion
Magnetic resonance imaging	Angiography to identify renovascular lesions
Formal angiography	Critical renal artery stenosis
Kidney Biopsy	
	Reserved for patients with unexplained AKI in whom acute tubular necrosis is not suspected. It is anticipated that additional therapy as with steroids, cytotoxic drugs, and plasma exchange may be required.

AKI, Acute kidney injury; CKD, chronic kidney disease; dsDNA, double-stranded DNA; MPGN, membranoproliferative glomerulonephritis; SLE, systemic lupus erythematosus

In addition to biochemical testing, there is a role for ultrasound and radiologic imaging in kidney disease, in particular for the exclusion of obstruction. Kidney biopsy is generally reserved for cases of AKI wherein an ultrasound scan has excluded obstructed kidneys, kidney sizes are maintained, the cause of AKI is otherwise unexplained, and an intrinsic pathology is suspected.

Metabolic acidosis is the most common acid-base disorder in patients with AKI. Reduced renal excretion of potassium and the effects of acidosis on the generation of extracellular potassium may lead to a very high concentration of potassium in the plasma. Severe hyperkalemia (a plasma potassium concentration >6.5 mmol/L) is associated with life-threatening cardiac arrhythmias. Emergency

treatment of hyperkalemia should be instituted as necessary. Infusion of high concentrations of glucose stimulates insulin secretion from the pancreas and the uptake of potassium into the intracellular space. A fall in potassium concentration should be expected within 60 minutes. In addition, low-dose rapid-acting insulin is sometimes administered with the glucose bolus. Serum potassium concentration should be monitored hourly until the risk of a life-threatening cardiac event has passed and no evidence of potassium rebound

POINTS TO REMEMBER

Causes of AKI

Prerenal AKI:

- Hemorrhage
- Diarrhea
- Postoperative fluid and blood losses
- Sepsis
- Acute cardiac failure

Renal (intrinsic renal disease) AKI:

Tubular

Any of the “prerenal” causes that are severe or that are not corrected promptly leading to ATN. Other causes of ATN include:

- Drug nephrotoxicity
 - NSAIDs, ACE inhibitors
 - Aminoglycoside antibiotics
 - Amphotericin

Contrast nephropathy

Poisoning

TIN

- Allergic TIN associated with antibiotics and NSAIDs
- Sarcoidosis
- Pyelonephritis

Glomerular

- RPGN (ANCA-associated vasculitides, Goodpasture disease, SLE, other crescentic glomerulonephritides)
- Thrombotic microangiopathies
- Cryoglobulinemia
- Atheroembolism

Vascular

- Aortic dissection
- Renal vein thrombosis

Miscellaneous

- Rhabdomyolysis
- Urate nephropathy
- Hepatorenal syndrome

Postrenal AKI

- Bladder outflow obstruction
- Benign and malignant prostate disease
- Invasive bladder carcinoma
- Bilateral renal calculi or calculi within a single kidney
- Retroperitoneal fibrosis

ACE, Angiotensin converting enzyme; AKI, acute kidney injury; ANCA, antineutrophil cytoplasmic antibody; ATN, acute tubular necrosis; NSAIDs, nonsteroidal antiinflammatory drugs; RPGN, rapidly progressive glomerulonephritis; SLE, systemic lupus erythematosus; TIN, tubulointerstitial nephritis.

is found. Blood glucose concentration should be monitored because hypoglycemia may occur following exogenous insulin. When hyperkalemia persists despite appropriate medical measures, dialysis should be considered. Recovery from AKI usually occurs within days or weeks following removal of the initiating event. However, uncomplicated AKI has a mortality rate of 5% to 10%, although AKI complicating the failure of a nonrenal organ system in the intensive care unit setting is associated with mortality rates approaching 50% to 70%.

DISEASES OF THE KIDNEY

Diabetic Nephropathy

Diabetic nephropathy is a clinical diagnosis based on the finding of proteinuria in a patient with diabetes mellitus. Overt nephropathy is characterized by protein loss greater than 0.5 g/day, approximately equivalent to albumin loss of greater than 300 mg/day or category A3 albuminuria. For a variety of reasons, it is preferable to assess proteinuria as albuminuria (see Chapter 21), and albumin has long been uniformly adopted as the “criterion standard” in evaluating diabetes-related kidney damage. Patients with albuminuria exceeding 30 mg/day have pathologically increased albuminuria. Diabetic nephropathy is the most common cause of ESRD in the United States, accounting for approximately 40% of incident patients in RRT programs. The prevalence of diabetes mellitus as a cause of ESRD is variable among ethnic groups within the United States, with whites having rates approximately 25% of those observed among African Americans. Among patients who require dialysis, those with diabetes mellitus have a 22% higher mortality at 1 year and a 15% higher mortality at 5 years than patients without diabetes. The cornerstones of treatment for diabetic nephropathy consist of (1) glycemic control; (2) blood pressure control, particularly with drugs that block the RAAS; and (3) management of cardiovascular risk.

Hypertension

Hypertension is second only to diabetes mellitus as a primary diagnosis of ESRD for incident patients commencing dialysis in the United States (see Fig. 35.5). The incidence is higher in older people and especially among the black population in the United States. Hypertension often develops as a consequence of CKD because of alterations in salt and water metabolism and activation of the sympathetic nervous and renin-angiotensin systems. Hypertension can act as an accelerating force in the development of ESRD. Treatment of hypertension to predefined target blood pressure values is critical in preventing progression to ESRD.

Glomerular Diseases

Glomerular disease is suggested clinically by the finding of blood and protein in the urine on urine reagent strip testing. Proteinuria of greater than 1 g/day (0.88 g/g creatinine;

100 mg/mmol creatinine) in the absence of an overflow-type proteinuria, such as myoglobinuria or light chain–related disease, is invariably glomerular in origin. Although a detailed discussion of each glomerular disease is beyond the scope of this book, the most important diseases are discussed to illustrate the spectrum of disease. For further information regarding clinical guidelines, the reader is directed to the KDIGO *Clinical Practice Guideline for Glomerulonephritis*. In the United Kingdom, glomerulonephritis accounts for 14% of new cases of established renal failure.

Primary Glomerular Disease

Glomerulonephritis can be primary (affecting only the kidneys) or secondary (in which the kidneys are involved as part of a systemic process). Histopathologic classification of glomerulonephritis may appear slightly cumbersome, but it is readily simplified by consideration of the glomerular structures and cells that may be involved and the presence or absence of immune complexes. In essence, only three cell types are involved—endothelial, epithelial, and mesangial—plus the acellular GBM. The glomerular cells and the GBM have a limited range of response to injury—namely, proliferation, scarring (sclerosis), and GBM thickening. The term *focal* is used if fewer than half of the glomeruli are involved in the disease process as seen on light microscopy, whereas *diffuse glomerulonephritis* refers to cases in which all glomeruli are involved. Immune deposits identified following immunofluorescence or immunoperoxidase staining do not define whether a disease is focal or diffuse.

IgA nephropathy. *IgA nephropathy* is an example of a focal glomerulonephritis with focal mesangial cell proliferation demonstrated by light microscopy. However, diffuse and global deposition of the immunoglobulin IgA can be demonstrated following immunostaining. It is the most common type of glomerulonephritis worldwide and has a particularly high prevalence around the Pacific rim. The disease tends to be slowly progressive (in terms of loss of kidney function), depending, as with most kidney diseases, on the degree of proteinuria, kidney function at the time of diagnosis, and degree of interstitial fibrosis on kidney biopsy. Up to 50% of patients exhibit increased concentrations of serum IgA, although diagnosis depends on kidney biopsy findings. Clinical presentation varies considerably from asymptomatic microscopic hematuria to macroscopic hematuria, proteinuria including nephrotic syndrome, and crescentic glomerulonephritis with kidney failure. Episodic macroscopic hematuria is seen in some patients at the same time as an upper respiratory tract infection.

Treatment options range from tonsillectomy in patients with macroscopic hematuria associated with respiratory infection to no treatment in those with isolated microscopic hematuria or those with proteinuria of less than 1 g/day. In progressive disease, all patients are treated in a similar generic fashion as for most kidney diseases, including targeting blood pressure to less than 125/75 mm Hg and using comprehensive RAAS blockade to minimize proteinuria. In addition,

selected patients may receive corticosteroids in the form of prednisone.

Nephrotic syndrome. *Acute nephrotic syndrome* is defined as heavy proteinuria (>3 g/day), reduced serum albumin concentration, and edema. In comparison with nephritic syndromes, nephrotic patients may exhibit an otherwise bland urinary sediment with little hematuria. Nephrotic syndrome can occur in patients of any age, from neonates to the elderly. Although the underlying kidney disease tends to vary with age, in all cases the lesion is within the glomerulus and is associated with damage to the specialized visceral epithelial cells, the podocytes. Proteinuria is a consequence of a reduction in the charge-selective properties of the filtration barrier, particularly the GBM, and of alterations in the slit diaphragms of interdigitating foot processes of adjacent podocytes.

The most common causes of nephrotic syndrome are minimal change disease (MCD), focal segmental glomerulosclerosis (FSGS), and membranous nephropathy. Detection of autoantibodies directed to M-type phospholipase A₂ receptor PLA₂R (anti-PLA₂R antibody) in patients with membranous nephropathy indicates primary disease rather than a secondary process and guides therapy.

Secondary causes include diabetic nephropathy, amyloidosis, and SLE. A kidney biopsy is generally undertaken in all adult patients who present with nephrotic syndrome. Nephrotic syndrome is associated with increased cardiovascular disease as a result of marked hyperlipidemia and increased risk of infection and thromboembolic disease. In addition, AKI may supervene in cases of nephrotic syndrome, and prolonged proteinuria with a poor response to treatment may lead to kidney failure.

The management of nephrotic syndrome depends on the underlying glomerular lesion, although general principles apply in all cases (Box 35.1). In addition to general measures, specific treatment targeted at inducing remission from proteinuria usually requires a combination of immunosuppressive drugs, including corticosteroids and cytotoxic drugs.

BOX 35.1 Management of Nephrotic Syndrome

- Low-sodium diet
- Protein intake of 1.0 g/kg per day
- Fluid management: usually includes loop diuretics
- Thromboembolism prophylaxis: may include formal anticoagulation in high-risk patients (serum albumin <20 g/L or in nephrotic syndrome due to membranous nephropathy or mesangioproliferative glomerulonephritis)
- Vigilance for infections
- Treatment of hyperlipidemia with 3-hydroxy-3-methylglutaryl-Coenzyme A (HMG)-CoA-reductase inhibitors (statins)
- Treatment of hypertension, primarily with RAAS blockade
- Supportive treatment of AKI
- Education and psychological support for patients and relatives

AKI, Acute kidney injury; RAAS, renin-angiotensin-aldosterone system.

Rapidly Progressive Glomerulonephritis

Rapidly progressive glomerulonephritis (RPGN) is a heterogeneous group of disorders characterized by a fulminant clinical course that leads to kidney failure in only weeks or months. The clinical picture of RPGN is often preceded by a systemic illness for several months.

These syndromes are often characterized by focal glomerulonephritis with glomerular ischemia, infarction, and tissue death (necrosis). Following release of inflammatory cytokines and chemokines from the necrotic capillaries, there is proliferation of the epithelial cells of the Bowman capsule. The proliferated cells lie on top of adjacent cells and form a partial circle around the inner rim of the Bowman capsule, which is referred to as a *crescent*. Proliferating epithelial cells and macrophages eventually compress the glomeruli and obstruct the proximal convoluted tubules, thus severely compromising nephron function.

Anti-GBM antibodies may be present along the GBM in anti-GBM disease. Most commonly, however, there is no or little Ig deposition within the glomerulus (so-called pauci-immune). Approximately 80% of patients with active pauci-immune necrotizing and crescentic glomerulonephritis have been shown to possess antineutrophil cytoplasmic antibodies (ANCA) irrespective of the presence or absence of a concomitant systemic vasculitis. This strong association has allowed serologic discrimination of this type of glomerulonephritis from other types of RPGN. Two subtypes of ANCA have been described—cytoplasmic (C-ANCA) and perinuclear (P-ANCA)—reflecting the patterns observed by indirect immunofluorescence microscopy using alcohol-fixed neutrophils as a substrate. C-ANCAs are directed toward a plasma proteinase (PR3) in neutrophil primary granules, whereas the P-ANCAs target antigen is usually myeloperoxidase (MPO). Immunoassays have been used to measure anti-PR3 and anti-MPO antibody titers. ANCAs appear in the plasma of almost all patients with active and generalized disease and are useful in diagnosis of the disease. However, false positives and false negatives may occur, necessitating histologic diagnosis where possible.

In addition to measurement of ANCA, C-reactive protein (CRP) is extremely helpful in assessment of the acute-phase reaction in active disease processes and is critical in helping to define disease remission. In patients in whom the CRP has returned to normal, disease remission is indicated; this prompts the clinician to reduce immunosuppressant treatment doses.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a chronic inflammatory disease of unknown cause that can affect the skin, joints, kidneys, lungs, nervous system, serous membranes, and/or other organs of the body. Renal involvement, termed lupus **nephritis**, occurs in up to 60% of adults with SLE. Lupus nephritis is especially common in black and Hispanic patients in the United States. It may present variably from incidental hematuria and proteinuria, nephrotic syndrome, or a fulminating RPGN. Most (75%) patients with SLE develop abnormal

urinalysis or impaired kidney function during the course of the disease. Detection of lupus nephritis involves urine testing for blood and protein and tests of kidney function. In addition, serologic testing for autoantibodies to nuclear antigens and measurement of complement components C3 and C4 are undertaken. Significant hypocomplementemia and increased anti-double stranded DNA (anti-dsDNA) titers suggest active disease. Combined use of corticosteroids and intravenous or oral cyclophosphamide has been the conventional treatment for diffuse proliferative lupus nephritis since the 1970s. Recent data suggest that mycophenolate mofetil and corticosteroids can be as effective as but not superior to intravenous cyclophosphamide for induction treatment for lupus nephritis.

Interstitial Nephritis

A variety of chemical, bacterial, and immunologic injuries to the kidney may cause generalized or localized changes that primarily affect the tubulointerstitium rather than the glomeruli. This group of disorders is characterized by alterations in tubular function that, in advanced cases, may cause secondary vascular and glomerular damage. **Interstitial nephritis** is associated with proteinuria that is less severe than in glomerular disease. In addition to infection-related **pyelonephritis**, interstitial nephritis may present in acute and chronic forms and has many causes. Acute allergic interstitial nephritis presents with AKI and marked inflammation of the interstitium. A drug hypersensitivity reaction is the most common form of acute interstitial nephritis. Urinary findings may be normal, or low-level proteinuria and eosinophils may be seen on light microscopy. More than 100 different drugs have been implicated, but NSAIDs and β -lactam antibiotics are the drugs most commonly identified. Treatment is directed at removing any causative agent. Steroids are used to promote early resolution of the clinical course, although patients can develop chronic interstitial fibrosis.

Monoclonal Light Chains and Kidney Disease

Ig molecules are formed in secretory B cells (plasma cells) and consist of heavy chains, which denominate the antibody isotype, and either kappa (κ) or lambda (λ) light chains. The proportion of Ig containing κ versus λ is 3:2 in humans. The molecular weight of light chains is approximately 23 kDa. Excess production of light over heavy chains appears to be required for efficient Ig synthesis, resulting in the release of free light chains (FLCs) into the circulation. In normal individuals, the small quantity of circulating polyclonal light chains is filtered by the glomerulus, and 90% is reabsorbed in the proximal tubule and degraded by proteases.

Myeloma is a neoplastic proliferation of a clone of plasma cells that produce excessive amounts of a monoclonal (M) protein and FLCs. In multiple myeloma, complete monoclonal Igs (usually IgG or IgA) are accompanied in the plasma by variable concentrations of FLCs that appear in the urine as **Bence Jones proteins** (named after Henry Bence Jones, who first described these in 1848). M-proteins and FLCs can be identified in the blood and/or the urine in 98% of patients

with myeloma using protein electrophoresis and immunofixation. Immunoparesis, with reduction in non-M-protein Ig, is characteristic of myeloma. The FLC immunoassay is now also used to detect monoclonal Ig. The kidneys are often affected in myeloma, with diverse clinical and pathologic presentations. The three most common forms of monoclonal Ig-mediated kidney disease are cast nephropathy, monoclonal Ig deposition disease (MIDD), and AL amyloidosis. Impairment of kidney function at presentation occurs in almost 50% of patients with myeloma. Although most recover following treatment for other factors contributing to renal impairment (e.g., dehydration, hypercalcemia, infection, nephrotoxic drugs), about 10% have severe renal involvement caused by the effects of monoclonal FLCs on the kidney. Severe kidney failure may occur in myeloma following deposition of light chains within tubules—so-called cast nephropathy (or myeloma kidney).

Polycystic Kidney Disease

Autosomal dominant **polycystic kidney disease** (ADPKD) is the second most common inherited monogenic disease (after familial hypercholesterolemia), with an estimated incidence of 1:1000. It is by far the most common inherited kidney disease; 12.5 million people worldwide are affected. Approximately 50% of ADPKD patients develop kidney failure by age 55 years. It is therefore important to make the diagnosis in affected families and to monitor kidney function regularly. The intervals between estimations of GFR will depend on the stage of CKD, as with other progressive kidney diseases. An important clinical observation is the highly variable phenotype within families. The disease causes the development of multiple kidney cysts and extrarenal cysts in the liver and pancreas. About 10% of ADPKD families have a strong family history of intracranial arterial aneurysm rupture. Hypertension is an early and frequent manifestation, and gross hematuria is a common presenting symptom. On the basis of effectiveness, cost, and safety, ultrasound is the imaging modality most commonly used to make the diagnosis.

ADPKD is caused by mutations in the genes (*PKD1* and *PKD2*) that encode polycystin 1 and 2, which are located in primary cilia. Mutations affecting *PKD1* are more prevalent than those of *PKD2* and tend to have a worse prognosis. Genetic testing is not used routinely as a screening tool because current techniques identify only 70% of the hundreds of different *PKD1* and *PKD2* mutations. Generic treatment should include treatment of hypertension with ACE inhibitors and/or ARBs and maintaining a fluid intake of 2 to 3 L/day to reduce the risk of kidney stone disease. Specific therapies are targeted at reducing cyst development and enlargement. Estimates of cyst volume can be determined using magnetic resonance imaging techniques and changes documented over a relatively short period of time. This has allowed the performance of clinical trials of novel drugs such as the vasopressin V₂-receptor antagonists, tolvaptan, and antiproliferative drugs such as sirolimus. Tolvaptan has been shown in the 3-year clinical study (TEMPO3:4) to slow the increase in size of the cysts, reduce pain associated with cysts, and slow the

rate of change in kidney function. Adverse events, primarily thirst and polyuria, and abnormalities in liver function tests are reported, and the drug is subject to a US Food and Drug Administration review.

Obstructive Uropathy

Benign prostatic hyperplasia (BPH) is one of the most common types of **obstructive uropathy** and is an almost universal finding in aging men. Among the most common symptoms are disorders of micturition, in particular increased frequency; in many cases this can progress to bladder outflow obstruction. Between 10% and 40% of men with bladder outflow obstruction caused by BPH present in acute retention. Approximately 5% of the men this group have high-pressure chronic retention of urine, which can result in upper urinary tract obstruction and consequently CKD as a result of glomerular and tubular damage.

Tubular Disease

Renal tubular acidoses and inherited tubulopathies are types of renal tubular disease.

Renal Tubular Acidoses

The **renal tubular acidoses (RTAs)** comprise a diverse group of both inherited and acquired disorders affecting either the proximal or distal tubule. They are characterized by a hyperchloremic, normal anion gap metabolic acidosis and urinary bicarbonate or hydrogen ion excretion inappropriate for the plasma pH. They are the result of either failure to retain bicarbonate or inability of the renal tubules to secrete hydrogen ion. Typically the GFR in RTA is normal or slightly reduced, and there is no retention of anions, such as phosphate and sulfate (as opposed to the acidosis of renal failure).

The three categories of RTA are distal (dRTA, type I); proximal (pRTA, type II); and type IV, which is secondary to aldosterone deficiency or resistance. The term “type III RTA” (mixed proximal/distal defect) has been abandoned because this is no longer considered a separate entity.

The finding of a hyperchloremic metabolic acidosis in a patient without evidence of gastrointestinal bicarbonate losses and with no obvious pharmacologic cause should prompt suspicion of an RTA. In addition to plasma electrolyte (including potassium) measurement, preliminary investigation should include measurement of urinary pH in a fresh early-morning urine sample. The finding of a urine pH greater than 5.5 in the presence of a systemic acidosis supports the diagnosis of dRTA.

Inherited Tubulopathies

The inherited tubulopathies comprise a heterogeneous set of rare disorders, including (1) **Bartter syndrome**, (2) **Gitelman syndrome**, (3) **Liddle syndrome**, (4) **pseudohypoaldosteronism type I**, (5) Dent disease, and (6) X-linked dominant hypophosphatemic rickets (previously known as vitamin D-resistant rickets). Most are characterized by electrolyte disturbances. In addition to these, general reasons to suspect a tubulopathy include (1) a familial disease pattern, (2) renal

impairment, (3) nephrocalcinosis, and (4) stone formation, especially if these should present at an early age. In cases in which a diuretic-sensitive channel is affected, these disorders will clearly mimic the effects of diuretic use (see discussion later in this chapter), and exclusion of covert use of diuretics is important. Although they are individually uncommon or rare, an awareness of these disorders is critical for the clinical biochemist considering the potential differential diagnoses in patients having electrolyte imbalances.

Diuretics

Diuretics are predominantly prescribed to treat either hypertension and/or disorders associated with fluid overload. All diuretics act by interfering with tubular reabsorption of sodium and/or chloride and therefore have accompanying effects on water retention. Different classes of diuretics act at different sites along the nephron. Classes include (1) loop, (2) thiazide, and (3) “potassium-sparing” diuretics. Many diuretics will cause hypokalemia to some degree, depending on the (1) potency, (2) dose, (3) duration of treatment, and (4) patient’s underlying potassium balance.

Diabetes Insipidus

Diabetes insipidus (DI) is a disorder in which there is an abnormal increase in urine output, fluid intake, and often thirst. DI is due to the absence of an ADH effect, either because of impaired or failed secretion (cranial or central DI) or lack of end-organ response to ADH (nephrogenic DI). A further disorder, psychogenic polydipsia, or compulsive water drinking, has been known to present as DI. The investigation of DI involves first demonstrating, by undertaking a water deprivation test, that the patient is unable to form a concentrated urine. If the patient fails to concentrate urine during the test, then synthetic ADH is given to establish whether the defect in concentrating ability is at the renal or pituitary level.

Renal Calculi

Nephrolithiasis is a condition marked by the presence of renal calculi. Such calculi (“kidney stones”) occur in the (1) renal pelvis, (2) ureter, and (3) bladder. Kidney stone formation is often considered to be a nutritional or environmental disease, linked to affluence, but genetic or anatomic abnormalities are also significant. Approximately 5% to 10% of the population of the western world are thought to have formed at least one kidney stone by the age of 70 years, and the prevalence of kidney stones may be increasing. In both males and females, the average age of first stone formation is decreasing. For most stone types, there is a male preponderance. The passage of a stone is associated with severe pain, called renal colic, which may last for 15 minutes to several hours and is commonly associated with nausea and vomiting.

The majority of kidney stones found in the western world are composed of one or more of the following substances: (1) calcium oxalate with or without phosphate (frequency 67%), (2) magnesium ammonium phosphate (12%), (3) calcium phosphate (8%), (4) urate (8%), (5) cystine (1% to 2%), and

(6) complex mixtures of the above (2% to 3%). These poorly soluble substances crystallize within an organic matrix, the nature of which is not well understood. Most kidney stones are treated by **lithotripsy**, which entails crushing a calculus within the urinary system, followed at once by the washing out of the fragments.

Prostaglandins and Nonsteroidal Antiinflammatory Drugs in Kidney Disease

The prostaglandins are a series of C₂₀ unsaturated fatty acid derivatives of cyclooxygenase (COX) on cell membrane arachidonic acid (see Chapter 23). The major renal vasodilatory prostaglandin is PGE₂, which is synthesized predominantly in the medulla of the kidney. The major vasoconstrictor prostaglandin is thromboxane A₂, which is produced primarily within the renal cortex. PGE₂ (1) increases renal blood flow rate, (2) inhibits sodium reabsorption in the distal nephron and collecting duct, and (3) stimulates renin release. These actions promote natriuresis and diuresis. In patients with CKD, renal PGE₂ excretion rates are three to five times higher than those in healthy subjects; therefore PGE₂ production represents a compensatory response to loss of nephron mass. Vasodilatory prostaglandins are synthesized following stimulation with renal sympathetic adrenergic and AII-dependent mechanisms to offset or modulate vasoconstriction. In the tubule, prostaglandins act as autocoids, exerting their effects locally near the site of synthesis.

NSAIDs have analgesic, antipyretic, and antiinflammatory effects. They also block the synthesis of COX products of arachidonic acid, which have a critical role in (1) renal hemodynamics, (2) control of tubular function, and (3) renin release. Analgesic nephropathy is a common cause of ESRD in a number of countries, reaching 10% in Switzerland and Australia, but it is essentially a preventable condition for which biochemical monitoring has proved useful. Older people demonstrate significant reductions of GFR within 1 week of ingestion of NSAIDs. Acute interstitial nephritis and nephrotic syndrome have been reported to occur with NSAIDs.

Toxic Nephropathy

A wide variety of nephrotoxins exist in the environment, in some cases associated with particular occupations (e.g., heavy metals, such as cadmium and lead). Both glomerular and tubulointerstitial damage may result from exposure to toxins; detection of both requires biochemical monitoring of GFR/serum creatinine concentration and tubular and glomerular proteinuria. Anatomic physiologic and biochemical features make the kidney susceptible to insult from a variety of medicinal and environmental agents. Factors contributing to the sensitivity of the kidney include its large blood flow, the concentration of filtered solutes during urine production, and the presence of a variety of xenobiotic transporters and metabolizing enzymes. **Toxic nephropathy** commonly occurs as a result of decreased renal perfusion because of precipitation within the tubule or due to direct toxic effects at the proximal tubule level. In some cases the conjugation of environmental

chemicals (e.g., mercury, cadmium) to glutathione and/or cysteine targets these chemicals to the kidney, where inhibition of renal function occurs through a variety of mechanisms that are not completely understood. Although some drugs can cause kidney damage in the presence of normal renal function, a far greater variety of drugs can cause problems in patients with kidney disease, predominantly because of accumulation resulting from decreased renal elimination. A list of drugs and environmental toxins commonly known to cause kidney damage is given in [Table 35.3](#).

RENAL REPLACEMENT THERAPY

RRT includes dialysis procedures such as hemodialysis (HD), **peritoneal dialysis (PD)**, continuous hemofiltration (HF),

and continuous **hemodiafiltration (HDF)**. These techniques are used to temporarily or permanently remove toxic substances from the blood when the kidneys cannot satisfactorily remove them from the circulation. In addition, kidney transplantation has become an effective form of RRT. Extensive laboratory support is required by an RRT program ([Table 35.4](#)).

Dialysis

Dialysis is the process of separating macromolecules from ions and low-molecular-weight compounds in solution based on the difference in their rates of diffusion through a semi-permeable membrane through which crystalloids can pass readily but colloids pass very slowly or not at all. Two distinct physical processes are involved: diffusion and ultrafiltration.

TABLE 35.3 Toxic Nephropathy: Causes, Patterns, and Markers

Compound Category	Drug/Toxin	Type of Renal Injury/Pathology	Biomarkers/Notes
Antibacterial agents	Aminoglycosides (e.g., neomycin, gentamicin, tobramycin, amikacin)	Acute tubular necrosis and interstitial nephritis. Nonoliguric AKI.	Plasma: ↓K, ↓Mg, ↓Ca Urine: ↑LMWP, ↑Glycosuria Nephrotoxicity major and common side effect
	Amphotericin	Initially distal tubular injury followed by medullary injury	Plasma: ↓K, ↑creatinine dRTA
Antiviral/antiprotozoal agents	Acyclovir	Nonoliguric AKI due to tubular obstruction and interstitial inflammation	Crystalluria and hematuria
	Pentamidine	Tubular toxicity	Plasma: ↓Mg, ↓Ca Urine: ↑Mg, ↑Ca
	Indinavir	Nephrolithiasis, irreversible kidney failure in some patients	Crystalluria and hematuria
Radiocontrast agents	Iothalamate, iodixanol	Oliguric or nonoliguric AKI, generally reversible. Proximal tubular damage.	↑Plasma creatinine after contrast administration
Antitumor drugs	Cisplatin	Irreversible dose-related and cumulative kidney failure. TIN with heavy proteinuria. Often AKI.	Urine: ↑Mg, ↑PO ₄ , tubular casts and ↑LMWP in early stages.
	Methotrexate	Nonoliguric AKI. Tubular atrophy and interstitial fibrosis.	Only seen in association with high-dose therapy
	Interleukin-2	Reversible AKI due to ↓RBF	Observed in up to 90% of cases of high-dose therapy
Other drugs	ACE inhibitors	Dramatic ↓GFR due to ↓efferent arteriolar tone	Especially in the setting of bilateral renal artery stenosis. ↑Plasma creatinine and K.
	5-Aminosalicylic acid (e.g., mesalazine, olsalazine)	Occasional ATN and irreversible kidney damage	Tubular proteinuria
	Cyclooxygenase (COX)-2 inhibitors	Probably a similar pattern of renal injury to NSAIDs (see below)	
	Lithium	Distal tubular damage with nephrogenic diabetes insipidus ± dRTA	
	Penicillamine	Membranous glomerulopathy with NS, occasionally AKI	Proteinuria
	NSAIDs	Several forms of nephropathy identified, including (1) hemodynamically mediated AKI, (2) TIN ± NS, (3) salt and/or water retention, (4) hyperkalemia, and (5) CKD/ESRD ("analgesic nephropathy")	Depends on type of effect

Continued

TABLE 35.3 Toxic Nephropathy: Causes, Patterns, and Markers—cont'd

Compound Category	Drug/Toxin	Type of Renal Injury/Pathology	Biomarkers/Notes
Heavy metals	Cadmium	Subtle but irreversible TIN	Fanconi syndrome with RTA. ↑Urinary metallothionein.
	Gold	Membranous glomerulopathy but normal GFR maintained	Proteinuria <3.5 g/24 h
	Lead	Proximal tubular atrophy with interstitial fibrosis	Reversible Fanconi syndrome in children with acute poisoning. In lead workers, urinary proteinuria <2 g/24 h in association with ↑plasma urate, hypertension ± gouty arthritis.
Other environmental agents	Mercury	Proximal tubular damage with ATN	Urine: 1LMWP
	Hydrocarbons (e.g., paints, dry-cleaning solvents)	ATN, chronic TIN, glomerulonephritis caused by renal cytochrome P450 metabolism of chloroform to toxic metabolites	Tubular proteinuria ± ↑plasma creatinine
	Paraquat, diquat	ATN secondary to IRBF due to shock and direct toxic effects of paraquat; intrinsic kidney damage due to production of reactive oxygen species	↑Plasma creatinine

ACE, Angiotensin converting enzyme; AKI, acute kidney injury; ATN, acute tubular necrosis; CKD, chronic kidney disease; dRTA, distal renal tubular acidosis; ESRD, end-stage renal disease; GFR, glomerular filtration rate; LMWP, low-molecular-weight proteinuria; NS, nephrotic syndrome; NSAIDs, nonsteroidal antiinflammatory drugs; RBF, renal blood flow; TIN, tubulointerstitial nephropathy.

The list of agents shown is not exclusive but illustrates the range of compounds that may affect the kidney. For further information, readers should consult: Palmer, B. F., & Henrich, W. L. (2004). Toxic nephropathy. In: B. M. Brenner (Ed.), *Brenner and Rector's the Kidney* (7th ed., Chapter 34) Philadelphia: Saunders.

TABLE 35.4 Laboratory Support for Dialysis Programs

Clinical Condition	Laboratory Tests
Acute Dialysis	
Dialysis disequilibrium	Urea and electrolytes, bicarbonate, calcium
Pyrexia	C-reactive protein, white cell count, blood cultures
Bleeding	Clotting screen, platelets
Chronic Dialysis	
Anemia	Ferritin, transferrin saturation, B12, folate
	Blood film, PTH, C-reactive protein
Sepsis	C-reactive protein, blood, urine specimens for microscopy, culture, and sensitivity
Nutrition	Albumin, phosphate
Cardiovascular disease risk	Lipid profile
Dialysis-related amyloid	β ₂ -microglobulin (not routinely measured)
CKD-MBD	Predialysis plasma calcium, phosphate (monthly in hemodialysis patients; every 3 months in peritoneal dialysis patients)
	Alkaline phosphatase
	PTH (at least every 3 months)
	Aluminum in patients receiving aluminum-based phosphate binders (every 3 months)
Adequacy of hemodialysis as assessed by urea clearance	Predialysis and postdialysis urea
Sepsis, abdominal pain in peritoneal dialysis	Microscopy and culture of peritoneal dialysate
Adequacy of peritoneal dialysis as assessed by weekly small solute clearance	Dialysate creatinine, urea
Peritoneal membrane characteristics assessed by peritoneal equilibration test (PET)	Plasma and dialysate glucose and creatinine

CKD, Chronic kidney disease; MBD, mineral; PTH, parathyroid hormone.

Fig. 35.6 A hemodialyzer setup.

No absolute recommendation of commencement of dialysis based on GFR alone can be made. KDIGO suggest that dialysis be initiated when one or more of the following are present: symptoms or signs attributable to kidney failure (serositis, acid-base or electrolyte abnormalities, pruritus), inability to control volume status or blood pressure, a progressive deterioration in nutritional status refractory to dietary intervention, or cognitive impairment. This often but not invariably occurs in the GFR range between 5 and 10 mL/min per 1.73 m². Not all individuals will be suitable for RRT, and in this setting it is important that the multidisciplinary team facilitate care for people on the “conservative management” pathway.

Dialysis procedures include (1) HD and (2) PD.

Hemodialysis

HD is the method most commonly used to treat advanced and permanent kidney failure. Clinically it is considered the default therapy that is used in patients unsuitable for the alternate modalities of PD and kidney transplantation. Operationally it involves connecting the patient to a circuit into which his or her blood flows to and from a semi-permeable large-surface-area membrane, the hemodialyzer (Fig. 35.6). After filtration to remove wastes and extra fluid, the cleansed blood is returned to the patient. This is a complicated and inconvenient therapy requiring a coordinated effort from a health care team that includes the patient, nephrologist, dialysis nurse, dialysis technician, dietitian, and others. Patients are dialyzed in home- or hospital-based units, with dialysis usually performed three times a week for sessions lasting between 3 and 5 hours. This dialysis schedule is largely empirical insofar as it reconciles adequate treatment with breaks between treatments to provide the patient with a reasonable quality of life.

HD relies on good vascular access, preferably via a surgically created upper limb arteriovenous fistula (AVF), to enable blood to be pumped around the extracorporeal circuit at a rate in excess of 300 mL/min.

Fluid management on HD is crucial for patient well-being and survival. Because conventional dialysis is based on a thrice weekly schedule, fluid is accumulated by the patient between dialysis sessions. Many patients are anuric or at least oliguric; therefore unrestricted fluid intake would result in fluid overload and complications of pulmonary edema and hypertension. Patients receiving HD are advised to restrict fluid intake to 1 L/day or so. This allowance is recommended to the individual patient by the dialysis nursing staff and the dietitian to ensure that adequate nutrition is maintained. Nevertheless many patients find the fluid restriction very difficult to maintain; therefore large weight gains between dialysis sessions are a common occurrence.

Assessment of adequacy of hemodialysis. Assessment of adequacy of dialysis treatment for individual patients in the clinical setting includes consideration of the patient’s well-being, cardiovascular risk, nutritional status, and degree of achievable ultrafiltration. It also includes estimates of a number of laboratory parameters such as hemoglobin, phosphate, and albumin and clearance of the small solutes urea and creatinine. Although a full description of adequacy is beyond the scope of this text, in practice a simple calculation may be performed to obtain an estimate of dialysis adequacy: the urea reduction ratio (URR). The URR is the percentage fall in plasma urea attained during a dialysis session and is measured as follows:

$$\frac{[(\text{Predialysis \{urea\}} - \text{Postdialysis \{urea\}}) / (\text{Predialysis \{urea\}})] \times 100 \%}{}$$

Observational studies in populations of dialysis patients have shown that variations in URR are associated with major differences in mortality.

Peritoneal Dialysis

Peritoneal dialysis (PD) is a type of dialysis in which dialysate is passed into the patient’s peritoneal cavity, with the peritoneum then employed as the dialysis membrane (Fig. 35.7). Use of PD varies among countries, depending on access to

Fig. 35.7 Diagrammatic sketch of peritoneal dialysis. To convert glucose concentration in mmol/L to mg/dL, multiply by 18. (Redrawn from Nolph, K. D. [1989]. Peritoneal anatomy and transport physiology. In: J. F. Maher [Ed.], *Replacement of renal function by dialysis* [3rd ed., Chapter 23]. Dordrecht, The Netherlands: Kluwer Academic Publishers/Springer.)

HD. For example, in 2013 in the United Kingdom, 3 months after entering an RRT program, 20% of incident patients were receiving PD (compared with 66% receiving HD and 10% with a functioning transplant); whereas in Mexico, 90% of patients received PD.

Operationally, PD uses the patient's own peritoneal membrane (surface area approximately 2 m²), across which fluids and solutes are exchanged between the peritoneal capillary blood and the dialysis solution placed in the peritoneal cavity. Fluid removal (ultrafiltration) is achieved by using dialysis fluids containing high concentrations of dextrose acting as an osmotic agent; as dextrose passes across the peritoneal membrane, the concentration gradient diminishes and the rate of fluid removal decreases. Conventional therapies use four daily exchanges of approximately 2 L of fluid, with approximately 10 L of spent dialysate generated (including ultrafiltration). RRF is critical to the success of PD because only a few milliliters per minute can contribute substantially to urea clearance and C_{Cr} , with each additional milliliter resulting in an extra 10 L of clearance per week. Practical reasons for opting for PD include preservation of RRF and vascular access sites, a home treatment facilitating increased patient autonomy, flexibility as to where the treatment can be administered, and ease of self-treatment, with lower capital costs involved. Blood pressure control and extremes of fluid shifts are not as problematic as those that occur on conventional HD.

Automated PD is now widely available. It requires a programmable machine to regulate flow, dwell time, and drainage, and may be performed at night. Solute clearance can be increased by leaving fluid in the peritoneum during the day and by performing an additional daytime exchange.

Peritonitis, a particular complication of PD, typically presents with a cloudy dialysate effluent and abdominal pain. Additional features such as vomiting and a high temperature suggest serious infection. Blood and dialysate samples should be taken for urgent microbiologic analysis and antibiotics administered via the dialysis catheter directly into the peritoneum. If antibiotic treatment fails, then the catheter is removed and the patient is converted to HD. In the majority of cases, the episode of peritonitis responds to treatment and PD can continue, although it is likely that repeated episodes will cause scarring and fibrosis of the peritoneal membrane, with permanent loss of ultrafiltration. Long-term serious complications may occur, such as sclerosing encapsulating peritonitis caused by adhesions and peritoneal thickening encasing the peritoneal contents and causing bowel obstruction. This unusual condition is associated with increased frequency of peritonitis episodes and longer duration of PD.

Malnutrition in Dialysis Patients

Dialysis patients with ESRD tend to have a poor appetite. Protein metabolism is altered in the setting of chronic acidosis and low-grade inflammation. These factors in combination place patients at risk of protein and energy malnourishment. Nutritional screening is recommended in dialysis patients. Such screening may involve measurement of weight, a recent history of edema-free weight loss, the body mass index, and subjective global assessment. Serum albumin is often used as a marker of malnutrition, even though it is a relatively poor nutritional marker. However, good evidence indicates that the lower the albumin concentration, the worse the long-term prognosis.

Kidney Transplantation

Kidney transplantation is the most effective form of RRT in terms of long-term survival and quality of life. Approximately, 100,000 patients are on the waiting list for a kidney transplant, and almost 17,000 kidney transplants are performed annually in the United States. Median waiting time for a listed patient depends on his or her age, with children given priority listing. Although patients with kidney failure should have equitable access to kidney transplantation, currently only 23% of adult patients on dialysis in the United Kingdom are on the active transplant waiting list. Waiting time spent on dialysis has been shown to be an important factor in determining mortality. The very best outcomes are achieved following preemptive (i.e., before dialysis has become necessary) live donor transplants. Typically, graft and patient survival at 1-year are in excess of 90%. Long-term graft survival remains a major problem, with half of transplants failing within 14 years, usually as a result of chronic allograft injury or death with a functioning graft. Transplantation medicine provides a constant challenge to balance the immunologic risk of damage to the allograft (rejection) versus the well-being of the recipient while avoiding excess immunosuppression, as the latter increases the likelihood of opportunistic infection and malignancy. In addition, many of the powerful immunosuppressive drugs have idiosyncratic side-effect profiles.

Preoperative Assessment

Some patients are considered unsuitable candidates for transplantation (Box 35.2). Laboratory assessment includes indicators of general operative health (e.g., electrolytes, acid-base status, clotting profile, full blood cell count, cross-matching). In addition, a full screen for infectious diseases—particularly cytomegalovirus (CMV), Epstein-Barr virus, hepatitis B and C, varicella-zoster virus, and human immunodeficiency virus status—is undertaken; these infections can be activated by immunosuppressive therapy.

The Operation

The donor kidney is usually placed extraperitoneally in the right or left iliac fossa. Anastomoses are constructed joining the transplant renal artery and vein to the recipient's respective iliac vessels. The ureter is joined to the bladder. The recipient's native kidneys are left in situ in almost all cases. Living donor kidneys can be retrieved through open surgery or with the aid of laparoscopic techniques. The workup for a live donor transplant is beyond the scope of this chapter.

Postoperative Assessment

During the initial postoperative phase of 1 to 2 weeks, careful monitoring of serum creatinine and urine output is required to monitor graft function. Most grafts produce measurable amounts of urine within a matter of hours, and this is a clear sign of a functioning graft; however, in a certain proportion, perhaps 5% to 10% of cases, primary nonfunction is apparent. In this subgroup, continuing dialysis support is necessary. In some patients the condition resolves without treatment, but in others a percutaneous kidney biopsy may be necessary to establish whether the graft is still viable and what form of therapy should be initiated. In otherwise uncomplicated cases, the serum creatinine concentration falls rapidly postoperatively (Fig. 35.8). Early allograft rejection episodes are suspected if the creatinine does not fall to the expected level or if there is a creatinine concentration indicating allograft dysfunction.

Immunosuppression and therapeutic drug monitoring. The currently used immunosuppressive drugs and regimens have potentially numerous and serious side effects; these are summarized in Table 35.5.

Cyclosporin is insoluble and is presented for clinical use as a microemulsion. It has a narrow therapeutic window; therefore in clinical transplantation it is important to monitor the blood concentration frequently. The most widely accepted practice is to monitor the “trough” concentration (C-0) just before the next dose. Accepted trough concentrations range from 100 to 300 µg/L. The highest concentrations are targeted during the induction phase of treatment for 2 to 3 months; subsequently lower maintenance concentrations are desirable. The trough concentration within the blood may not provide a truly accurate guide to total drug exposure because wide variation in absorption is seen over the first 2 to 4 hours following dosing. This is important in that most of the pharmacodynamic effects of cyclosporin occur within 2 hours.

BOX 35.2 Exclusion Criteria for Consideration for a Kidney Transplant

Serious concomitant illness (particularly if likely to shorten life expectancy or to be exacerbated by immunosuppressive treatment)
 Active malignancy
 Inoperable ischemic heart disease
 Severe chronic lung disease
 Active systemic infection (e.g., tuberculosis)
 Active immunologic disease
 Severe irreversible hepatic disease
 Severe peripheral vascular disease
 Severe obesity (body mass index >40 kg/m²)
 Lower urinary tract dysfunction not amenable to surgical repair
 Substance abuse
 Significant psychiatric disturbance

Fig. 35.8 Posttransplantation biochemical profile. *Open squares* represent the course of a patient who experienced an early rejection episode (confirmed by biopsy, 1) and requires initial hemodialysis support. *Solid squares* represent the typical profile of an uncomplicated transplant recipient. To convert creatinine concentration in µmol/L to mg/dL, multiply by 0.011.

Studies from Canada suggest that trough concentrations do not reflect clinical outcomes in terms of acute rejection rates, although high trough concentrations were associated with increased nephrotoxicity. Among kidney transplant patients, the trough level of tacrolimus is correlated with acute rejection episodes and nephrotoxicity. Trough concentrations also guide sirolimus therapy (see Chapter 30).

MMF is morpholinoethyl ester of mycophenolic acid (MPA), a potent and reversible inhibitor of inosine monophosphate dehydrogenase isoform 2 (IMPDH); it has become the single most used immunosuppressant in solid organ transplantation. Excellent results have been obtained with a fixed-dose regimen. IMPDH is a target for immunosuppression because lymphocytes depend on the de novo guanosine nucleotide synthesis pathway for DNA synthesis and cell division. MMF, because it is a prodrug of MPA, is rapidly absorbed following an oral dose and is deesterified to MPA, which is highly protein-bound. Free MPA concentrations

TABLE 35.5 Noninfectious Complications of Immunosuppressant Drugs

Drug	Drug Dose	Target Therapeutic Range ^a	Toxicity Profile
Corticosteroids—e.g., prednisone	Dose depends on weight of patient and time since transplant. Typically 40 mg daily during first week and tapering to 5 mg at 6 months and withdrawal at 12 months.	Not appropriate.	Increased risk of developing diabetes mellitus Deterioration in diabetes control Osteopenia Osteoporosis Psychosis Fat redistribution Hypertension Dyslipidemia Cataracts Weight gain
Calcineurin Inhibitors			
Cyclosporin	Variable; depends on weight, time since transplant, and achieved drug concentration. Given in two divided doses and predose trough concentration measured in morning blood sample.	200–300 µg/L for first 3–12 months. Thereafter, aim for 100 µg/L.	Nephrotoxicity Hypertension Neurotoxicity Hemolytic-uremic syndrome Tubular electrolyte abnormalities (hypophosphatemia, hypomagnesemia, hyperkalemia) Hirsutism Gingival hyperplasia Bone pains Dyslipidemia
Tacrolimus		Level depends on time since transplant. Typical early (less than 3 months) targets are 8–12 µg/L and thereafter 4–8 µg/L.	As for cyclosporin, except no hirsutism or gingival hyperplasia Increased risk of diabetes mellitus Cardiomyopathy (children) Alopecia
Mycophenolate mofetil	Initially 2 g daily in divided doses.	Not routinely measured.	Abdominal pain Diarrhea Myelosuppression
Sirolimus	Dose depends on weight and achieved drug concentration. The drug is administered once daily.	Level depends on time since transplant. Typical early (less than 3 months) targets are 8–12 µg/L and thereafter 4–8 µg/L.	Lymphocele (a fluid-filled collection near to transplanted kidney) Thrombocytopenia Hyperlipidemia
Azathioprine	Usual starting dose of 2 mg/kg body weight in a single daily dose.	Levels not measured. Because the enzyme thiopurine methyltransferase (TPMT) metabolizes azathioprine, the risk of myelosuppression is increased in patients with low activity of the enzyme. Enzyme activity may be determined prior to commencing treatment, and full blood counts are performed for several weeks following commencement of drug.	Myelosuppression Severe interaction if used with allopurinol (treatment for gout)
Selected Biological Agents			
AntiCD25 monoclonal antibodies: basiliximab and daclizumab	Given at time of transplant and once thereafter.		Very well tolerated
Polyclonal antithymocyte globulin (ATG) and antilymphocyte globulin (ALG), and monoclonal OKT3	Given in response to refractory rejection episodes in selected patients.		Increased risk of malignancy, posttransplant lymphoproliferative disease Hypersensitivity reactions

^aThese are not recommendations but are illustrative and will vary among centers.

determine the level of immunosuppressive activity, and this can be affected by hypoalbuminemia and renal insufficiency. Therapeutic drug monitoring of MPA is possible using high-performance liquid chromatography (HPLC) and immunoassay techniques. However, it has not been universally accepted in kidney transplantation programs because prospective studies have given conflicting information of its value.

In summary, long-term graft failure is a major problem, and graft loss accounts for the return of increasing numbers of patients to dialysis. The most common cause of graft loss is death with a functioning graft. Kidney failure carries a considerable burden of cardiovascular morbidity. Although some risk factors, such as volume overload and anemia, are improved following transplantation, others, including dyslipidemia and hypertension, persist. The drugs used to prevent rejection can exacerbate these. Challenges to the nephrology community are complex and include improving access to transplantation, reducing side effects of the powerful drugs used to prevent rejection, and reducing cardiovascular risk profiles for individual patients.

Simultaneous Pancreas-Kidney Transplantation

Patients with kidney failure and diabetes mellitus, predominantly type 1, but increasingly certain patients with type 2, and limited secondary complications of diabetes may be considered for simultaneous pancreas and kidney (SPK) transplantation. Patients tend to be younger than kidney-only

recipients (e.g., aged between 20 and 40 years). Patient survival now reaches over 95% at 1 year posttransplant and over 83% after 5 years.

The surgical technique for SPK involves whole-organ pancreas transplantation with the duodenal segment draining either into the urinary bladder through a duodenocystostomy or, more commonly today, enterically via an anastomosis between the graft duodenal segment and the recipient's small bowel. The kidney is attached as usual to the iliac vessels, and the donor ureter is inserted into the bladder separately. Postoperatively, blood glucose concentrations are monitored closely, and intravenous insulin is given as necessary. Exocrine pancreatic secretion can be measured in the urine for bladder-drained pancreas allografts. The major fear is rejection, and a number of parameters are monitored, including plasma glucose, amylase, lipase, and 12- or 24-hour urinary amylase (again for bladder-drained allografts). For patients with bladder drainage, enteric conversion may be required for refractory problems such as dehydration, metabolic acidosis, chronic urethritis, urinary tract infection, and recurrent reflux pancreatitis. Because of high fluid, bicarbonate, and electrolyte losses into the urine in these patients, the need for supplementation is increased in SPK recipients. There is a long-term need for high-dose oral sodium bicarbonate supplementation in bladder-drained pancreatic transplantation because of exocrine secretory losses. Hyperamylasemia is common postoperatively and may or may not signify allograft rejection.

REVIEW QUESTIONS

1. It is difficult to measure the GFR of a kidney directly; therefore which one of the following is assessed to determine GFR?
 - a. Renal blood flow
 - b. Renal threshold
 - c. Serum creatinine
 - d. Urine albumin
2. Which one of the following tests evaluates renal tubular (including loop of Henle) function?
 - a. Urine osmolality
 - b. Inulin clearance
 - c. Urine albumin
 - d. Urine protein
3. The structural and functional unit of the kidney is the nephron. What structures make up a nephron?
 - a. Only the structures located in the kidney cortex
 - b. The glomeruli, tubules, and associated blood vessels
 - c. The ureters, bladder, and urethra
 - d. Only the structures located in the kidney medulla
4. Pyelonephritis is
 - a. caused by a lack of intrinsic factor.
 - b. the destruction of kidney glomeruli by immune complexes.
 - c. a tumor of the stomach.
 - d. inflammation of both the lining of the renal pelvis and the parenchyma of the kidney, especially due to bacterial infection.
5. Which one of the following hormones synthesized in cells of the JGA is involved in control of blood pressure through its action on angiotensinogen?
 - a. Erythropoietin
 - b. Antidiuretic hormone
 - c. Renin
 - d. Aldosterone
6. Regarding laboratory findings, uremia/azotemia specifically refers to
 - a. reduced renal function.
 - b. elevated nitrogenous compounds in blood.
 - c. elevated serum proteins in blood.
 - d. decreased urine albumin.
7. The most common glomerular disease caused by damage to the glomerular membrane from the deposition of immune complexes is
 - a. IgA nephropathy.
 - b. chronic glomerulonephritis.
 - c. uremic syndrome.
 - d. pyelonephritis.
8. A disorder in which there is an abnormal increase in urine output, fluid intake, and often thirst and that is caused by the absence of antidiuretic hormone is
 - a. diabetes mellitus.
 - b. IgA nephropathy.
 - c. diabetes insipidus.
 - d. nephrolithiasis.

9. Which one of the following hormones affects water reabsorption in the proximal tubule, the loop of Henle, the distal tubule, and the collecting duct of the kidney?
 - a. Aldosterone
 - b. Renin
 - c. 1,25(OH)₂ vitamin D₃
 - d. Antidiuretic hormone
10. A drug prescribed to an individual to treat hypertension and/or disorders associated with fluid overload is referred to as
 - a. an ACE inhibitor.
 - b. a diuretic.
 - c. cystatin C.
 - d. an exogenous marker.

Physiology and Disorders of Water, Electrolyte, and Acid-Base Metabolism

Mark A. Cervinski, Christopher McCudden, Marc Berg, Mitchell G. Scott

OBJECTIVES

- Define the following:
 - Acid-base balance
 - Aldosterone
 - Anion gap
 - Antidiuretic hormone
 - Compensation
 - Depletional hyponatremia
 - Dilutional hyponatremia
 - Hyper- and hypovolemia
 - Interstitial fluid
 - Solute diuresis
- State the significance of and describe the total body water (TBW) distribution between compartments, including approximate volume and composition of each compartment, electrolyte distribution, and active/passive transport for ion exchange; list the hormonal regulators of water and sodium.
- For each of the following electrolytes, state and describe regulatory mechanisms, disorders, and causes/effects of these disorders:
 - Chloride
 - Potassium
 - Sodium
- State the Henderson-Hasselbalch equation, and explain each of its components; explain its relation to compensatory mechanisms in acid-base disturbances.
- Categorize the physiological buffer systems relative to their specific roles in the regulation of blood pH.
- Explain the specific respiratory and renal mechanisms important in the regulation of acid-base balance.
- For each of the acid-base imbalances listed below, list the causes and state the primary deficit, compensatory mechanisms, and laboratory values obtained with each:
 - Metabolic acidosis
 - Metabolic alkalosis
 - Respiratory acidosis
 - Respiratory alkalosis
- State the formula for and calculate the anion gap; discuss the clinical usefulness of anion gap, including eight causes of an increased anion gap and four causes of normal anion gap acidosis.
- Compare chloride responsive, chloride resistant, and exogenous base metabolic alkalosis, including causes and laboratory values.
- Assess and solve case studies related to electrolyte disturbances and acid-base balance disorders.

KEY WORDS AND DEFINITIONS

Acid-base balance The homeostatic maintenance of acids and bases within the body to achieve a physiological pH (approximately 7.40).

Acidemia An arterial blood pH less than 7.35.

Alkalemia An arterial blood pH greater than 7.45.

Anion gap (AG) The difference between the serum sodium concentration and the sum of the serum chloride and bicarbonate concentrations; the anion gap is high in some forms of metabolic acidosis.

Chronic obstructive pulmonary disease (COPD) Any disorder characterized by persistent or recurring obstruction of bronchial air flow, such as chronic bronchitis, asthma, or pulmonary emphysema.

Compensated acidosis A state of acidosis in which the pH of the blood has been returned toward normal by compensatory mechanisms.

Depletional hyponatremia A condition characterized by low plasma concentration of sodium associated with low total body sodium and normal blood volume; also called euvoletic hyponatremia.

Diabetes insipidus A condition associated with increased thirst, polyuria, and large volume of dilute urine, exceeding 3 L/day, and causing dehydration.

Dilutional hyponatremia A condition characterized by low plasma concentration of sodium resulting from loss of sodium from the body with nonosmotic retention of water.

Extracellular fluid (ECF) A general term for all the body fluids outside the cells, including the interstitial fluid, plasma, lymph, and cerebrospinal fluid (CSF).

Henderson-Hasselbalch equation An equation that defines the relationship between pH, bicarbonate, and the partial pressure of dissolved carbon dioxide gas.

Hyperkalemia A concentration of serum potassium above 5.0 mmol/L.

Hypernatremia A concentration of serum sodium above 150 mmol/L.

Hypervolemia Abnormal increase in the volume of circulating fluid (plasma) in the body.

Hypokalemia A concentration of serum potassium below 3.5 mmol/L.

Hyponatremia A concentration of serum sodium below 136 mmol/L.

Hypovolemia Abnormally decreased volume of circulating fluid (plasma) in the body.

Intracellular fluid (ICF) The portion of the total body water (TBW) with its dissolved solutes that is within the cell membranes.

Ketoacidosis A condition characterized as acidosis accompanied by the accumulation of ketone bodies (ketosis) in the body tissues and fluids.

Metabolic acidosis A pathological process that leads to the accumulation of acid that lowers the bicarbonate concentration and decreases pH.

Metabolic alkalosis A pathological process that leads to the accumulation of base that raises the bicarbonate concentration and increases pH.

Respiratory acidosis A pathological process that leads to the accumulation of carbon dioxide that raises the PCO_2 and decreases pH; usually caused by emphysema or hypoventilation.

Respiratory alkalosis A pathological process that leads to the excessive elimination of carbon dioxide, which lowers the PCO_2 and increases the pH; caused by hyperventilation.

Sodium–hydrogen exchanger (Na^+ – H^+ exchanger) A membrane protein that is primarily responsible for maintaining the balance of sodium; also called the sodium–hydrogen antiporter.

Total body water (TBW) Any of various estimates of the water content of the human body, taking into consideration the person's height, weight, and age.

The human body is in a dynamic state of flux as fluids and electrolytes are constantly being gained and lost. Homeostasis within a narrow window is necessary for life, and the body must defend against excessive gains or losses. These homeostatic systems require the interaction of multiple organ systems and a variety of chemical buffers and highly specialized mechanisms of the lungs and kidneys work together to regulate water, electrolytes, and pH between and within intracellular and extracellular compartments. Perturbations in the dynamic equilibria of water, electrolytes, and pH may arise from external (e.g., trauma, changes in altitude, ingestion of toxic substances) or internal (e.g., normal metabolism, disease state) sources.

Water accounts for 60% of body weight in adolescents and adult males and $\approx 55\%$ for adult females. As depicted in Fig. 36.1, approximately two-thirds of **total body water (TBW)** is distributed into the **intracellular fluid (ICF)** compartment, and one-third exists in the **extracellular fluid (ECF)** compartment. The ECF may be further subdivided by the capillary endothelium into interstitial ($\approx 75\%$ of ECF) and intravascular ($\approx 25\%$ of ECF) compartments. The average adult has ≈ 5 L of blood volume (intravascular compartment) and a plasma volume of ≈ 3.0 L when the hematocrit is 40%. Although fluid from other clinically relevant ECF compartments (e.g., cerebrospinal fluid [CSF], urine) are analyzed in the clinical laboratory, most laboratory tests used to determine hydration status and electrolyte and acid-base status are performed on samples from the *intravascular* compartment.

The minimum daily requirement for water can be estimated from renal (1200 to 1500 mL in urine) and “insensible” losses (≈ 400 to 700 mL due to evaporation from the skin and respiratory tract). Activity, environmental conditions, and disease all have dramatic effects on daily water (and electrolyte) requirements. On average, an adult must take in ≈ 1.5 to

2.0 L of water daily to maintain fluid balance. Table 36.1 lists common causes and clinical manifestations of expansion and contraction of the ECF compartment.

WATER AND ELECTROLYTES—COMPOSITION OF BODY FLUIDS

The primary cationic (positively charged) electrolytes are sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), and magnesium (Mg^{2+}), whereas the anions (negatively charged) include chloride (Cl^-), bicarbonate (HCO_3^-), phosphate (HPO_4^{2-} , $H_2PO_4^-$), sulfate (SO_4^{2-}), organic ions such as lactate, and negatively charged proteins. Electrolyte concentrations of the body fluid compartments are shown in Table 36.2. Plasma or serum Na^+ , K^+ , Cl^- , and HCO_3^- concentrations, commonly analyzed in an *electrolyte profile*, provide the most relevant information about the osmotic, hydration, and acid-base status of the body. Although hydrogen (H^+) is a cation, its concentration is approximately 1 million-fold lower in plasma than the major electrolytes listed in Table 36.2 (10^{-9} mol/L vs. 10^{-3} mol/L) and is negligible in terms of osmotic activity.

In order to maintain electroneutrality, any increase in the concentration of one anion is accompanied by a corresponding decrease in other anions, by an increase in one or more cations or a combination of both. The converse is true for any decrease in anion concentration. In the case of polyvalent ions (e.g., Ca^{2+} , Mg^{2+}), it is important to distinguish between the substance concentration of the ion itself and the concentration of the ion charge. Thus, although the concentration of total calcium ions in normal plasma is ≈ 2.5 mmol/L, the concentration of the total calcium ion *charge* is 5.0 mmol/L (also called 5 milliequivalents per liter [mEq/L]).

Fig. 36.1 Volume and distribution of total body water (TBW). The intracellular and extracellular fluid compartments (ICF and ECF, respectively) are separated by cellular plasma membranes, and within the ECF, interstitial and intravascular fluids are separated by the capillary endothelium (blue cells). The volumes indicated represent water and not total volume. Endothelial cells, *blue*; interstitial cell, *gray*; collagen matrix fibers, *black cables*.

TABLE 36.1 Causes and Clinical Manifestations of Changes in Extracellular Fluid Volume

	Clinical Manifestations	Causes
ECF loss	Thirst, anorexia, nausea, light-headedness, orthostatic hypotension, syncope, tachycardia, oliguria, decreased skin turgor and “sunken eyes,” shock, coma, death	Trauma (and other causes of acute blood loss), “third-spacing” of fluid (e.g., burns, pancreatitis, peritonitis), vomiting, diarrhea, diuretics, renal or adrenal (i.e., sodium wasting) disease
ECF gain	Weight gain, edema, dyspnea (secondary to pulmonary edema), tachycardia, jugular venous distention, portal hypertension (ascites), esophageal varices	Heart failure, cirrhosis, nephrotic syndrome, iatrogenic (intravenous fluid overload)

ECF, Extracellular fluid.

TABLE 36.2 Electrolyte and Water Composition of Body Fluid Compartments

Component	Plasma	Interstitial Fluid	Intracellular Fluid ^a
Volume, H ₂ O (TBW = 42 L)	3.5 L	10.5 L	28 L
Na ⁺	140	145	12
K ⁺	4	4	156
Ca ²⁺	2.4	2–3	0.3
Mg ²⁺	1	0.5–1	13
Trace elements	1	—	—
Cl [−]	103	114	4
HCO ₃ [−]	27	31	12
Protein [−]	16	—	55
Organic acids [−]	5	—	—
HPO ₄ ^{2−}	1	—	—
SO ₄ ^{2−}	0.5	—	—

^aThese values are derived from skeletal muscle.

All electrolyte values are expressed in millimoles per liter of *fluid*. Because the H₂O content of plasma is ≈93% by volume, the corresponding electrolyte concentrations in plasma water are ≈10% higher.

TBW, Total body water.

EXTRACELLULAR AND INTRACELLULAR COMPARTMENTS

Plasma

Plasma generally has a volume of 1300 to 1800 mL/m² of body surface and constitutes approximately 5% of the body volume (≈3.5 L for a 66 kg subject). Total body volume is derived from body mass by using an estimated body density of 1.06 kg/L. [Table 36.2](#) describes the electrolyte composition of plasma. The mass concentration of water in normal

plasma is approximately 0.933 kg/L, depending on the protein and lipid content (see “Electrolyte Exclusion Effect” in [Chapter 24](#)).

Interstitial Fluid

Interstitial fluid is essentially an ultrafiltrate of blood plasma. When all extracellular spaces except plasma are included, the volume accounts for about 26% (10.5 L) of the total body

volume (see Fig. 36.1). Plasma is separated from the interstitial fluid by capillary endothelial lining, which acts as a semipermeable membrane and allows the passage of water and diffusible solutes but not compounds of high molecular mass such as proteins. The “impermeability” to proteins is not absolute, and in some pathologic conditions causing “shock,” such as bacterial sepsis, the permeability of the vascular endothelium increases dramatically, resulting in leakage of albumin, a reduction in the effective circulating volume, and hypotension.

Intracellular Fluid

The exact composition of ICF is difficult to measure and varies by tissue type. Data for ICF (see Table 36.2), therefore, are considered only approximations. The ICF constitutes $\approx 66\%$ of the total body volume (see Fig. 36.1).

Distribution of Ions by Active and Passive Transport

The electrolyte compositions of blood plasma and interstitial fluid are similar (both are ECFs) and differ markedly from that of ICF (see Table 36.2). The major ECF ions are Na^+ , Cl^- , and HCO_3^- , but in ICF, the main ions are K^+ , Mg^{2+} , organic phosphates, and protein. These unequal distributions of ions are the consequence of active and passive transport of ions and larger molecules. The difference in Na^+ concentration, for instance, is due to active transport of Na^+ from inside to outside the cell against its electrochemical gradient. This gradient is maintained predominantly by an active sodium pump deriving its energy from glycolysis generated adenosine triphosphate (ATP). A Na^+/K^+ -ATPase frequently couples the active transport of Na^+ out of the ICF with transport of K^+ into the cell against the K^+ concentration gradient.

ELECTROLYTES

Disorders of Na^+ , K^+ , Cl^- , and HCO_3^- will now be separately considered, even though disorders of electrolyte and water homeostasis need a systematic evaluation rather than an individual review of each ion.

SODIUM

Disorders of Na^+ homeostasis can occur because of excessive loss, gain, or retention of Na^+ , or that of H_2O . It is difficult to separate disorders of Na^+ and H_2O balance because of their close relationship in establishing normal osmolality in all body water compartments. As described in detail in Chapter 35, the primary organ for regulating body water and extracellular Na^+ is the kidney.

The kidney is responsible for clearing uremic toxins from the circulation as well as for maintaining electrolyte homeostasis across a wide range of gains and losses. In the proximal tubules, 70% to 80% of filtered Na^+ is actively reabsorbed, with H_2O and Cl^- following passively to maintain electrical neutrality and osmotic equivalence. In the descending loop of Henle, H_2O , but not electrolytes, is passively reabsorbed

because of the high osmotic strength of interstitial fluid in the renal medulla. In the ascending loop of Henle, Cl^- is reabsorbed actively, with Na^+ following. At the distal tubule, the first of the two primary $\text{Na}^+/\text{H}_2\text{O}$ regulating processes occurs. Here, aldosterone stimulates the cortical collecting ducts to reabsorb Na^+ (with water following passively) and secrete K^+ (and to a lesser extent, H^+) to maintain electrical neutrality. Aldosterone is produced by the adrenal cortex in response to angiotensin II derived via the action of renin. The secretion of renin by renal juxtaglomerular cells is stimulated by low Cl^- , by β -adrenergic activity, and by low arteriolar pressure. Thus, when the kidneys are hypoperfused (as occurs when blood volume decreases, or when the renal arteries are obstructed), the distal tubules, under the influence of aldosterone, reclaim Na^+ .

Further water regulation in the kidney occurs from the distal tubule through the collecting duct, where tubular permeability to H_2O is under the influence of antidiuretic hormone (ADH), also known as vasopressin (see Chapters 35 and 40). ADH is released by the posterior pituitary under the influence of baroreceptors in the aortic arch and of hypothalamic chemoreceptors that are responsive to circulating osmolality, which is primarily a reflection of Na^+ concentration. When ECF volume is decreased, or when plasma osmolality is increased, ADH is secreted, tubular permeability to H_2O increases via aquaporins, and H_2O is reabsorbed in an attempt to restore blood volume or to decrease osmolality. In contrast, when ECF volume is increased or osmolality decreased, ADH secretion is inhibited, and more H_2O is excreted in urine (diuresis).

The body's only nonrenal mechanism for restoring $\text{Na}^+/\text{H}_2\text{O}$ homeostasis is ingestion of H_2O . Thirst is stimulated by decreased blood volume or hyperosmolality. It is important to remember that baroreceptors that influence renal handling of Na^+ and H_2O , and thirst, sense changes only in the intravascular blood volume and not the total ECF, while osmoreceptors in the brain sense the osmolality of the ECF surrounding the cells. Laboratory assessment of water and electrolyte disorders is made primarily from the blood volume (plasma); the clinician must assess the status of TBW and blood volume before interpreting laboratory values (see Table 36.1).

Hyponatremia

Hyponatremia is defined as a decreased plasma Na^+ concentration (defined as <130 to 135 mmol/L). Hyponatremia manifests clinically as nausea, generalized weakness, and mental confusion at values less than 120 mmol/L, and severe mental confusion plus convulsions at less than 105 mmol/L. The Na^+ concentration at which symptoms develop depends on how quickly hyponatremia develops, and symptoms may manifest at higher Na^+ concentrations (≈ 125 mmol/L) when hyponatremia develops rapidly. Central nervous system (CNS) symptoms are due to the movement of H_2O into cells to maintain osmotic balance and subsequent swelling of CNS cells. These symptoms can occur more rapidly in children, so there is a need to be particularly vigilant in the pediatric population.

Fig. 36.2 Algorithm for the differential diagnosis of hyponatremia. *GI*, Gastrointestinal; *RTA*, renal tubular acidosis; *SIADH*, syndrome of inappropriate secretion of antidiuretic hormone. (Modified from Kirkpatrick, W., & Kreisberg, R. [1986]. Acid-base and electrolyte disorders. In P. Liu [Ed.], *Blue book of diagnostic tests* [pp. 239–254]. Philadelphia: WB Saunders.)

Hyponatremia can be hypo-osmotic, hyperosmotic, or iso-osmotic. Thus measurement of plasma osmolality is an important initial step in the assessment of hyponatremia. Of these, the most common form is hypo-osmotic hyponatremia due to the large role that Na^+ plays in maintaining osmolality. Fig. 36.2 describes an algorithm for laboratory measurements and physical examination findings in the differential diagnosis of plasma Na^+ less than 135 mmol/L.

Hypoosmotic Hyponatremia

Typically when plasma Na^+ concentration is low, calculated or measured osmolality will also be low. This type of hyponatremia can be due to excess loss of Na^+ (**depletional hyponatremia**) or increased ECF volume (**dilutional hyponatremia**). Differentiating these initially requires clinical assessment of TBW and ECF volume by history and physical examination.

Depletional hyponatremia results from a loss of Na^+ from the ECF space that exceeds the concomitant loss of water. The net loss of Na^+ from the ECF space stimulates thirst and production of ADH, both of which contribute to the maintenance of hyponatremia. **Hypovolemia** is apparent in the physical examination (orthostatic hypotension, tachycardia, decreased skin turgor). If urine Na^+ is low (<10 mmol/L), the kidneys are properly retaining filtered Na^+ and the loss is extrarenal, most commonly from the gastrointestinal (GI) tract or skin (see Fig. 36.2). Preventing ongoing loss and restoring ECF volume with isotonic fluid is sufficient to correct hyponatremia in these situations. Alternatively, if urine Na^+ is increased in this setting (generally >20 mmol/L), renal loss of Na^+ is likely. Renal loss of Na^+ occurs with (1) osmotic diuresis, (2) use of diuretics (which inhibit reabsorption of Cl^- and Na^+ in the ascending loop), (3) adrenal insufficiency (lack of aldosterone or cortisol prevents distal tubule reabsorption of Na^+), or

(4) salt wasting nephropathies, as can occur with interstitial nephritis and tubular recovery after acute tubular necrosis or obstructive nephropathy. Renal loss of Na^+ in excess of H_2O can also occur in metabolic alkalosis from prolonged vomiting, because increased renal HCO_3^- excretion is accompanied by Na^+ ions. In this case, urine sodium is increased (>20 mmol/L), but urine chloride remains low. In proximal renal tubular acidosis (RTA) type 2, bicarbonate is lost because of a defect in HCO_3^- reabsorption and is accompanied by Na^+ to maintain electrical neutrality. As with extrarenal Na^+ loss, management of hyponatremia attributable to renal Na^+ loss is centered on reversing the underlying cause and restoration of ECF volume.

Dilutional hyponatremia is a result of excess H_2O retention and often can be detected during the physical examination as edema. In advanced renal failure, water is retained because of decreased filtration and H_2O excretion. When ECF is increased but the circulating blood volume is decreased, as occurs in hepatic cirrhosis or nephrotic syndrome, a vicious cycle is established. The decreased blood volume is sensed by baroreceptors and results in increased aldosterone and ADH, even though ECF volume is excessive. The kidneys reabsorb Na^+ and H_2O in response to increased aldosterone and ADH to restore the blood volume, resulting in further increases in ECF and further dilution of Na^+ .

In hypoosmotic hyponatremia with a normal or euvolemic volume status, the most common causes are syndrome of inappropriate ADH (SIADH), primary polydipsia, and endocrine disorders such as secondary adrenal insufficiency and severe hypothyroidism (see Fig. 36.2). SIADH describes hyponatremia attributable to “inappropriate” ADH release, which stimulates excessive H_2O retention and increased urine osmolality. In secondary adrenal insufficiency, due to lack of adrenocorticotrophic hormone (ACTH), glucocorticoid secretion is impaired. In the absence of cortisol and ACTH, increased corticotropin-releasing hormone (CRH) secretion stimulates ADH release and causes hyponatremia. Severe hypothyroidism impairs free H_2O excretion due to reduced cardiac output and glomerular filtration rate (GFR) in myxedema. Finally, euvolemic hyponatremia can also be found in primary polydipsia when water intake is greater than the renal capacity to excrete excess H_2O .

Hyperosmotic Hyponatremia

Hyponatremia in the presence of increased quantities of other solutes in the ECF is the result of an extracellular shift of water or an intracellular shift of Na^+ to maintain osmotic balance between ECF and ICF compartments. The most common cause of this type of hyponatremia is severe hyperglycemia but may also occur in the setting of mannitol diuresis (see Fig. 36.2). As a rule, Na^+ is decreased by ≈ 1.6 to 2.0 mmol/L for every 100 mg/dL (5.6 mmol/L) increase in glucose above 100 mg/dL (5.6 mmol/L).

Isosmotic Hyponatremia

If the measured Na^+ concentration in plasma is decreased, but measured plasma osmolality, glucose, and urea are

normal, the most likely explanation is pseudohyponatremia caused by the *electrolyte exclusion effect* (see Chapter 24). This occurs when Na^+ is measured by an indirect ion-selective electrode in patients with severe hyperlipidemia or hyperproteinemia.

Hypernatremia

Hypernatremia (plasma $\text{Na}^+ >150$ mmol/L) is always hyperosmolar. Symptoms of hypernatremia are primarily neurologic (because of neuronal cell loss of H_2O to the ECF) and include tremors, irritability, ataxia, confusion, and coma. As with hyponatremia, the speed at which hypernatremia develops determines the plasma Na^+ concentration at which symptoms occur. Acute development may cause symptoms at 160 mmol/L, whereas in chronic hypernatremia, symptoms may not occur until Na^+ exceeds 175 mmol/L.

In many cases, the symptoms of hypernatremia may be masked by underlying conditions. Hypernatremia rarely occurs in an alert patient with a normal thirst response and access to water. Most cases are observed in patients with altered mental status or infants, both of whom may not be capable of rehydrating themselves.

Hypernatremia arises in the setting of (1) hypovolemia (excessive water loss or failure to replace normal water losses), (2) **hypervolemia** (a net Na^+ gain in excess of water gain), or (3) normovolemia. Again, assessment of TBW status by physical examination and measurement of urine Na^+ and osmolality are important steps in establishing a diagnosis (Fig. 36.3).

Hypovolemic Hypernatremia

Hypernatremia in the setting of decreased ECF is caused by renal or extrarenal loss of hypo-osmotic fluid, leading to dehydration. Once hypovolemia is established by physical examination, measurement of urine Na^+ and osmolality is used to determine the source of fluid loss. Patients with large extrarenal fluid losses will have concentrated urine (often >800 mOsmol/L) with low urine Na^+ (<20 mmol/L), reflecting a proper renal response to conserve Na^+ and water to restore ECF volume. Extrarenal causes include diarrhea, skin losses (burns, fever, or excessive sweating), and respiratory losses coupled with failure to replace the water. When extrarenal loss is excluded, and the patient has normal mental status and access to H_2O , a hypothalamic disorder (tumor or granuloma) inducing **diabetes insipidus** (DI) should be suspected. An additional consideration in the setting of poorly controlled diabetes mellitus is osmotic diuresis due to plasma glucose values greater than 600 mg/dL (33.3 mmol/L). This condition, referred to as hyperosmolar hyperglycemic nonketotic syndrome, occurs most commonly in elderly subjects with type 2 diabetes mellitus.

Normovolemic Hypernatremia

Hypernatremia in the presence of normal ECF volume typically arises due to insensible losses through the lungs or skin and is often characterized by concentrated urine as the kidneys conserve water. Normovolemic hypernatremia arising from insensible losses is frequently a prelude to hypovolemic

Fig. 36.3 Algorithm for the differential diagnosis of hypernatremia. (Modified from Kirkpatrick, W., & Kreisberg, R. [1986]. Acid-base and electrolyte disorders. In P. Liu [Ed.], *Blue Book of Diagnostic Tests* [pp. 239–254]. Philadelphia: WB Saunders.)

hypernatremia. Water or solute diuresis resulting in polyuria (generally defined as >3 L urine output/day) may also result in normovolemic hypernatremia (see Fig. 36.3). Solute diuresis is exemplified by the osmotic diuresis of diabetes mellitus and generally is characterized by urine osmolality greater than 300 mOsm/L and hyponatremia (see previous discussion in this chapter). Water diuresis, a manifestation of DI, is characterized by dilute urine (osmolality <250 mOsm/L) and hypernatremia. DI can be central or nephrogenic. Central DI is due to decreased or absent ADH secretion resulting from head trauma, hypophysectomy, pituitary tumor, or granulomatous disease. Nephrogenic DI is due to renal resistance to ADH as a result of drugs (e.g., lithium, demeclocycline, amphotericin); electrolyte disorders (e.g., hypercalcemia, hypokalemia); sickle cell anemia; or Sjögren syndrome. When thirst and access to water are uncompromised, many patients with DI will remain normonatremic since their free water losses are offset by intake. Such patients only display symptoms of polyuria and polydipsia. However, overt hypernatremia can develop with progression of underlying causes, impaired thirst, or restricted access to water. Administration of ADH (in the form of desmopressin) can be used to treat central DI, although patients with nephrogenic DI may be resistant to it.

Hypervolemic Hypernatremia

The presence of excess TBW and hypernatremia indicates a net gain of water and Na^+ , with Na^+ gain in excess of water (see Fig. 36.3). This rare condition is observed most commonly in

hospitalized patients receiving hypertonic saline or sodium bicarbonate.

POTASSIUM

The major intracellular cation is K^+ , and only about 2% of total body K^+ is present in the ECF. Nevertheless, plasma K^+ is often a good indicator of total K^+ stores unless the K^+ concentration is abnormal due to cellular shifts. Disturbance of K^+ homeostasis has serious consequences. For example, a decrease in extracellular K^+ (hypokalemia) is characterized by muscle weakness, irritability, and paralysis. Plasma K^+ concentrations less than 3.0 mmol/L are often associated with neuromuscular symptoms and indicate a critical degree of intracellular depletion. At lower concentrations, tachycardia and cardiac conduction defects develop and can lead to cardiac arrest.

High extracellular K^+ (**hyperkalemia**) concentrations may produce symptoms of mental confusion, weakness, tingling, flaccid paralysis of the extremities, weakness of the respiratory muscles, bradycardia, and cardiac conduction defects. Prolonged, severe hyperkalemia greater than 7.0 mmol/L can lead to peripheral vascular collapse and cardiac arrest. Symptoms or electrocardiogram (EKG) abnormalities are usually present at K^+ concentrations greater than 6.5 mmol/L. Potassium concentrations greater than 10.0 mmol/L in most cases are fatal, though fatalities can occur at significantly lower values.

Fig. 36.4 Algorithm for the differential diagnosis of hypokalemia. *GI*, Gastrointestinal; *NG*, nasogastric; *WBC*, white blood cell. (Modified from Kirkpatrick, W., & Kreisberg, R. [1986]. *Acid-base and electrolyte disorders*. In P. Liu [Ed.], *Blue Book of Diagnostic Tests* [pp. 239–254]. Philadelphia: WB Saunders.)

Hypokalemia

Causes of **hypokalemia** (plasma K^+ <3.5 mmol/L) are classified as redistribution of extracellular K^+ into ICF, or true K^+ deficits, caused by decreased intake or loss of potassium-rich body fluids (Fig. 36.4).

Redistribution

Intracellular redistribution of K^+ is illustrated by the fall in plasma K^+ following insulin therapy for diabetic hyperglycemia. Insulin plays a crucial role in maintaining the intracellular distribution of K^+ through active cellular transport as well as glucose control. Redistribution hypokalemia is also a feature of alkalosis, in which K^+ moves from ECF into cells in exchange for H^+ efflux and renal conservation of H^+ at the expense of urinary K^+ loss. Other causes of intracellular redistribution are listed in Fig. 36.4. Clinically, redistributive hypokalemia is generally a transient phenomenon that is reversed once underlying conditions are corrected. Hypokalemia is highly prevalent in cancer patients but must be differentiated

from pseudohypokalemia. Pseudohypokalemia can occur in settings of very high white blood cell or platelet counts. In some patients in leukemic blast crisis there can be a time-dependent transport of K^+ into the leukemic cells after the blood sample is drawn. In these settings, it is important to process the samples as quickly as possible.

True Potassium Deficit

Hypokalemia reflecting true total body deficits of K^+ can be classified into renal and nonrenal losses (see Fig. 36.4). If urine excretion of K^+ is less than 30 mmol/day, it can be concluded that the kidneys are properly functioning and are reabsorbing K^+ . The cause may be decreased K^+ intake or extrarenal loss of K^+ -rich fluid. Causes of decreased intake include chronic starvation and postoperative intravenous fluid therapy with K^+ -poor solutions. GI loss of K^+ occurs most commonly with diarrhea and loss of gastric fluid through vomiting.

Urine excretion exceeding 30 mmol/day in a hypokalemic setting is inappropriate and indicates that the kidneys are

Fig. 36.5 Algorithm for the differential diagnosis of hyperkalemia. ACE, Angiotensin-converting enzyme. (Modified from Kirkpatrick, W., & Kreisberg, R. [1986]. Acid-base and electrolyte disorders. In P. Liu [Ed.], *Blue Book of Diagnostic Tests* [pp. 239–254]. Philadelphia: WB Saunders.)

the primary source of K^+ loss. Renal losses of K^+ may occur during the diuretic (recovery) phase of acute tubular necrosis and during states of excess mineralocorticoid (primary or secondary aldosteronism) or glucocorticoid (Cushing syndrome) when the distal tubules increase Na^+ reabsorption and K^+ excretion. Renal loss of K^+ is also caused by thiazide and loop diuretics. In addition to the redistribution of K^+ into cells in an alkalotic setting, K^+ can be lost from the kidneys in exchange for reclaimed H^+ ions. This cause of true hypokalemia is associated with low urine Cl^- and alkaline urine. True potassium deficit requires replacement of potassium. Although there are dietary sources of potassium, such as potatoes and tomatoes, significant K^+ losses may require oral or intravenous supplementation with potassium chloride.

Hyperkalemia

Hyperkalemia (plasma $K^+ > 5.0$ mmol/L) is a result of (singly or in combination) (1) redistribution, (2) increased intake, or (3) increased retention. In addition, preanalytical conditions—such as hemolysis, thrombocytosis ($>106/\mu L$), and leukocytosis ($>105/\mu L$ together with delayed sample analysis)—have been known to cause marked pseudohyperkalemia, as described in detail in [Chapter 24](#).

Redistribution

The transfer of intracellular K^+ into ECF invariably occurs in acidemia as K^+ shifts outward as the result of pH-induced changes in Na^+/K^+ -ATPase activity. When acidemia is corrected,

normokalemia will be restored rapidly. Extracellular redistribution of K^+ may also occur in (1) tissue hypoxia; (2) insulin deficiency (e.g., diabetic ketoacidosis); (3) massive intravascular hemolysis; (4) severe burns; (5) intense and sustained muscular activity, as in status epilepticus; (6) rhabdomyolysis; (7) tumor lysis syndrome, as well as (8) iatrogenic causes. Redistributive hyperkalemia can be corrected by reversing the aberrations that cause K^+ to shift out of cells. Insulin and sodium bicarbonate are commonly used and have a quick onset of action, particularly in the diabetic or acidemic setting.

Potassium Retention

When glomerular filtration or renal tubular function is decreased, hyperkalemia will often occur. In the absence of severe renal failure, hyperkalemia may not develop, and if it does it is seldom prolonged. Decreased excretion of K^+ in moderate and acute renal disease and end-stage renal failure (with oliguria or anuria) are the most common causes of prolonged hyperkalemia ([Fig. 36.5](#)). Hyperkalemia occurs along with Na^+ depletion in adrenocortical insufficiency (e.g., Addison disease) because diminished Na^+ reabsorption results in decreased tubular K^+ secretion. Drugs that block the production of aldosterone, such as inhibitors of angiotensin-converting enzyme (ACE inhibitors; e.g., lisinopril), nonsteroidal anti-inflammatory drugs, and angiotensin II receptor blockers, may also cause hyperkalemia. Excess administration of potassium-sparing diuretics that block distal tubular K^+ secretion (e.g., triamterene, spironolactone) may also cause hyperkalemia.

CHLORIDE

In the absence of acid-base disturbances, Cl^- concentrations in plasma generally will follow those of Na^+ . However, determination of plasma Cl^- concentration is useful in the differential diagnosis of acid-base disturbances and is essential for calculating the anion gap. Fluctuations in serum or plasma Cl^- have little clinical consequence but do serve as signs of an underlying disturbance in fluid or acid-base homeostasis. The specific replacement of chloride is rarely targeted at chloride deficit independently, but it is a corner stone of management for metabolic alkalosis.

Hypochloremia

In general, causes of hypochloremia parallel causes of hyponatremia. Persistent gastric secretion and prolonged vomiting result in significant loss of Cl^- and ultimately in hypochloremic alkalosis and depletion of total body Cl^- with retention of HCO_3^- by the nephron to reabsorb the filtered Na^+ load. **Respiratory acidosis**, which is accompanied by increased HCO_3^- , is another common cause of decreased Cl^- with normal Na^+ .

Hyperchloremia

Increased plasma Cl^- concentration, similar to increased Na^+ concentration, occurs with dehydration, prolonged diarrhea with loss of sodium bicarbonate, DI, and overtreatment with normal saline solutions, which have a Cl^- content of 150 mmol/L. A rise in Cl^- concentration may also be seen in **respiratory alkalosis** because of renal compensation for excreting HCO_3^- .

Points to Remember

- Physical examination is important in assessing total body water status and hyponatremic or hypernatremic disorders.
- Urine electrolytes are important to determine if the kidneys are functioning properly in disorders of electrolyte and water balance.
- Patient history can be important in assessing electrolyte disorders. Examples include vomiting, diarrhea, water deprivation, excess perspiration, anuria, diabetes, and so on.

ACID-BASE PHYSIOLOGY

Normal metabolic processes result in the production of large amounts of metabolic acids. These products of metabolism are transported to the lungs and kidneys via the ECF and blood with no appreciable change in the ECF pH, and with only a minimal difference between arterial (pH 7.35 to 7.45) and venous (pH 7.32 to 7.42) blood. This is accomplished by the buffering capacity of blood and by respiratory and renal regulatory mechanisms.

ACID-BASE BALANCE AND ACID-BASE STATUS

Interpretation of the **acid-base balance** in physiology involves an accounting of the carbonic (H_2CO_3 , HCO_3^- , CO_3^{2-} , and

CO_2) and noncarbonic acids and conjugate bases in terms of input (intake plus metabolic production) and output (excretion plus metabolic conversion) over a given time interval. For example, during a 24-hour period, a 70 kg person exhales approximately 20 moles of CO_2 (volatile form of carbonic acid) through the lungs, and excretes about 70 to 100 mmol (or ≈ 1 mmol/kg) of nonvolatile acids (mainly sulfuric and phosphoric acids) through the kidneys.

Acid-Base Parameters—Definitions and Abbreviations

Acids are chemical substances that can donate protons (H^+ ions) in solution, and *bases* are substances that accept protons. Strong acids readily give up H^+ , whereas strong bases readily accept H^+ . Thus the conjugate base of a strong acid is a weak base and vice versa.

Acidemia is defined as an arterial blood pH less than 7.35, and **alkalemia** indicates an arterial blood pH greater than 7.45. *Acidosis* and *alkalosis* refer to pathologic states that often lead to acidemia or alkalemia.

pH and pK

The pH of a solution is defined as the negative logarithm of the hydrogen ion activity ($\text{pH} = -\log a\text{H}^+$). A decrease in 1 pH unit represents a 10-fold increase in H^+ activity. pH is measured using potentiometry (see [Chapter 24](#)) and is an assessment of H^+ ion activity. In the setting of pH assessment, an assumption is made that H^+ activity is equivalent to concentration. The H^+ concentration of blood is thus equal to 40 nmol/L at pH 7.4.

The pK (also known as pK' and pKa) is the pH at which an acid is half-dissociated, existing as equal proportions of acid and conjugate base. Acids have pK values less than 7.0, whereas bases have pK values greater than 7.0. The lower the pK, the stronger the acid, and the higher the pK, the stronger the conjugate base.

The pH of plasma is the function of two independent variables:

1. PCO_2 , which is regulated by the lungs and represents the acid component of the carbonic acid/bicarbonate buffer system
2. The concentration of titratable base (base excess or deficit, which is defined later), which is regulated by the kidneys

Bicarbonate and Dissolved Carbon Dioxide

Bicarbonate is the second largest fraction (behind Cl^-) of plasma anions. Conventionally, it is defined to include (1) plasma bicarbonate ion (HCO_3^-), (2) carbonate ion (CO_3^{2-}), and (3) CO_2 bound in plasma carbamino compounds (R-C-NH-COOH). Actual bicarbonate ion concentration is not measured in clinical laboratories. The analyte usually measured in plasma is total CO_2 , which includes bicarbonate and dissolved CO_2 (dCO_2) but is often referred to as “serum bicarb”.

Henderson-Hasselbalch Equation

The **Henderson-Hasselbalch equation** is described in detail in [Chapter 24](#). However, it is important to review here because it enhances understanding of pH regulation of body fluids as it

Fig. 36.6 Scheme demonstrating the relation between pH and the ratio of bicarbonate concentration to the concentration of dissolved CO₂. If the ratio in blood is 20:1 ($c\text{HCO}_3^- = 27 \text{ mmol/L}$, $cd\text{CO}_2 = 1.35 \text{ mmol/L}$), the resultant pH will be 7.4, as demonstrated by the solid beam. The dotted line shows a case of uncompensated alkalosis (bicarbonate excess) with a bicarbonate concentration of 44 mmol/L and a $cd\text{CO}_2$ of 1.1 mmol/L. The ratio therefore is 40:1, and the resultant pH is 7.7. In a case of uncompensated acidosis, the pointer of the balance would point to a pH between 6.8 and 7.35, depending on the $c\text{HCO}_3^-/cd\text{CO}_2$ ratio. (From Weisberg, H. F. [1959]. A better understanding of anion-cation ["acid-base"] balance. *Surgical Clinics of North America*, 39, 93–120.)

relates to compensatory mechanisms in acid-base disturbances. The equation described in Chapter 24 can be written as follows:

$$\text{pH} = 6.1 + \log \frac{c\text{HCO}_3^-}{cd\text{CO}_2},$$

where $cd\text{CO}_2$ is equal to α (0.0306 mmol/L per mm Hg) PCO_2 and 6.1 is the pK' for the carbonic acid/bicarbonate system.

The average normal ratio of the concentrations of bicarbonate and $d\text{CO}_2$ in plasma is 25 (mmol/L)/1.25 (mmol/L) = 20/1. It follows then that any change in the concentration of bicarbonate or $d\text{CO}_2$ relative to each other must be accompanied by a change in pH. Such changes in this important ratio can occur through a change in $c\text{HCO}_3^-$ (the renal component) or in PCO_2 (the respiratory component). Clinical conditions characterized as *metabolic* disturbances of acid-base balance are classified as primary disturbances in $c\text{HCO}_3^-$. Those characterized as *respiratory* disturbances are classified as primary disturbances in $cd\text{CO}_2$ (PCO_2). Various compensatory mechanisms attempting to reestablish the normal ratio of $c\text{HCO}_3^-/cd\text{CO}_2$ may result in changes in bicarbonate concentration, $d\text{CO}_2$ concentration, or both. Application of the Henderson-Hasselbalch equation to human acid-base physiology are illustrated in Fig. 36.6.

BUFFER SYSTEMS AND THEIR ROLE IN REGULATING THE PH OF BODY FLUIDS

A buffer is a mixture of a weak acid and a salt of its conjugate base that resists changes in pH when a strong acid or base is added to the solution. If concentrations of the acid and base components of a buffer are equal, the pH will equal the pK . Generally, buffers work best at resisting pH changes in the interval of ± 1 pH unit of its pK and are more effective at higher molar concentrations. The action of buffers in the regulation

of body pH can be demonstrated by using the bicarbonate buffer system as an example. If a strong acid is added to a solution containing HCO_3^- , and H_2CO_3 , the H^+ will react with HCO_3^- to form more H_2CO_3 , and subsequently CO_2 and H_2O . The H^+ ions are thereby bound, and the increase in the H^+ concentration will be minimal.

Bicarbonate and Carbonic Acid Buffer System

The most important buffer of plasma is the bicarbonate/carbonic acid pair even though its pK is 6.1, and normal plasma pH is 7.4. The normal bicarbonate/ $d\text{CO}_2$ ratio is 20:1, which is outside the 10:1 or 1:10 ratio at which buffers work best. However, the effectiveness of the bicarbonate buffer is based on the fact that the lungs can readily dispose of or retain CO_2 , and is present at higher concentrations than other buffers with the exception of Hb. In addition, the renal tubules can regulate bicarbonate through increased or decreased reclamation (see Chapter 35).

Phosphate Buffer System

At a plasma pH of 7.4, the ratio $c\text{HPO}_4^{2-}/c\text{H}_2\text{PO}_4^-$ is 4:1 ($pK' = 6.8$). The total concentration of this buffer in both erythrocytes and plasma accounts for about 5% of the nonbicarbonate buffer value of plasma. Organic phosphate, in the form of 2,3-diphosphoglycerate (present in erythrocytes in a concentration of approximately 4.5 mmol/L), accounts for about 16% of the nonbicarbonate buffer value of erythrocytes and plays a vital role in the titration and excretion of acids in urine.

Plasma Protein and Hemoglobin Buffer System

Proteins, especially albumin, account for the greatest portion (>90%) of the nonbicarbonate buffer value of plasma. The

Fig. 36.7 Partial pressures of oxygen and carbon dioxide in air, blood, and tissue. Values shown are approximations in mm Hg and are calculated assuming a 5% shunt. Blue arrows show directions of gradients. (Modified from Tietz, N. W. [1987]. *Fundamentals of Clinical Chemistry* [3rd ed.]. Philadelphia: WB Saunders.)

imidazole groups of histidine ($pK \sim 7.3$) are the most important components of proteins in the physiological pH range encountered in plasma. For example, albumin contains 16 histidine residues per molecule.

The hemoglobin within erythrocytes also plays a significant role in the physiologic buffering system of whole blood through the diffusion of CO_2 produced by cellular respiration in peripheral tissues into the erythrocyte and its conversion to HCO_3^- and H^+ through the action of carbonic anhydrase. The H^+ initially decreases the erythrocyte fluid pH; however, this decrease in pH is rapidly compensated by the release of oxygen to the tissues from O_2Hb , which involves the conversion of stronger acid (O_2Hb) into weaker acid (HHb) that readily accepts the H^+ . The reduced hemoglobin (HHb) also contributes to the buffering capacity of whole blood by binding CO_2 in the form of carbamino- CO_2 . The HCO_3^- produced by the action of carbonic anhydrase is shunted out of the erythrocyte in exchange for plasma Cl^- to

maintain electroneutrality referred to as the *chloride shift*. In the alveoli, the low PCO_2 and high PO_2 cause a reversal of reactions detailed briefly above to remove CO_2 (and thus acid) from circulation.

RESPIRATORY MECHANISM IN THE REGULATION OF ACID-BASE BALANCE

In addition to supplying O_2 to tissue cells for normal metabolism, the respiratory mechanism contributes to maintenance of normal body pH through elimination or retention of CO_2 in **metabolic acidosis** and **alkalosis**, respectively.

Exchange of Gases in the Lungs and Peripheral Tissues

Diffusion of O_2 and CO_2 across alveolar and cell membranes is governed by gradients in the partial pressure of each gas (Fig. 36.7). Dry air inspired at a pressure of 1 atm (760 mm Hg) consists of 21% O_2 ($PO_2 \approx 160$ mm Hg), 0.03% CO_2 (PCO_2

≈ 0.25 mm Hg), 78% nitrogen, and $\approx 0.1\%$ other inert gases. As inspired air passes over the mucous membranes of the upper respiratory tract, it is warmed to 37°C , becomes saturated with water vapor, and mixes with air in the respiratory tree and alveoli, resulting in partial pressures of at the alveolar membrane of ≈ 105 mm Hg for O_2 , ≈ 40 mm Hg for CO_2 , and ≈ 47 mm Hg for H_2O . Venous blood on the opposite side of the alveolar membrane has $\text{PO}_2 \approx 40$ mm Hg and $\text{PCO}_2 \approx 46$ mm Hg. Thus the gradient for O_2 is inward, toward the blood, and for CO_2 , it is outward, toward the alveoli. CO_2 removal is so efficient that the PCO_2 in expired air is more than 100 times the PCO_2 in inspired air (see Fig. 36.7). In arterial blood, the PO_2 is slightly lower than in alveolar air (90 to 100 vs. 105 mm Hg) as the result of shunting of about 5% of blood that does not equilibrate.

At the arterial end of capillaries in peripheral tissues, the PO_2 of 95 mm Hg is substantially higher than the average PO_2 at the surface of tissue cells (20 mm Hg), and the PCO_2 at 40 mm Hg is substantially lower than that in the cells (50 to 70 mm Hg). Thus, in the tissue capillary, the gradient for O_2 is inward to the cell; for CO_2 , it is outward to the capillary blood.

RENAL MECHANISMS IN THE REGULATION OF ACID-BASE BALANCE

The average pH of plasma and of the glomerular filtrate is ≈ 7.4 , whereas the average urinary pH is ≈ 6.0 , reflecting renal excretion of nonvolatile acids. Various functions of the kidneys respond to different alterations in acid-base status. In the case of acidosis, excretion of acids is increased and base is conserved; in alkalosis, the opposite occurs. The pH of the urine changes correspondingly and may vary in *random* specimens from pH 4.5 to 8.0. The ability to excrete variable amounts of acid or base makes the kidney the final defense mechanism against changes in body pH. Renal excretion of acid and conservation of HCO_3^- occur through several mechanisms, including (1) Na^+ - H^+ exchange, (2) production of ammonia and excretion of NH_4^+ , and (3) reclamation of HCO_3^- .

Na^+ - H^+ Exchange

Nearly all mammalian cells contain a plasma membrane ATP-hydrolyzing protein capable of exchanging sodium ions for protons—the so-called Na^+ - H^+ exchanger. In the renal tubules the Na^+ - H^+ exchangers extrude H^+ ions into the tubular fluid in exchange for Na^+ ions, and their activity is enhanced in states of acidosis and is inhibited in alkalosis.

The proximal tubules, however, cannot maintain an H^+ gradient of more than ≈ 1 pH unit, whereas the distal tubules cannot maintain more than ≈ 3 pH units. Thus maximum urine acidity is reached at $\approx \text{pH } 4.4$.

Potassium ions compete with H^+ at the Na^+ - H^+ exchangers in the renal tubule. If intracellular K^+ concentration of renal tubular cells is high, more K^+ and less H^+ are exchanged for Na^+ . As a result, urine is less acidic, and body fluid pH decreases. If K^+ is depleted, more H^+ ions are exchanged for Na^+ ; urine becomes more acidic and body fluids more alkaline. In essence, hyperkalemia contributes to acidosis and hypokalemia to alkalosis.

Renal Production of Ammonia and Excretion of Ammonium Ions

Renal tubular cells are able to generate ammonia from glutamine and other amino acids derived from muscle and liver cells according to the following reaction:

The ammonium ion produced dissociates into ammonia and hydrogen ions to a degree dependent on the pH. Hydrogen ions secreted into the tubular lumen through the Na^+ - H^+ exchangers lower the pH of tubular fluid, and at the acidic pH of urine, the equilibrium between NH_4^+ and NH_3 shifts markedly to the left, strongly favoring the formation of NH_4^+ . Due to its positive charge, the NH_4^+ formed in the tubular lumen cannot readily cross cell membranes and is trapped in the tubule to be excreted in urine with phosphate, chloride, or sulphate anions.

Excretion of H^+ as H_2PO_4^-

Hydrogen ions secreted into the tubular lumen by the Na^+ - H^+ exchanger may also react with HPO_4^{2-} to form H_2PO_4^- . Acidemia increases phosphate excretion and thus provides additional buffer for reaction with H^+ . A decrease in the GFR results in a decrease in H_2PO_4^- excretion.

Reclamation of Filtered Bicarbonate

The unmodified glomerular filtrate has the same concentration of HCO_3^- as plasma; however, with increasing acidification of proximal tubule fluid, the HCO_3^- concentration is decreased. The H^+ excreted into the proximal tubule by the Na^+ - H^+ exchanger is buffered by HCO_3^- and converted to H_2CO_3 by carbonic anhydrase, which then dissociates to form CO_2 and H_2O . The increased CO_2 in the tubular fluid freely diffuses into tubular cells, where it reacts with H_2O through the action of cytoplasmic carbonic anhydrase form H_2CO_3 and ultimately HCO_3^- and H^+ . The HCO_3^- formed in this process is used to restore or maintain normal plasma pH.

Normally, $\approx 90\%$ of filtered HCO_3^- (or about 4500 mmol/day) is reclaimed in the proximal tubule. When plasma HCO_3^- concentration increases above ≈ 28 mmol/L, the capacity of the proximal and distal tubules to reclaim HCO_3^- is exceeded, and HCO_3^- is excreted in urine. Type II RTA is caused by a decreased ability to reabsorb HCO_3^- in the proximal tubules, leading to a decrease in blood pH.

TABLE 36.3 Classification and Characteristics of Simple Acid-Base Disorders

	Primary Change	Compensatory Response	Expected Compensation
Metabolic			
Acidosis	$\downarrow \text{dHCO}_3^-$	$\downarrow \text{PCO}_2$	$\text{PCO}_2 = 1.5 (\text{dHCO}_3^-) + 8 \pm 2$ PCO_2 falls by 1–1.3 mm Hg for each mmol/L fall in dHCO_3^- Last two digits of pH = PCO_2 (e.g., if $\text{PCO}_2 = 28$, pH = 7.28) $\text{dHCO}_3^- + 15 = \text{last two digits of pH}$ ($\text{dHCO}_3^- = 15$, pH = 7.30)
Alkalosis	$\uparrow \text{dHCO}_3^-$	$\uparrow \text{PCO}_2$	PCO_2 increases 6 mm Hg for each 10-mmol/L rise in dHCO_3^- $\text{dHCO}_3^- + 15 = \text{last two digits of pH}$ ($\text{dHCO}_3^- = 35$, pH = 7.50)
Respiratory			
Acidosis			
Acute	$\uparrow \text{PCO}_2$	$\uparrow \text{dHCO}_3^-$	dHCO_3^- increases by 1 mmol/L for each 10 mm Hg rise in PCO_2
Chronic	$\uparrow \text{PCO}_2$	$\uparrow \text{dHCO}_3^-$	dHCO_3^- increases by 3.5 mmol/L for each 10 mm Hg rise in PCO_2
Alkalosis			
Acute	$\downarrow \text{PCO}_2$	$\downarrow \text{dHCO}_3^-$	dHCO_3^- falls by 2 mmol/L for each 10 mm Hg fall in PCO_2
Chronic	$\downarrow \text{PCO}_2$	$\downarrow \text{dHCO}_3^-$	dHCO_3^- falls by 5 mmol/L for each 10 mm Hg fall in PCO_2

From Narins, R. G., & Gardner, L. B. (1981). Simple acid-base disturbances. *Medical Clinics of North America*, 65, 321–346.

CONDITIONS ASSOCIATED WITH ABNORMAL ACID-BASE STATUS AND ABNORMAL ELECTROLYTE COMPOSITION OF BLOOD

Blood acid-base abnormalities are accompanied by characteristic changes in plasma electrolyte concentrations. Hydrogen ions cannot accumulate without concomitant accumulation of anions, such as Cl^- or lactate, or without exchange for cations, such as K^+ or Na^+ . Consequently, plasma electrolyte composition is often determined with measurements of blood gases and pH to assess acid-base disturbances.

Acid-base disturbances are traditionally classified as (1) metabolic acidosis, (2) metabolic alkalosis, (3) respiratory acidosis, or (4) respiratory alkalosis with renal and respiratory compensatory responses (Table 36.3)

An acidosis can only occur as the result of one (or a combination) of three mechanisms: (1) increased addition of acid, (2) decreased elimination of acid, and (3) increased loss of base. Similarly, alkalosis occurs only by (1) an addition of base, (2) decreased elimination of base, and (3) increased loss of acid. This concept can be illustrated by depicting the body as a two-tank vat, one of acid and one of base, with inputs and outputs for each vat (Fig. 36.8).

Metabolic Acidosis (Primary Bicarbonate Deficit)

The primary perturbation in metabolic acidosis is decreased plasma bicarbonate. Bicarbonate is “lost” in buffering acid created through increased production (such as the generation of acetoacetic acid in diabetic ketoacidosis) or decreased elimination of acid (seen in renal failure or some types of RTA). Serum bicarbonate can fall with resultant metabolic acidosis if there is a net loss of bicarbonate in the

Fig. 36.8 Simple depiction of the body as a two-vat system of acid and base. At equilibrium, input and output from each vat are equal. (From Dufour, D. R. [1995]. Acid-base disorders. In D. R. Dufour & R. H. Christenson [Eds.], *Professional practice in clinical chemistry: a review* [pp. 604–635]. Washington, DC: AACC Press.)

urine (secondary to decreased tubular reabsorption) or in the GI tract (e.g., duodenal/pancreatic fluid loss in severe diarrhea).

The resulting drop in pH from decreased HCO_3^- stimulates respiratory compensation via hyperventilation, resulting in a lower PCO_2 and increased pH.

BOX 36.1 Conditions of Metabolic Acidoses With High and Normal Anion Gaps

Cause	Retained Acid(s)	Other Laboratory Findings
High Anion Gap (MUD PILES)		
Methanol	Formate	↑ Osmolal gap (>15 mOsmol/kg)
Uremia	Sulfuric, phosphoric, organic	↑ Urea and serum creatinine
Diabetes mellitus	Acetoacetate and β-hydroxybutyrate	↑ Plasma and urine glucose, hydroxybutyrate
Paraldehyde toxicity/Paracetamol (acetaminophen)	Acetate, chloracetate/pyroglutamate (5-oxoproline)	
Isoniazid or Iron	Organic, mainly lactate	
Lactic acidosis	Lactate	
Ethylene glycol	Hippurate, glycolate, oxalate	↑ Osmolal gap (>15 mOsmol/kg), urine oxalate crystals
Salicylate	Salicylate	Respiratory alkalosis
Normal Anion Gap		
Gastrointestinal fluid loss/diarrhea	Primary loss of bicarbonate	Hypokalemia
Acetazolamide	Bicarbonate wasting	
Renal Tubular Acidosis		
Type 1	Decreased H ⁺ secretion	Hypokalemia
Type 2	Bicarbonate wasting	Hypokalemia
Type 4	Aldosterone deficiency or resistance	Hyperkalemia
Pancreatitis		
Pancreatic fistula	Bicarbonate wasting	

Increased Anion Gap Acidosis (Organic Acidosis)

Metabolic acidoses are classified as those with an increased anion gap or a normal anion gap (Box 36.1). The concept of the **anion gap** was originally devised as a quality control rule when it was noted that if the sum of Cl⁻ and HCO₃⁻ values was subtracted from the Na⁺ values [Na⁺ - (Cl⁻ + HCO₃⁻)], the difference, or “gap,” averaged 12 mmol/L in healthy subjects. This *apparent* gap is due to unmeasured anions (e.g., proteins, SO₄²⁻, H₂PO₄²⁻) that are present in plasma. In reality, unmeasured cations (calcium, magnesium, organic cations) should be included in the equation with sodium (and occasionally potassium), but their plasma molar concentrations

Fig. 36.9 Simple “Gamblegram” depiction of normal gap, anion gap acidosis, and nonanion gap acidosis. Cations, Na⁺ and K⁺, are in left bar for each condition, whereas measured (Cl⁻ and HCO₃⁻) and unmeasured (U⁻) anions are in right bar for each condition.

BOX 36.2 A New Mnemonic for High Anion Gap Acidosis (GOLD MARK)

G Glycols (ethylene and propylene)
O Oxoproline
L L-Lactate
D D-Lactate (short-bowel syndrome)
M Methanol
A Aspirin
R Renal failure
K Ketoacids

are relatively small compared with circulating sodium concentration. The anion gap should be assessed in the electrolyte profiles of all patients as it is increased, and is often the first indication of a metabolic acidosis. The gap is also slightly increased in the absence of acidosis by very low calcium, magnesium, or potassium concentrations, because lower concentrations of these “unmeasured” cations will result in lower values of anions (Fig. 36.9).

All anion gap metabolic acidosis, excluding inborn errors of metabolism, can be explained by one (or a combination) of eight underlying mechanisms included in the common mnemonic device MUDPILES (see Box 36.1) or the updated GOLD MARK (Box 36.2).

Methanol

Although nontoxic itself, methanol is metabolized by the liver to formaldehyde and formic acid, the accumulation of which results in a high anion gap acidosis. Ocular symptoms include optic papillitis, retinal edema, and blindness due to optic nerve atrophy. Coma may result as well. Methanol and other ingested alcohols such as ethylene glycol, ethanol, and isopropanol will increase plasma osmolality. Thus, in the presence of a high anion gap acidosis, determination of the osmolal gap (see Chapter 24) will help determine the source of the unmeasured anion and may indicate specific toxicologic analyses.

Uremia of Renal Failure

Loss of functional renal tubular mass results in decreased ammonia formation, decreased $\text{Na}^+\text{-H}^+$ exchange, and decreased GFR. All lead to decreased acid excretion (see [Chapter 35](#)), and acidosis usually develops if GFR falls below 20 mL/min.

Ketoacidosis

The pathogenesis of [ketoacidosis](#) is discussed in detail in [Chapter 33](#). Ketoacids such as β -hydroxybutyrate accumulate during diabetic ketoacidosis, as well as in starvation and alcoholic malnutrition. Ketoacids represented unmeasured anions and their accumulation causes a decrease in HCO_3^- and a high anion gap. Treatment is directed at the process generating the ketoacids—most commonly insulin deficiency or starvation.

Paracetamol (Pyroglutamic Acid)

Chronic paracetamol (acetaminophen in the United States) use by patients with decreased glutathione stores can lead to an accumulation of pyroglutamic acid (5-oxoproline) that results in an anion gap. Pyroglutamic acid is a glutathione dependent intracellular intermediate in the γ -glutamyl cycle. An anion gap acidosis usually only develops in chronic paracetamol users that have other comorbidities such as malnutrition, chronic renal failure, or liver disease.

Isoniazid, Iron, or Ischemia

The “three I’s” of high anion gap acidosis share a common feature: the accumulation of organic acids, especially lactic acid. Thus the “three I’s” actually represent special cases in the general category of lactic acidosis; in the GOLD MARK mnemonic these three are represented by the “L” for lactic acidosis. Both isoniazid, an antimycobacterial agent commonly used in the treatment or prophylaxis of tuberculosis, and iron toxicity involve the production of toxic peroxides that act as mitochondrial poisons and interfere with normal cellular respiration. Ischemia results from many causes and leads to cellular hypoxia, anaerobic metabolism, and accumulation of organic acids, mainly lactate.

Lactic Acidosis

Lactic acid, present in blood as the lactate ion ($\text{pK} = 3.86$), is an intermediate of carbohydrate metabolism that is derived mainly from muscle cells and erythrocytes (see [Chapter 22](#)). It represents the end product of anaerobic metabolism and is normally metabolized by the liver. Therefore blood lactate concentration is affected by the rates of production and metabolism, both of which are dependent on adequate tissue perfusion. An increase in the concentration of lactate to greater than 3 mmol/L defines lactic acidosis.

Lactic acidosis caused by tissue hypoxia is seen most commonly in the setting of shock but can also be seen in severe anemia, sepsis, cardiopulmonary insufficiency, and due to drugs and toxins such as ethanol, methanol, and metformin, among others. Severe tissue oxygen deprivation blocks aerobic oxidation of pyruvic acid in

the tricarboxylic acid cycle, resulting in the reduction of pyruvate to lactate. During vigorous exercise, an aerobic threshold may be met (depending on multiple factors) and anaerobic metabolism may develop, with lactate concentrations increasing significantly to ≈ 12 mmol/L. If the lactate-generating condition can be corrected, lactate is rapidly metabolized to CO_2 , which then is eliminated via an intact respiratory system.

A special cause of lactic acidosis attributable to the bacterial production of D-lactate in the intestine is also possible. D-lactic acidosis is a rare cause of an anion gap acidosis and should only be considered in patients with “short-bowel” syndromes or following other GI surgeries resulting in “blind loops.” Most lactate measurement methods do not detect D-lactate (for more detail, see [Chapter 22](#)).

Ethylene Glycol

Ethylene glycol is metabolized primarily to glycolic and oxalic acids, which leads to an acidosis with high anion and osmolal gaps. Accumulation of toxic metabolites may also contribute to lactic acid production that further contributes to the acidosis. Precipitation of calcium oxalate and hippurate crystals in the urinary tract may lead to acute renal failure. Clinically patients develop a variety of neurologic symptoms that may lead to coma.

Salicylate Intoxication

Acidosis generally occurs with blood salicylate concentrations above 30 mg/dL (2.1 mmol/L). Salicylate, itself an unmeasured anion, alters peripheral metabolism, leading to the production of various organic acids and a high anion gap acidosis. Salicylate toxicity can be complex, with a number of superimposed acid-base disturbances occurring simultaneously, such as respiratory alkalosis due to salicylate induced increased respiration rate.

Normal Anion Gap Acidosis (Inorganic Acidosis)

In contrast to high anion gap acidosis, in which bicarbonate is consumed from buffering excess H^+ , the cause of a normal anion gap acidosis is the loss of bicarbonate-rich fluid from the kidney or the GI tract (see [Box 36.1](#)). As bicarbonate is lost, more Cl^- ions are reabsorbed with Na^+ or K^+ to maintain electrical neutrality, resulting in hyperchloremia. Normal anion gap acidosis can be divided into *hypokalemic*, *normokalemic*, and *hyperkalemic* acidosis, which can be helpful in the differential diagnosis of this type of disorder.

Gastrointestinal Losses

Diarrhea may cause acidosis as a result of loss of Na^+ , K^+ , and HCO_3^- . One of the primary exocrine functions of the pancreas is production of HCO_3^- to neutralize gastric contents on entry into the duodenum. If the water, K^+ , and HCO_3^- in the intestine are not reabsorbed, a hypokalemic, normal anion gap metabolic acidosis will develop. The resulting hyperchloremia is due to replacement of lost bicarbonate with Cl^- to maintain electrical balance.

Renal Tubular Acidoses

These syndromes are characterized by loss of bicarbonate due to decreased tubular secretion of H^+ (distal or type I RTA) or decreased reabsorption of HCO_3^- (proximal or type II RTA), resulting in bicarbonate “wasting” in the urine. Because the major urine-acidifying power of the kidneys rests in the distal tubules, proximal and distal RTAs may be differentiated by measurement of urine pH. In proximal RTA, urine pH becomes less than 5.5, whereas in distal RTA, the distal tubules are compromised and urine pH is greater than 5.5. Type IV RTA is due to decreased aldosterone concentration or aldosterone resistance, leading to decreased Na^+ reabsorption and thus decreased H^+ and K^+ secretion. It can be differentiated from Type I by increased serum K^+ .

Compensatory Mechanisms in Metabolic Acidosis

The buffer systems of blood (mainly the bicarbonate/carbonic acid buffer) minimize pH changes. The compensation mechanisms for metabolic acidoses seek to return arterial blood pH to 7.4. It is important to note that compensation does not overshoot, and in fully **compensated metabolic acidosis**, arterial blood pH will not exceed 7.4.

Respiratory Compensatory Mechanism

The respiratory compensatory mechanism responds immediately to a decrease in pH by increasing the rate and depth of respiration to increase CO_2 elimination. However, the maximal response may take several hours to develop. The increased rate and depth of respiration results in the elimination of carbonic acid as CO_2 , a decrease in PCO_2 (hypocapnia), and thus a decrease in $cdCO_2$. [Table 36.3](#) depicts expected compensation in various cases of acidoses and alkaloses, and corresponding laboratory values.

Renal Compensatory Mechanism

If possible, the kidneys respond to restore a normal pH through increased acid excretion and preservation of base (increased rate of Na^+-H^+ exchange, increased ammonia formation, and increased reabsorption of bicarbonate). When the renal compensating mechanisms are functioning, urine acidity and ammonia are increased.

POINTS TO REMEMBER

In determining the differential for an anion gap acidosis, two mnemonic devices MUDPILES and GOLDMARK can be helpful (see [Boxes 36.1 and 36.2](#)).

Volume depletion is very often accompanied by a hypochloremic metabolic alkalosis.

Normal anion gap acidosis is due to loss of bicarbonate-rich fluid via the GI tract (diarrhea, pancreatic fistula) or the renal tubules.

METABOLIC ALKALOSIS (PRIMARY BICARBONATE EXCESS)

Alkalosis occurs when excess base is added to the system, base elimination is decreased, or acid-rich fluids are lost (see the [At a Glance](#) box). Respiratory compensation is achieved via hypoventilation and subsequent elevation of PCO_2 . However, hypoxia limits compensation and prevents PCO_2 from increasing above 55 mm Hg. Above pH 7.55, tetany may develop, even in the presence of a normal serum total calcium concentration as the ionized calcium concentration decreases due to increased binding of calcium by albumin. Measurement of urine Cl^- can be helpful, as causes of metabolic alkalosis fall into Cl^- responsive, Cl^- resistant, and exogenous base categories (see the box “[At a Glance](#)” and [Fig. 36.4](#)).

At a Glance

Conditions Leading to Metabolic Alkalosis

Chloride Responsive (Urine Cl^- Less Than 10 mmol/L)

- Contraction alkaloses
 - Prolonged vomiting or nasogastric suction
 - Pyloric or upper duodenal obstruction
 - Prolonged or abusive diuretic therapy (loop diuretics)
 - Dehydration
- Posthypercapnic state
- Cystic fibrosis (systemic ineffective reabsorption of Cl^-)

Chloride-Resistant (Urine Cl^- Greater Than 20 mmol/L)

- Mineralocorticoid excess
 - Primary hyperaldosteronism (adrenal adenoma or, rarely, carcinoma)
 - Bilateral adrenal hyperplasia
 - Secondary hyperaldosteronism
 - Congenital adrenal hyperplasia (resulting from adrenal enzyme deficiencies in cortisol production [11β - or 17α -hydroxylase])
- Glucocorticoid excess
 - Primary adrenal adenoma (Cushing syndrome)
 - Pituitary adenoma secreting adrenocorticotropic hormone (Cushing disease)
 - Exogenous cortisol therapy
 - Excessive licorice ingestion
- Bartter syndrome (defective renal Cl^- reabsorption)

Exogenous Base

- Iatrogenic
 - Bicarbonate-containing intravenous fluid therapy
 - Massive blood transfusion (sodium citrate overload)
 - Antacids and cation-exchange resins in dialysis patients
 - High-dose carbenicillin or penicillin (associated with hypokalemia)
- Milk-alkali syndrome

Most causes of Cl^- responsive metabolic alkalosis occur as a result of *hypovolemia* (see the box “[At a Glance](#)”). The loss of acidic gastric secretions via prolonged vomiting or nasogastric suction, or the use of certain diuretics, can severely deplete the ECF and result in an acid-base disorder referred to as contraction alkalosis. Several proposed mechanisms

exist but Cl^- depletion is integral. Hydrochloric acid loss from the stomach is particularly important as both hypovolemia and hypochloremia can quickly develop. In this case, the kidneys preferentially reabsorb Na^+ to restore volume, and excess HCO_3^- is reabsorbed in the absence of sufficient Cl^- to maintain electrical neutrality. In addition, H^+ and K^+ are secreted in exchange for Na^+ . Urine Cl^- will be less than 10 mmol/L in this setting (see Fig. 36.4). Treatment consists of correcting TBW deficit and chloride replacement, usually as NaCl.

Cl^- Resistant Metabolic Alkalosis

This condition is far less common than Cl^- responsive metabolic alkalosis and is almost always associated with an underlying disease (e.g., primary hyperaldosteronism, Cushing syndrome, Bartter syndrome) or with addition of exogenous base. In these conditions, urine Cl^- will usually be greater than 20 mmol/L.

In states of adrenocortical excess, K^+ and H^+ are “wasted” and Na^+ reabsorbed by the kidney due to the effect of aldosterone or cortisol. The hypokalemia produces an alkalosis through enhanced renal excretion of H^+ as NH_4^+ and increased HCO_3^- reabsorption. The decreased tubular K^+ concentration observed in diseases in which endogenous mineralocorticoids, glucocorticoids, or both are increased include primary and secondary hyperaldosteronism, bilateral adrenal hyperplasia, pituitary ACTH-producing adenoma (Cushing disease), and primary adrenal adenomas producing glucocorticoids (Cushing syndrome) or aldosterone.

Exogenous Base

Excess exogenous base states can include citrate toxicity, often following massive blood transfusion (citrate is metabolized to HCO_3^-), aggressive intravenous therapy with bicarbonate solutions, and ingestion of large quantities of antacids in the treatment of gastritis or peptic ulcer (*milk-alkali syndrome*).

Compensatory Mechanisms in Metabolic Alkalosis

The compensatory mechanisms for metabolic alkalosis include both respiratory and renal compensation. The increase in pH depresses the respiratory center, leading to hypoventilation and retention of PCO_2 . This compensation is, however, limited by the resultant hypoventilation induced hypoxia. The kidneys respond to the alkalosis by decreased Na^+ - H^+ exchange, decreased formation of ammonia, and decreased reclamation of bicarbonate. However, this response is blunted in the presence of hypokalemia and hypovolemia.

RESPIRATORY ACIDOSIS

Respiratory acidosis is produced only by conditions that decrease pulmonary elimination of CO_2 , resulting in an increased PCO_2 (hypercapnia) and dCO_2 (and thus H_2CO_3 , which dissociates to H^+ and HCO_3^-). This, in turn, causes a decrease in the $\text{cHCO}_3^-/\text{cdCO}_2$ ratio. Causes of decreased CO_2 elimination (see the box “At a Glance”) are classified as acute or chronic.

At a Glance

Conditions Leading to Respiratory Acidosis

Factors That Directly Depress the Respiratory Center

- Narcotics and barbiturates
- CNS trauma, tumors, and degenerative disorders
- Infections of the CNS such as encephalitis and meningitis
- Comatose states such as cerebrovascular accident secondary to intracranial hemorrhage
- Primary central hypoventilation

Conditions That Affect the Respiratory Apparatus

- COPD (most common cause)
- Severe pulmonary fibrosis
- Status asthmaticus (severe)
- Disease of the upper airways such as laryngospasm or tumor
- Pulmonary infection (severe)
- Impaired lung motion secondary to pleural effusion or pneumothorax
- Acute respiratory distress syndrome
- Chest wall disease and chest wall deformity
- Neurologic disorders affecting the muscles of respiration
- Opioids

Others

- Abdominal distention, as in peritonitis and ascites
- Extreme obesity (pickwickian syndrome)
- Sleep disorders such as sleep apnea

Compensatory Mechanisms in Respiratory Acidosis

Compensation for respiratory acidosis occurs immediately via buffers, and over time via the kidneys and, if possible, the lungs. Excess H_2CO_3 present in blood is buffered to a great extent by hemoglobin and protein buffer systems. The kidneys respond to respiratory acidosis similarly to the way that they respond to metabolic acidosis—namely, with (1) increased Na^+ - H^+ exchange, (2) increased ammonia formation, and (3) increased reclamation of bicarbonate. Renal compensation is not effective before 6 to 12 hours and is not maximal for 2 to 3 days. In chronic respiratory acidosis, such as in patients with **chronic obstructive pulmonary disease (COPD)**, full renal compensation may be seen even in patients with very high PCO_2 (>60 mm Hg).

The increased PCO_2 , and resultant fall in pH, stimulates the CNS respiratory center, resulting in an increased rate and depth of respiration, provided that the primary defect is not CNS disease. Pulmonary elimination of CO_2 results in a decrease in cdCO_2 ; thus the ratio of $\text{cHCO}_3^-/\text{cdCO}_2$ and pH approach normal.

RESPIRATORY ALKALOSIS

A decrease in PCO_2 (hypocapnia) and the resulting primary deficit in cdCO_2 (respiratory alkalosis) are caused by an increased rate and/or depth of respiration. Excessive pulmonary elimination of CO_2 reduces PCO_2 and causes an increase in pH and the $\text{cHCO}_3^-/\text{cdCO}_2$ ratio. This shift also

results in a decrease in cHCO_3^- , which partially ameliorates the change in pH. Analogous to causes of respiratory acidosis, causes of respiratory alkalosis can be classified as those

with a direct stimulatory effect on the respiratory center and those due to effects on the pulmonary system (see the box “At a Glance”).

POINTS TO REMEMBER

- Respiratory acidosis results in an increased PCO_2 secondary to the inability of the lungs to eliminate CO_2 .
- Respiratory alkalosis is the result of excess elimination of CO_2 via hyperventilation.
- Respiratory compensatory mechanisms in primary metabolic acidosis or alkalosis settings should not be interpreted as respiratory disorders.

At a Glance

Factors Causing Respiratory Alkalosis

Nonpulmonary Stimulation of Respiratory Center

- Anxiety, hysteria
- Febrile state
- Gram-negative septicemia
- Metabolic encephalopathy (e.g., secondary to liver disease)
- CNS infection such as meningitis and encephalitis
- Cerebrovascular accident
- Intracranial surgery
- Hypoxia (e.g., severe anemia, high altitudes [acute condition])
- Drugs and agents such as salicylates, catecholamines, and progesterone
- Pregnancy, mainly third trimester
- Hyperthyroidism

Pulmonary Disorders

- Pneumonia
- Pulmonary emboli
- Interstitial lung disease
- Large right-to-left shunt ($\text{PCO}_2 < 50$ mm Hg)
- Congestive heart failure
- Respiratory compensation after correction of metabolic acidosis

Others

- Ventilator-induced hyperventilation

Compensatory Mechanisms in Respiratory Alkalosis

The compensatory mechanisms respond to respiratory alkalosis in two stages. In the first stage, erythrocyte and tissue buffers

provide H^+ ions that consume a small amount of HCO_3^- . The second stage becomes operational in prolonged respiratory alkalosis and depends on renal compensation as described for metabolic alkalosis (decreased reclamation of bicarbonate).

REVIEW QUESTIONS

- Total body water (TBW) makes up approximately 60% of adult body weight. The majority of TBW is located in which one of the following compartments?
 - Extracellular fluid (ECF)
 - Intracellular fluid (ICF)
 - Interstitial fluid
 - Plasma
- The anion gap, an estimate of anions not directly measured in serum, is correctly calculated by which one of the following formulae?
 - $(\text{Na}) + (\text{Cl} + \text{HCO}_3)$
 - $(\text{Na}) - (\text{Cl} + \text{HCO}_3)$
 - $(\text{Cl}) + (\text{HCO}_3 + \text{Na})$
 - $(\text{HCO}_3 - \text{Na}) - (\text{Cl})$
- Hypernatremia commonly occurs in:
 - decreased production of antidiuretic hormone (ADH).
 - decreased aldosterone.
 - the syndrome of inappropriate ADH (SIADH) secretion.
 - decreased cortisol.
- A decrease in PCO_2 and a resulting primary deficit in cdCO_2 is referred to as
 - metabolic acidosis.
 - metabolic alkalosis.
 - respiratory acidosis.
 - respiratory alkalosis.
- Low blood volume will cause synthesis of this hormone by the kidneys, which in turn causes production of aldosterone, which will increase kidney reabsorption of sodium and retention of water.
 - Insulin
 - Renin
 - Antidiuretic hormone (ADH)
 - Erythropoietin
- The use of spironolactone in addition to an increased dietary intake of this particular electrolyte can lead to this disorder characterized by mental confusion, bradycardia, and possible eventual cardiac arrest.
 - Sodium; hypernatremia
 - Sodium; hyponatremia
 - Potassium; hyperkalemia
 - Potassium; hypokalemia

7. Which one of the following is the primary cause of respiratory acidosis?
 - a. Hyperventilation
 - b. Overdose of antacids
 - c. Chronic obstructive pulmonary disease (COPD)
 - d. Uncontrolled diabetes mellitus
8. Respiratory compensation of a metabolic alkalosis involves hypoventilation to increase PCO_2 . Which of the following is the maximum PCO_2 achievable, and what limits PCO_2 from increasing beyond that threshold?
 - a. 55 mm Hg, hypoxia
 - b. 65 mm Hg, CO_2 solubility
 - c. 80 mm Hg, diffusion
 - d. 15 mm Hg, tetany/seizures
9. In the absence of an acid/base disorder, the normal ratio of bicarbonate to dissolved carbon dioxide in whole blood is approximately
 - a. 10:1
 - b. 1:20
 - c. 20:1
 - d. 1:10
10. Of the following causes of metabolic acidosis, which will present with an anion gap within the reference interval?
 - a. Uremia of kidney failure
 - b. Renal tubular acidosis type II
 - c. D-Lactic acidosis
 - d. Acetaminophen ingestion

Liver Disease

*William Rosenberg, Tony Badrick, Sudeep Tanwar**

OBJECTIVES

1. Define the following:
 - Acinus
 - Ascites
 - Bilirubin
 - Cholestasis
 - Cirrhosis
 - Gallbladder
 - Hepatic lobule
 - Hepatitis
 - Hepcidin
 - Jaundice
 - Model for end-stage liver disease (MELD) score
 - Portal hypertension
 - Portal triad
2. Describe the microscopic and macroscopic anatomy of the hepatic system, including functional units, lobules, hepatobiliary ducts, blood supply, intrinsic cell types, and functional organization.
3. Detail the major functions of the liver, including the mechanisms of bilirubin excretion, substances synthesized and their functions, and substances metabolized and their sources.
4. List the causes and consequences of each of the following clinical manifestations of liver disease:
 - Disordered hemostasis
 - Liver enzyme release
 - Jaundice
 - Portal hypertension
5. List the enzymes synthesized in the liver, their subcellular location, tissue specificity, and mechanisms of enzyme release and clearance.
6. Compare and contrast acute liver injury with chronic liver injury, including manifestations of injury, target cells involved, specific means of cell death, and laboratory analyses used to distinguish between them.
7. List and describe five types of viral hepatitis, including type of virus, mode of transmission, involvement in liver cancer, methods of prevention, and laboratory tests used to diagnose the presence of the virus.
8. Describe the following types of liver disease, including causes, clinical presentation, and laboratory findings:
 - Acute alcoholic hepatitis
 - Alcoholic liver disease
 - Autoimmune hepatitis
 - Cholestatic hepatitis
 - Cholestatic liver diseases
 - Cirrhosis
 - Drug-induced liver injury (DILI)
 - Ischemic hepatitis
 - Primary biliary cholangitis (PBC)
 - Primary sclerosing cholangitis (PSC)
 - Toxic hepatitis
9. State the formula for calculating a MELD score; calculate a MELD score given appropriate values and determine prognosis in cirrhosis.
10. Describe hepatocellular carcinoma (HCC) including prevalence, risk factors, screening tests, and laboratory findings.
11. Assess and solve case studies related to liver disease.

KEY WORDS AND DEFINITIONS

Alcoholic hepatitis An acute or chronic degenerative and inflammatory lesion of the liver in the alcoholic that is potentially progressive though sometimes reversible.

Alcoholic liver disease Liver injury caused by excessive ethanol (alcohol) ingestion.

Apoptosis Programmed cell death as signaled by the nuclei in normally functioning human and animal cells when age or state of cell health and condition dictates.

Ascites Seros fluid that accumulates in the abdominal cavity.

*The authors gratefully acknowledge the original contributions by Drs. D. Robert Dufour, Keith G. Tolman, and Robert Rej, upon which portions of this chapter are based.

Autoimmune hepatitis (AIH) A form of hepatitis, usually with hypergammaglobulinemia and serum autoantibodies.

Bile A greenish-yellow fluid secreted by the liver and stored in the gallbladder.

Cholestasis Suppression of the normal flow of bile.

Chronic hepatitis A collective term for a clinical and pathologic syndrome that has several causes and is characterized by varying degrees of hepatocellular necrosis and inflammation for at least 6 months.

Cirrhosis Liver disease characterized pathologically by loss of the normal microscopic lobular architecture with fibrosis and nodular regeneration.

Drug-induced liver injury (DILI) A disease of the liver that is caused by prescribed medications, over-the-counter medications, vitamins, hormones, herbs, illicit (“recreational”) drugs, and environmental toxins.

Fulminant hepatic failure A condition characterized by the development of severe liver injury with impaired synthetic capacity and encephalopathy in patients with previous normal liver or at least well-compensated liver disease.

Fulminant hepatitis A rare and frequently fatal form of acute hepatitis B in which the patient’s condition rapidly deteriorates with hepatic encephalopathy, necrosis of the hepatic parenchyma, coagulopathy, renal failure, and coma.

Gallstones Solid formations in the gallbladder, most commonly composed of cholesterol and bile salts.

Hemochromatosis A rare genetic disorder, due to abnormalities in genes that regulate iron metabolism.

Hepatic failure A condition of severe liver dysfunction that is accompanied by a loss of normal liver functions.

Hepatitis Inflammation of the liver. Typically divided into acute (duration of weeks to months) and chronic (lasting for more than 6 months).

Hepatocellular carcinoma (HCC) A cancer arising from hepatocytes.

Hepatocyte An epithelial liver cell that performs most of the synthetic and metabolic functions of the liver.

Hepcidin A hormone produced by liver cells, in response to signals from a complex pathway, that decreases iron mobilization across intestinal and macrophage membranes, preventing excess iron in the blood (see also Chapter 28).

Jaundice A clinical finding characterized by hyperbilirubinemia and deposition of pigment in the skin, mucous membranes, and sclera with resulting yellow appearance; also called *icterus*.

Model for End-Stage Liver Disease (MELD) Score A scoring system for assessing the severity of chronic liver disease.

Necrosis The sum of the morphologic changes indicative of cell death and caused by the progressive degradative action of enzymes; it may affect groups of cells or part of a structure or an organ.

Nonalcoholic fatty liver disease (NAFLD) A condition characterized by the buildup of extra fat in liver cells that is not caused by alcohol.

Nonalcoholic steatohepatitis (NASH) An inflammatory disease of the liver of uncertain pathogenesis.

Portal hypertension Any increase in the pressure in the portal vein (which carries venous blood from the intestines and spleen to the liver) due to anatomic or functional obstruction (e.g., cirrhosis) to blood flow in the portal venous system.

Primary biliary cholangitis (PBC) A rare form of liver disease, formerly called primary biliary cirrhosis, that results in the irreversible destruction of the small bile ducts within the liver.

Primary sclerosing cholangitis (PSC) A chronic, nonbacterial inflammatory narrowing of the bile ducts (usually the larger ducts outside of the liver).

Reye syndrome A sudden, sometimes fatal, disease of the brain (encephalopathy) caused by specific forms of acute injury to the liver.

Sjögren syndrome A systemic autoimmune disease in which immune cells attack and destroy the glands that produce tears and saliva.

Varices Enlarged and tortuous veins, most commonly found in the esophagus (termed *esophageal varices*).

Viral hepatitis Liver inflammation caused by viruses. Specific hepatitis viruses have been labeled A, B, C, D, and E.

Viral load The measurement of the amount of virus in the blood. It is expressed as the copies of virus per milliliter of body fluid and used to guide treatment decisions and monitor response to treatment.

Wilson disease An autosomal recessive disorder associated with excessive quantities of copper in the tissue, particularly the liver and central nervous system.

ANATOMY OF THE LIVER

The adult liver weighs approximately 1.2 to 1.5 kg. It is located beneath the diaphragm in the right upper quadrant of the abdomen and is protected by the ribs and held in place by ligamentous attachments.

Gross Anatomy

The liver is divided into left and right anatomic lobes by the falciform ligament (Fig. 37.1). It has a dual blood supply. The portal vein carries blood from the spleen and nutrient-enriched blood from the gastrointestinal (GI) tract supplying

Fig. 37.1 Structure of the liver. (From Dorland, W. A. N. [2003]. *Dorland's Illustrated Medical Dictionary* [30th ed.]. Philadelphia: Saunders, plate 26.)

approximately 70% of the blood supply; the hepatic artery, a branch of the celiac axis, provides oxygen-enriched arterial blood. These two blood supplies merge and flow into the sinusoids that course between individual hepatocytes. Venous drainage from the liver ultimately converges into the right and left hepatic veins, which exit on the posterior surface of the liver and join the inferior vena cava near its entry into the right atrium.

Biliary drainage originates at the bile canaliculi that merge to form ductules that drain into the intrahepatic bile ducts, which ultimately join to form the right and left hepatic bile ducts to exit the liver at the porta hepatis forming the common hepatic duct. The hepatic duct is joined by the cystic duct that drains the gallbladder, to form the common bile duct (see Fig. 37.1) which then enters the duodenum (usually with the pancreatic duct) at the ampulla of

Vater. The gallbladder, which is located on the undersurface of the right lobe of the liver, stores and concentrates 30 to 50 mL of **bile**.

Microscopic Anatomy

The functional anatomic unit of the liver is the acinus, adjacent to the portal triad (which consists of a branch of each of the portal vein, hepatic artery, and bile duct). Each acinus is supplied by a terminal branch of the portal vein and of the hepatic artery and is drained by a terminal branch of the bile duct. The blood vessels radiate toward the periphery, forming sinusoids, which perfuse the liver and ultimately drain into the central (terminal) hepatic vein (Fig. 37.2). The sinusoids are lined by fenestrated endothelial cells (which allow free filtration of blood) and phagocytic Kupffer cells (see Fig. 37.1) derived from blood monocytes.

Fig. 37.2 A low-magnification scanning electron micrograph depicting a portion of a liver lobule from a rat liver. CV, Central vein; PLV, perilobular venules; PV, portal vein. (From Zakim, O., & Boyer, T. D. [1996]. *Hepatology: A Textbook of Liver Disease* [3rd ed., p. 9]. Philadelphia: WB Saunders.)

Hepatocytes are the major functioning cells in the liver and are responsible for approximately 70% of liver mass. They perform most of the metabolic and synthetic functions of the liver. Hepatic stellate cells are located between the endothelial lining of the sinusoids, and the hepatocytes are within a small cleft referred to as the space of Disse. In their normal, quiescent state, stellate cells serve as a site of storage for fat-soluble vitamins, particularly vitamin A. When stimulated, stellate cells are morphologically and functionally transformed. They synthesize collagen and are the cells responsible for fibrosis and, eventually, cirrhosis. They also synthesize nitric oxide, which helps to regulate intrahepatic blood flow.

The blood supply to each acinus is zonal (Fig. 37.3). Zone 1, the area immediately adjacent to the portal tract, is enriched with lysosomes and mitochondria and forms a base for hepatic regeneration. Zone 2 predominantly contains hepatocytes that perform the major metabolic functions of the liver. The periphery of the acinus, zone 3, is enriched with endoplasmic reticulum, is active metabolically, and has relatively low oxygen tension. This area is most susceptible to injury.

Ultrastructure of the Hepatocyte

Hepatocytes contain a well-developed organelle substructure (Fig. 37.4). Mitochondria, which constitute approximately 18% of hepatocyte volume, are the sites of oxidative phosphorylation and energy production. The smooth endoplasmic reticulum contains microsomes that are involved in bilirubin conjugation; detoxification (cytochrome P₄₅₀-dependent isoenzymes); and steroid, cholesterol, and bile acid synthesis.

Several microsomal enzymes, including γ -glutamyltransferase (GGT), are induced by many drugs and inhibited by others. This is the site of most drug metabolism and many important drug interactions.

Peroxisomes are found near the smooth endoplasmic reticulum and contain oxidases that use molecular oxygen to modify a variety of substrates, leading to the production of hydrogen peroxide. They also contain catalase, which decomposes hydrogen peroxide. Peroxisomes catalyze the β -oxidation of fatty acids that have 7 to 18 chain lengths. Approximately 5% to 20% of the metabolism of ethanol also occurs in the peroxisomes. Lysosomes are dense organelles that contain hydrolytic enzymes that act as scavengers. Deposition of iron, lipofuscin, bile pigments, and copper occurs in the lysosomes. The Golgi apparatus lies near the canaliculus and is involved in the secretion of various substances, including bile acids and albumin.

BIOCHEMICAL FUNCTIONS OF THE LIVER

The liver is involved in various excretory, synthetic, and metabolic functions. Clinical laboratories perform numerous tests that are useful in the biochemical assessment of these functions.

Hepatic Excretory Function

Organic compounds of both endogenous and exogenous origin are extracted from the sinusoidal blood, biotransformed, and excreted into the bile or urine. Assessment of

Fig. 37.3 Blood supply of the simple liver acinus. Zones 1, 2, and 3 indicate corresponding volumes in a portion of an adjacent acinar unit. Oxygen tension and the nutrient level in the blood in sinusoids decrease from zone 1 through zone 3. *BD*, Bile duct; *CV*, central vein; *HA*, hepatic artery; *PV*, portal vein. (From Zakim, O., & Boyer, T. D. [1996]. *Hepatology: A Textbook of Liver Disease* [3rd ed., p. 10]. Philadelphia: WB Saunders.)

this excretory function provides valuable clinical information. The most frequently used tests involve the measurement of plasma concentrations of endogenously produced compounds, such as bilirubin and bile acids. In specialist centers, these tests may be augmented by determination of the rate of clearance of exogenous compounds, such as aminopyrine, lidocaine, and caffeine.

Bilirubin

Bilirubin derived from heme is mainly a product of red blood cell turnover. It is extracted and biotransformed in the liver and excreted in bile and urine. The chemistry, biochemistry, and analytical methodology for bilirubin and related compounds are discussed in [Chapter 28](#).

Bilirubin is transported from sites of production (mainly the spleen) and is loosely bound to albumin in its native, unconjugated form. Bilirubin is transported across the hepatocyte membrane and is rapidly conjugated with glucuronic acid to produce bilirubin glucuronides, which are then excreted into bile by an energy-dependent process.

The measurement of unconjugated (indirect) and conjugated (direct) bilirubin fractions can be used to identify the

likely cause of hyperbilirubinemia into prehepatic, hepatic, and posthepatic causes.

Bile Acids

Regulation of bile acid metabolism is a major function of the liver. Cholesterol homeostasis is in large part maintained by the conversion of cholesterol to bile acids and subsequent regulation of bile acid metabolism. Bile acids facilitate both hepatic excretion of cholesterol and solubilization of lipids for intestinal absorption.

Hepatic Synthetic Function

The liver has extensive synthetic capacity and plays a major role in the regulation of protein, carbohydrate, and lipid metabolism (see [Chapters 18, 22, and 23](#)). The liver is vital to the regulation of blood glucose and to the synthesis of proteins, triglycerides, fatty acids, cholesterol, and bile acids.

Protein Synthesis

The liver is the primary site of the synthesis of most plasma proteins (see [Chapter 18](#)) in the rough endoplasmic reticulum of hepatocytes, followed by release into the hepatic sinusoids. Many factors may affect plasma protein concentrations. The extensive functional reserve and relatively long half-life of proteins such as albumin mean that reduction in protein production is indicative of extensive liver damage. For this reason, the sensitivity and specificity of protein concentrations for diagnosis of liver disease are far from ideal. Short-lived hepatic proteins (such as transthyretin and prothrombin) fall quickly, whereas those of proteins with longer half-lives are normal or minimally changed. Serial determination of plasma proteins provides prognostic information; for example, worsening of prothrombin time (PT) during acute [hepatitis](#) suggests a poor prognosis.

Plasma proteins

Albumin. Albumin, the most commonly measured plasma protein, is synthesized exclusively by the liver. With liver disease, hypoalbuminemia is noted primarily in cirrhosis, [autoimmune hepatitis \(AIH\)](#), and [alcoholic hepatitis](#). One important consideration in measurement of albumin is the inaccuracy of dye-binding methods in patients with liver disease. Although bromocresol green measurements tend to overestimate albumin concentration at low concentrations, bromocresol purple methods give falsely low values in patients with [jaundice](#) because of the interference of bilirubin at the site of binding.

Transthyretin. This protein has a short half-life of 24 to 48 hours, making it a sensitive indicator of current synthetic ability. Transthyretin is typically decreased in cirrhosis (among other conditions) as a result of decreased synthesis. It is more commonly used as a measurement of nutritional status.

Immunoglobulins. Plasma immunoglobulin (Ig) concentrations are commonly increased in cirrhosis, AIH, and [primary biliary cirrhosis \(PBC\)](#), but they are normal in most other types of liver disease. IgG is increased in AIH and cirrhosis; IgM is increased in PBC. IgA tends to be increased

Fig. 37.4 Portions of two human liver cells showing the relationship of the organelles and a typical bile canaliculus (BC). Arrowheads indicate light junctions. *g*, Glycogen; *G*, Golgi; *L*, lysosome; *M*, mitochondria; *Mb*, microbody; *N*, nucleus; *SER*, smooth endoplasmic reticulum. (From Zakim, O., & Boyer, T. D. [1996]. *Hepatology: A Textbook of Liver Disease* [3rd ed., p. 20]. Philadelphia: WB Saunders.)

in all types of cirrhosis. None of these findings are specific, and they are seldom used in the diagnosis of liver disease, but serial measurement of IgG levels can be used to monitor disease activity in AIH.

Ceruloplasmin. The concentration of this protein is decreased in Wilson disease, cirrhosis, and many causes of chronic hepatitis, but it may be increased by inflammation, cholestasis, **hemochromatosis**, pregnancy, and estrogen therapy (see section on Wilson disease).

Alpha₁-antitrypsin. Concentrations of this protein, which is the major serine protease inhibitor (serpin) in plasma, is decreased in homozygous deficiency and cirrhosis, and is increased by acute inflammation. It is discussed in greater detail later in the section on alpha₁-antitrypsin (AAT) deficiency.

Alpha fetoprotein. The concentration of this protein, a normal component of fetal blood, falls to adult values by 1 year of age. Mild increases are seen in patients with acute and chronic hepatitis and indicate hepatocellular regeneration. It is present at higher concentrations in **hepatocellular carcinoma (HCC)**.

Coagulation proteins. The coagulation proteins, inhibitors of the coagulation system, including antithrombin, protein C, and protein S, are synthesized in the liver. Some of the coagulation factors (II, VII, IX, and X) or coagulation inhibitors (protein C and S) require vitamin K for posttranslational carboxylation within the hepatocyte. Activated protein C in plasma inhibits coagulation by inactivating factors V and VIII. Parenchymal liver disease of sufficient severity to impair protein synthesis or obstructive liver disease,

sufficient to impair intestinal absorption of vitamin K, is therefore a potential cause of bleeding disorders. Because of the great functional reserve of the liver, failure of hemostasis usually does not occur except in severe or long-standing liver disease.

Lipid and lipoprotein synthesis. The liver plays a key role in the metabolism of lipids and lipoproteins (see [Chapter 23](#)). On a daily basis, approximately 33% of the fatty acids originating from adipose tissue enter the liver, where they undergo esterification into triglycerides or are oxidized. Oxidation is favored in the fasting state and esterification is favored in the nonfasting state. Excessive esterification results in fatty liver, a disorder in which excess triglycerides are deposited in large vacuoles that displace other cellular components. Most cholesterol is synthesized endogenously, in the liver. Hepatic cholesterol and cholesterol of dietary origin enter the hepatic pool, where they are converted to bile acids, incorporated into lipoproteins, or used in the synthesis of liver cell membranes. The relative rates of secretion of bile acids, cholesterol, and lecithin are important factors in the pathogenesis of cholesterol gallstones.

Urea synthesis. Patients with end-stage liver disease may have low concentrations of urea in plasma (see [Chapter 35](#)). The rate of urea excretion in urine is lower in these patients than that in healthy individuals. In addition, plasma concentrations of urea precursors—ammonia and amino acids—are elevated. Lower specific activities of enzymes involved in urea synthesis are also seen. These findings suggest that patients with liver disease have an impaired ability to metabolize protein nitrogen and to synthesize urea. The rate of hepatic urea

Fig. 37.5 Major metabolic pathways for the use of ammonia by the hepatocyte. Solid bars indicate the sites of primary enzyme defects in various metabolic disorders associated with hyperammonemia: (1) carbamyl phosphate synthetase 1, (2) ornithine transcarbamylase, (3) argininosuccinate synthetase, (4) argininosuccinate lyase, (5) arginase, (6) mitochondrial ornithine transport, (7) propionyl coenzyme-A (CoA) carboxylase, (8) methylmalonyl CoA mutase, (9) L-lysine dehydrogenase, and (10) N-acetyl glutamine synthetase. Dotted lines indicate the site of pathway activation (+) or inhibition (-). (From Flannery, O. B., Hsia, Y. E., & Wolf, B. [1982]. Current status of hyperammonemia syndromes. *Hepatology*, 2, 495-506.)

synthesis also depends on exogenous intake of nitrogen and on endogenous protein catabolism.

Hepatic Metabolic Function

A recurring theme is the central importance of the liver in metabolic and regulatory pathways. The functional expression of the complex, integrated organelle structure includes the metabolism of drugs (activation and detoxification) and the disposal of exogenous and endogenous substances, such as galactose and ammonia. In addition, metabolic abnormalities due to specific inherited enzyme deficiencies can affect the liver. A classic example is galactosemia. In this condition, congenital absence of galactose 1-phosphate uridylyltransferase allows accumulation of the toxic metabolite galactose 1-phosphate, which causes injury to the liver, brain, and kidneys.

Ammonia Metabolism

Biochemistry and physiology. The major source of circulating ammonia is the GI tract. Plasma ammonia concentration in the hepatic portal vein is typically 5-fold to 10-fold higher than that in the systemic circulation. It is derived from the action of bacterial proteases, ureases, and amine oxidases on the contents of the colon and from the

hydrolysis of glutamine in both the small and large intestines. Under normal circumstances, most of the portal vein ammonia load is metabolized to urea in hepatocytes through the Krebs-Henseleit (urea) cycle during the first pass through the liver; this process includes intramitochondrial and cytosolic enzyme-catalyzed steps (Fig. 37.5).

Ammonia enters the tissue of the central nervous system by passive diffusion. The rate of entry increases in proportion to the plasma concentration and is dependent on pH. Ammonia crosses the blood-brain barrier more readily than the ammonium ion. Fasting venous plasma ammonia concentration is useful in the differential diagnosis of encephalopathy to determine if it is hepatic in origin. In acute liver failure, ammonia concentrations in excess of 200 $\mu\text{mol/L}$ are associated with cerebral edema and a poor prognosis.

Carbohydrate Metabolism

Because the liver is a major processor of dietary and endogenous carbohydrates, liver disease affects carbohydrate metabolism in a variety of ways (see Chapters 22 and 33). However, none of the conventional modes of evaluating carbohydrate metabolism have value in the diagnosis of liver disease. Because the liver is the major site of both glycogen storage

Fig. 37.6 Natural history of liver disease. With acute injury to the liver, several outcomes are possible. In many individuals, damage is clinically inapparent and recovery occurs with clearance of the causative agent. In some, clinical acute hepatitis occurs. In most of these, clearance of the causative agent results in complete recovery; in a small minority, damage is so severe that acute liver failure (fulminant hepatitis) develops, which is usually fatal without liver transplantation. A variable percentage of persons with acute liver injury (dependent on the cause) progress to chronic hepatitis. In some, recovery eventually occurs naturally or following treatment of the underlying cause. Among those in whom chronic hepatitis persists, many will never progress to cirrhosis. Most of those who do will remain well for many years, but approximately 3% per year develop decompensated cirrhosis (bleeding varices, ascites, hepatic encephalopathy) or hepatocellular carcinoma. These are the most common causes of death from liver disease.

and gluconeogenesis, hypoglycemia is a common complication in certain liver diseases, particularly **Reye syndrome**, **fulminant hepatic failure**, advanced cirrhosis, and HCC.

Hepatic Storage Function

The liver serves as a major site for storage of energy-rich carbohydrate substrates. Hepatic glycogen is released to other tissues when the need exists.

Nutritional and Metabolic Abnormalities

Severe metabolic and nutritional derangements have been observed in cirrhotic patients, including alterations in glucose metabolism caused by insulin resistance, and hypokalemia caused by secondary hyperaldosteronism. In addition, hypoalbuminemia is frequently present because of decreased production and sinusoidal leakage of albumin in patients with **portal hypertension**. In patients with chronic cholestasis, impaired delivery of bile salts to the duodenum may result in malabsorption of lipids and fat-soluble vitamins, leading to deficiencies in vitamins A, D, E, and K (see [Chapters 23 and 27](#)).

Disordered Hemostasis in Liver Disease

The liver manufactures most of the soluble clotting factors (except for factor VIII and von Willebrand factor) and a number of inhibitors of clotting (proteins C and S, antithrombin III). The liver also clears activated clotting factors from the circulation. Bile acids are necessary for vitamin K absorption and are needed to produce the active forms of several clotting factors, as well as proteins C and S. Disorders of fibrinogen also occur in liver disease.

Enzymes Released from Diseased Liver Tissue

Because hepatic function is often normal in many patients with liver disease, the plasma activities of several cytosolic,

mitochondrial, and membrane-associated enzymes are measured because they are increased in many forms of liver disease.

DISEASES OF THE LIVER

The liver has a limited number of ways of responding to injury. Acute injury to the liver may be asymptomatic but often presents as jaundice. The major acute liver disorders are acute hepatitis and cholestasis. Chronic liver injury generally takes the clinical form of chronic hepatitis; its long-term complications include cirrhosis and HCC.

Mechanisms and Patterns of Injury

Cell death occurs by **necrosis** (death of cell), **apoptosis** (programmed cell death), or both. The target cell determines the pattern of injury, with hepatocyte injury leading to hepatocellular disease and biliary cell injury leading to cholestasis. All cellular injury induces fibrosis as an adaptive or healing response, with the duration of injury and genetic factors determining whether cirrhosis and ultimately carcinoma occur ([Fig. 37.6](#)).

In general, the aminotransferase enzymes and alkaline phosphatase (ALP) are used to distinguish the pattern (see the following “At a Glance” box), the plasma albumin determines the chronicity, and the PT or factor V concentration determines the severity. Classically, liver fibrosis has been assessed using liver biopsy, but in recent years several non-invasive methods of assessment of liver fibrosis have been described and evaluated. Although liver biopsy yields incomparable information about the nature, severity, and chronicity of liver disease, noninvasive tests may provide more accurate assessment of liver fibrosis, and in particular, disease severity and prognosis.

AT A GLANCE

Algorithm for using abnormal liver function tests to classify and diagnose various types of liver disease.

Abnormal Liver-Associated Enzymes

ALP, Alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; URL, upper reference limit.

Initial evaluation is best accomplished by examining the pattern of liver-associated enzymes. If elevation primarily affects one of the aminotransferases, then hepatocellular disease is likely; an increase primarily in ALP suggests a cholestatic disorder. If only ALP is elevated, then it is appropriate to consider nonhepatic sources before further investigation (using measurement of other canalicular enzymes such as GGT or ALP isoenzymes). If the liver is the source of elevated ALP, then an imaging study to evaluate the ducts is the next test performed; dilated ducts establish a mechanical cause of obstruction, and normal ducts indicate intrahepatic cholestasis requiring further evaluation, as discussed in the text. Predominant increases in aminotransferases suggest hepatocellular injury; values more than 10 times the upper reference limit (URL) usually indicate acute hepatitis, and lower values are typical of chronic hepatitis. If aspartate aminotransferase (AST) is higher than alanine aminotransferase (ALT), common causes include early hepatic injury, nonhepatic injury (such as muscle injury), and with mildly increased values, cirrhosis.

Disorders of Bilirubin Metabolism

Defects in bilirubin metabolism resulting in jaundice are known to occur at each step in the metabolic pathway (see Chapter 28).

Hepatic Viral Infection

Five viruses (hepatitis A, B, C, D, and E) have been identified as causes of infections that primarily target the liver. In addition, certain other viruses may infect the liver as part of a more generalized infection, of which the more important causes include cytomegalovirus (CMV), Epstein-Barr virus (EBV), and herpes simplex virus (HSV). Several other viruses have been proposed as causes of liver injury; these include hepatitis G virus (HGV), transfusion-transmitted

virus, and the closely related SEN virus. Although all three are bloodborne chronic viral infections, and in the case of transfusion-transmitted virus and SEN, have been known to replicate in the liver, none of these viruses appear to cause acute or chronic liver injury. The various hepatitis viruses are outlined in Table 37.1.

Hepatitis A Virus

The incidence of hepatitis A virus (HAV) has fallen over the past four decades due to the introduction of effective vaccination. Hepatitis A is most common in young adult men, particularly in people exposed to sewage, those who eat raw seafood or inject drugs, and in men who have sex with men. It tends to be most virulent in middle-aged and older people. Epidemics have been associated with waterborne and foodborne contamination. It is estimated 50% to 70% of infected adults develop jaundice (more than hepatitis B virus [HBV] or hepatitis C virus [HCV]), and mortality is almost 2% with infection in those older than 60 years of age. HAV infection in children is rarely associated with jaundice and so is usually not detected clinically. Hepatitis A may cause severe hepatitis and death in those who have chronic hepatitis, particularly hepatitis B or C.

HAV is not cytopathic but causes liver injury by stimulating both cellular and humoral immune responses. The incubation period of hepatitis A is 15 to 50 days. The clinical course of acute hepatitis A is usually that of a mild flulike illness that lasts for a few days to a few weeks. There is no chronic form of hepatitis A, but cholestasis (manifested by several weeks of jaundice and pruritus) may occur in some adults. Relapse has been known to happen 1 to 3 months after the acute illness in up to 5% of patients.

Diagnosis of hepatitis A is based primarily on serologic tests for antibodies to HAV. Total anti-HAV is believed to be protective and occurs with natural exposure to HAV and to HAV vaccine. With natural exposure, HAV antibodies appear to persist for life. IgM antibodies to HAV are always present at the time of diagnosis of acute hepatitis A and generally remain present for 3 to 6 months, although they may persist for longer in approximately 14% of individuals. False-positive results can be identified through reference to the clinical context.

Three types of effective vaccines are available. A monovalent vaccine against HAV, a combined HAV and HBV vaccine, and a combined HAV and typhoid vaccine. Vaccination followed by a booster at 12 months will provide immunity for up to 20 years.

Hepatitis B Virus

HBV is the commonest cause of acute hepatitis and the most common chronic viral infection worldwide. It is estimated 350 million individuals are chronically infected with HBV, and several times as many individuals have been exposed to HBV. The prevalence of chronic HBV infection varies worldwide, being highest in Central and Southeast Asia, Central Africa, and Southern Europe (prevalence >8% of the population) and intermediate (2% to 8%) in most of the rest of Asia, Africa, and South America. In endemic areas, the incidence

TABLE 37.1 Types of Viral Hepatitis

	A	B	C	D	E	G
Type	RNA	DNA	RNA	Partial	RNA	RNA
Incubation period, days	45–50	30–150	15–160	30–150	20–40	Unknown

HAV, Hepatitis A virus; HBc, hepatitis B core antigen; HBsAg, hepatitis B surface antigen; HCV, hepatitis C virus; HDV, hepatitis D virus; HEV, hepatitis E virus; HGV, hepatitis G virus; IgM, immunoglobulin M; Min, minimal; PCR, polymerase chain reaction.

of new infection has decreased markedly where HBV vaccination is practiced. HBV is transmitted through body fluids, primarily by parenteral or sexual contact; it can be transmitted from mother to child, usually at or after delivery (termed vertical transmission). In parts of the world with high rates of chronic infection, much of the transmission is vertical. The residual risk from transfusion is estimated to be 1 in 600,000.

Hepatitis B is caused by a 42-nm DNA virus of the Hepadnavirus family. The S gene codes for several different length variants of surface protein; the smallest form, hepatitis B surface antigen (HBsAg), is produced independently of and in excess of the amount needed for viral replication; the largest form (S1) makes up the surface coat of circulating viral particles. The C gene encodes the hepatitis B core antigen (HBcAg), which is part of the infectious core of the virus. The X gene codes for a transactivating factor that may be involved with viral replication and the development of malignancy. The precore and basal core promoter regions code for production of hepatitis B e antigen (HBeAg), a protein found only in those with circulating viral particles. The final major viral protein is a polymerase, which has several different enzymatically active sites and functions including reverse transcription. This error-prone reproductive strategy and an extremely high replication rate results in a high frequency of mutation in HBV.

Hepatitis B e antigen and hepatitis B e antigen mutants. The most common HBV mutations involve the regions that code for production of HBeAg. These mutants are associated with undetectable HBeAg and are usually found in patients with

detectable levels of anti-HBe. They may be present at the time of infection or may develop during the course of disease. Infection with these mutant strains is associated with a higher risk of development of HCC, and risk is stronger for the basal core promoter mutations.

Polymerase mutants. Treatment with antiviral agents that inhibit the reverse transcriptase domain of HBV polymerase is currently the most widely used therapy for chronic HBV.

Hepatitis B surface antigen mutants. Mutations in the “a” determinant of HBsAg are rare but important HBsAg mutants because antibody to HBsAg, which is developed by natural exposure or by the HBV vaccine, is primarily directed against the “a” determinant. Mutations in HBsAg can lead to failure of detection by antibodies used in HBsAg assays. Use of assays with antibodies to multiple epitopes improves detection of such mutant strains.

Diagnostic tests for hepatitis B. The diagnostic evaluation of HBV infection requires the integration of results from biochemical, immunologic, and molecular tests (see the following “At a Glance” box).

HBsAg, the most widely used marker for detecting current hepatitis B infection, is detected by kits using antibody to HBsAg. False-positive results occur rarely, particularly during pregnancy; a neutralization assay is available. False-negative results can occur with mutants in the surface antigen, and they occur more commonly in early HBV infection. Most assays are qualitative. Increasingly quantitative measurement of HBsAg is being used to guide treatment.

Antibody to the HBcAg (anti-HBc) is the most commonly detected antibody against HBV. Two assays are usually used: IgM and total anti-HBc. IgM anti-HBc assays typically use a large dilution of plasma (1:100) before analysis to reduce the likelihood of positivity in individuals with chronic HBV. The total antibody assay measures both IgM and IgG antibodies. Anti-HBc appears to last longer than anti-HBs in natural infection and is still present in 97% of previously infected individuals more than 30 years after exposure. Isolated anti-HBc is a relatively common finding. Although this may represent a false-positive result, particularly as a transient phenomenon after influenza vaccination, current guidelines on hepatitis B recommend consideration of individuals with isolated anti-HBc as having been exposed to HBV.

Antibody to the HBsAg (anti-HBs) is considered evidence of immunity to hepatitis B and is the only marker found in those who have received the hepatitis B vaccine. The World Health Organization (WHO) has developed reference material that contains 10 IU/mL of anti-HBs. Current guidelines suggest that immunocompetent individuals who achieve an anti-HBs of ≥ 10 IU/mL have effective immunity to hepatitis B.

The HBeAg and antibody to the e antigen (anti-HBe) are typically used only in the setting of chronic HBV infection. HBeAg typically appears at approximately the same time as HBsAg in acute hepatitis. In chronic infection, HBeAg has historically been used as a marker of persistence of infectious virus; its clearance and the appearance of anti-HBe have been used as indicators of conversion to the nonreplicating state and remain goals of antiviral treatment. With widespread availability of HBV DNA assays with low detection limits, the discordance between HBeAg and the presence of infectious viral particles has become apparent. Although most untreated patients with HBV who are HBeAg positive have high viral loads (usually $>10^6$ IU/mL), detectable HBV DNA is also found (usually with lower viral load) in approximately 70% of those who are HBeAg negative, some of whom may have hepatitis that may be associated with elevated transaminases. When HBeAg-positive individuals are treated with polymerase inhibitors, loss of HBV DNA occurs in the majority. Loss of HBeAg during treatment, with development of anti-HBe, indicates a high likelihood that viral suppression will be maintained after discontinuation of treatment. In contrast, in those with HBV viremia who were HBeAg negative (and anti-HBe positive) before treatment, discontinuation of treatment usually leads to recurrence of viremia except in those with HBsAg levels less than 1000 IU/mL. Thus HBeAg remains an important marker for monitoring therapy but must be assessed in conjunction with HBV DNA for detection of those who harbor the infectious virus.

Hepatitis B viral DNA is now routinely measured using amplification techniques. The WHO has established an international reference material for HBV DNA and results are typically reported in international units per milliliter; conversion from copies per milliliter differs on the basis of viral load and is different for various assays. An approximate conversion factor is 5 copies/mL = 1 IU/mL. Data (primarily from Taiwan) have shown that risk of progression to cirrhosis or

HCC increases at viral loads at more than 10,000 copies/mL (2000 IU/mL). Current treatment guidelines suggest that this number should be used as one criterion in treatment decision making.

Hepatitis B mutants and genotypes are usually determined by direct sequencing or with the use of line probes.

AT A GLANCE

Course of acute type B hepatitis with recovery

(1) Onset of hepatitis with jaundice 3 months after exposure; (2) detection of hepatitis B surface antigen (HBsAg) 2 to 8 weeks after exposure, followed by appearance of its antibody (anti-HBs) 2 to 4 weeks after HBsAg is no longer detectable; (3) detection of hepatitis B e antigen (HBeAg) shortly after HBsAg disappears (this is usually followed by the appearance of antibody to HBeAg [anti-HBe], which persists); (4) detection of hepatitis B core antibody (anti-HBc) at the time of onset of disease 2 to 3 months after exposure. Anti-HBc immunoglobulin M will be detectable in high levels for approximately 5 months.

AST, Aspartate aminotransferase; SGOT, serum glutamic-oxaloacetic transaminase.

From Balistreri, W. F. (1984). Viral hepatitis: unique aspects of infection during childhood. *Consultant*, 24, 131–153.

Hepatitis C virus. The HCV is the cause of most cases previously known as non-A, non-B hepatitis. It was recognized in 1989 and fully characterized 2 years later. It is the commonest cause of chronic viral hepatitis in North America, Europe, and Japan and is estimated to infect approximately 170 million individuals worldwide. HCV infection primarily occurs through plasma; major risk factors are injection drug use and transfusion. Because of its mode of spread, HCV infection is rare in children. Vertical transmission may occur from an infected mother (estimated to occur in $\approx 5\%$ of infected women). Unsterile medical and dental procedures and ritual practices continue to account for new infections.

HCV is a single-stranded enveloped RNA virus of the flavivirus family, which includes other hepatitis viruses (yellow fever virus) and viruses that cause unrelated disease (such

Fig. 37.7 Structure of the hepatitis C genome.

as West Nile virus). HCV RNA contains one reading frame (Fig. 37.7). The resulting polypeptide is cleaved to core and envelope antigens, and a number of nonstructural proteins, including a polymerase and a protease. As an RNA virus, HCV is subject to a high rate of spontaneous mutation, giving rise to large numbers of variants. According to various global reviews, genotype 1 (G1) is the most common (46%; affecting ≈ 83 million cases, one-third of which are in East Asia), followed by G3 (22% to 31%; ≈ 54 million), G2 (13%; ≈ 22 million), and G4 (13%; ≈ 22 million).

Chronic HCV infection is associated with evidence of chronic liver injury in most cases. Elevations in aminotransferases are usually mild and fluctuate in most infected individuals. In 15% to 20% of cases, cirrhosis becomes evident within 30 years. HCC may develop once cirrhosis is present, at an average rate of 1.5% to 3% of cases per year. In North America, Europe, and Japan, HCV is the most common risk factor in the development of HCC. Various extrahepatic manifestations of chronic HCV infection may be noted; the most common are cryoglobulinemia and porphyria cutanea tarda (see Chapter 29). Epidemiologic evidence has linked HCV to increased risk of lymphoma and type 2 diabetes mellitus.

Diagnostic tests for hepatitis C. Measurement of the antibody to HCV (anti-HCV) is the principal screening test for HCV exposure. Current widely used assays incorporate enzyme-linked immunosorbent assays (ELISAs) using antigens from four different regions of the HCV genome. Tests become positive 9 to 12 weeks after exposure.

Reverse immunoblot assays (RIBAs) use similar principle to Western blotting. HCV antigens are blotted onto a membrane and reactivity is detected after incubation with serum. Results are interpreted as negative if there is less than 1+ reactivity with any of the four antigens, indeterminate if there is 1+ or greater reactivity to only a single antigen (or to more than one antigen along with the nonspecific yeast marker superoxide dismutase), and positive with 1+ or greater reactivity to multiple antigens.

HCV RNA measurement, typically performed using polymerase chain reaction (PCR) amplification, has become the most widely used test to detect current HCV infection. Rapid separation of serum from a clot is critical for accurate measurement of HCV RNA. Separation of serum from cells by centrifugation and refrigeration preserve the integrity of HCV RNA, and samples can be kept indefinitely if frozen. Samples collected in ethylenediaminetetraacetic acid are stable for 24 hours, even if plasma is not separated from red cells.

HCV RNA assays have been standardized against international reference material for quantification of HCV RNA

in international units per milliliter. Until recently, qualitative assays had significantly lower detection limits than quantitative assays, but quantitative assays using real-time PCR have equivalent or lower detection limits compared with qualitative assays.

Hepatitis C core antigen (HCV Ag) is produced by the most constant part of the HCV genome and has a similar time course to that of HCV RNA in both acute and chronic HCV infection; the currently available assay for HCV Ag becomes reliably positive when HCV RNA is 20,000 IU/mL or greater which is observed in 95% of untreated HCV RNA-positive individuals. In contrast to HCV RNA, HCV Ag is stable in storage. Currently, no commercial HCV Ag assays are available in North America.

Hepatitis C genotype shows regional diversity and is currently important for determining the selection of antiviral therapy, although pan-genotypic treatments are emerging. Several methods are currently used to determine the infecting genotype. Serologic assays are available but their correlation with direct tests is approximately 90%, and a significant minority of infected individuals have antibodies to more than one genotype. The most reliable method involves direct sequencing of regions of the genome that show characteristic patterns with specific genotypes and subtypes. Commercial assays using the 5'-untranslated region are the most widely used, although assays using the NS5b region are now available. Available assays show good agreement on genotype, but they differ in their detection limits. Sequencing methods have the advantage that they can be used to identify treatment resistance-associated variants that may develop under selection pressure from the new directly acting antiviral agents. Line probe assays are also widely used and show good agreement with direct sequencing assays.

Hepatitis D Virus (Delta Agent)

Hepatitis D virus (HDV) is an incomplete, 36-nm single-stranded antisense RNA virus that cannot replicate on its own. It is coated with HBsAg and is dependent on HBV for its activation. It is thus a satellite virus similar to that seen in plants. It is very infectious and strongly associated with intravenous drug use; approximately 10 million individuals have been infected worldwide, although the incidence is declining with the fall in incidence of HBV infection. It occurs as simultaneous infection with hepatitis B (coinfection) or as a superimposed infection in someone with chronic hepatitis B (superinfection). Coinfection usually runs the same time course as acute hepatitis B, and HDV is spontaneously cleared as the hepatitis B resolves, but the risk of **fulminant hepatitis** is higher than in HBV infection alone, and mortality is higher. Superinfection typically results in chronic HDV infection, suppression of HBV DNA replication, and more rapid progression to cirrhosis (estimated 4%/year) and HCC (estimated 3%/year). It should be assessed in all patients with HBV infection, due to its seriousness, and suspected in patients with HBV infection whose condition worsens. Although it is traditionally diagnosed serologically by detection of anti-HDV (total or IgM) and/or HDV Ag, HDV RNA measurements are often used as evidence of current infection.

TABLE 37.2 Laboratory Features of Different Forms of Acute Hepatitis

Type	AST/ALT	ALP	Bilirubin	PT (s)	Serology	Other
Viral	8–50× URL	<3× URL	5–15 mg/dL (86–256 μmol/L)	<15	Positive	
HAV					IgM anti-HAV	
HBV					HBsAg, IgM anti-HBc	
HCV					HCV RNA ± anti-HCV	
Alcoholic	<8× URL	>3× URL in 25%	5–15 mg/dL (85–256 μmol/L)	<15	Negative	AST > ALT
Toxic	>50× URL	Normal	<5 mg/dL <85 μmol/L)	>15	Negative	Toxin usually detectable; acute renal failure common
Ischemic	>50× URL	Normal	<5 mg/dL (<85 μmol/L)	>15	Negative	Acute renal failure common
Drug induced	8–50× URL	>3× URL in 50%	5–15 mg/dL (85–256 μmol/L)	<15	Negative	Eosinophilia, skin rash common
Autoimmune	8–50× URL	<3× URL	5–15 mg/dL (85–256 μmol/L)	<15	Positive ANA or ASMA	Low albumin, high globulins
Wilson	8–50× URL	Low normal or decreased	5–15 mg/dL (85–256 μmol/L)	<15	Negative	Hemolytic anemia, renal failure, low ALP common; low ceruloplasmin often absent

Hepatitis E Virus

Hepatitis E virus (HEV) is a 34-nm, single-stranded, unenveloped RNA virus. It accounts for sporadic and epidemic hepatitis in tropical and semitropical countries and in people returning from these areas. HEV RNA is frequently isolated from city sewage treatment plants in nonendemic areas. It is enterically transmitted and viral RNA has been detected in plasma and in stools. The specificity of antibody tests for open reading frame 2 antigen of HEV is high. The prevalence of antibodies to HEV is in the region of 21% in the United States. HEV has been isolated from a number of animals, notably rats and pigs, and HEV has been linked to ingestion of pork.

Detection of IgM anti-HEV antibodies is considered diagnostic of acute infection by HEV, but false-positive results have been reported with hepatitis due to CMV and EBV. Molecular tests for HEV RNA can be used to diagnose infection and monitor clearance. The clinical course is similar to that of HAV infection. HEV typically has a self-limited course, but increasingly cases of chronic infection are reported, particularly in organ transplantation recipients. A peculiar feature of this disease is its virulent course in late pregnancy in India, with mortality generally in the range of 20% to 25%, but rates as high as 50% have been reported. Mortality during pregnancy is not increased in other parts of the world. Mortality is increased among the elderly and in those with chronic liver disease.

Hepatitis G Virus

HGV, also known as GBV-C, is an RNA virus of the Flavivirus family and is closely related to HCV. It is most commonly transmitted by plasma but vertical transmission (i.e., from

mother to offspring) has also been reported. HGV infection appears to have no adverse consequences, and, although it has been called a hepatitis virus, viral RNA cannot be isolated from the liver in chronic infection.

Acute Hepatitis

Acute hepatitis refers to an acute injury directed against the hepatocytes. The injury may be mediated directly, which occurs with certain drugs, such as acetaminophen or with ischemia, or indirectly, which occurs with immunologically mediated injury from most of the hepatitis viruses and most drugs, including ethanol. Direct injury typically causes a rapid rise in cytosolic enzymes, such as AST, ALT, and lactate dehydrogenase (LDH), followed by a rapid fall, with rates of decline similar to known half-lives of the enzymes. Immunologic injury typically causes a gradual rise in cytosolic enzymes, followed by a plateau phase and gradual resolution of enzyme elevation. Although jaundice is a key clinical finding in acute hepatitis, it is often absent. An increase in AST activity to greater than 200 U/L or in ALT activity to greater than 300 U/L has sensitivity and specificity greater than 90% for acute hepatitis.

ALP usually is mildly elevated and typically is less than 3 times the URL in 90% of cases of acute hepatitis. Increased plasma concentration of bilirubin, when present, typically is predominantly due to direct reacting bilirubin. The distribution of direct bilirubin percentage is identical in acute hepatitis and bile duct obstruction. The features helpful in the differential diagnosis of acute hepatitis are summarized in Table 37.2.

Fig. 37.8 Metabolism of acetaminophen by the liver.

The outcome of acute hepatitis is variable. In most cases, complete recovery occurs, and liver regeneration leads to normal structure and function. In a small percentage of cases, massive destruction of the liver leads to acute (fulminant) hepatic failure, which is associated with high mortality unless liver transplantation is performed.

Acute Viral Hepatitis

All forms of acute viral hepatitis have similar pathology and a similar clinical course. They are all diagnosed on the basis of marked elevations in serum aminotransferase activities, usually to between 8 and 50 times the upper reference intervals, with only slight elevations in ALP and little or no effect on hepatic synthetic function. ALT is typically higher than AST because of slower clearance. Enzyme elevations typically peak before peak bilirubin occurs and remain increased for an average of 4 to 5 weeks (longer for ALT than AST because of its longer half-life). Bilirubin elevation is variable. The incidence, prevalence, and management of acute viral hepatitis are covered in the practice guideline of the World Gastroenterology Organisation.

Toxic Hepatitis

Toxic hepatitis refers to direct damage of hepatocytes by a toxin or toxic metabolite. Toxic reactions are usually predictable and are directly related to the dose of the agent ingested. In North America and Europe, the most common cause of toxic hepatitis (and the most common cause of acute liver failure) is acetaminophen. The metabolism of acetaminophen is affected by dose, induction of metabolic enzymes, and concentrations of glutathione (Fig. 37.8). When a large dose of acetaminophen is ingested (the average lethal dose as a single ingestion is 15 g), the metabolic pathways are overwhelmed, glutathione is depleted, and toxic intermediates accumulate, causing liver damage. In glutathione depletion due to starvation or metabolic enzyme induction (such as by ethanol),

toxicity can occur with relatively small doses of acetaminophen (total doses of 2 to 4 g). Toxicity can also occur with excessive cumulative doses of acetaminophen. Diagnosis is often based on history and increased acetaminophen concentrations. In late presentation or when a history cannot be obtained, measurement of acetaminophen-protein adducts allows diagnosis. The first laboratory abnormality to appear is an increase in PT, followed by increased activity of cytosolic enzymes, with AST tending to be higher than ALT. Peak activities (typically >100 times the URLs) usually occur by 24 to 48 hours, followed by rapid clearance at rates approximating the known half-lives of the enzymes. PT elevations are typical and are more than 4 seconds greater than the control value in most cases. Prognosis is related most closely to the prolongation of PT; persistent elevation of PT 4 days after ingestion is associated with a poor prognosis. Other markers of risk include development of acute renal failure and the presence of lactic acidosis, particularly if the pH is less than 7.30 ($[H^+] > 50 \text{ nmol/L}$).

Ischemic Hepatitis (Shock Liver)

Hepatic hypoperfusion (ischemic hepatitis) is one of the most common causes of elevated cytosolic enzymes, which may exceed 10,000 IU/L; in hospital patients, it is the cause of most cases of acute hepatitis. Ischemic hepatitis may follow any cause of shock; the most common causes are septic and cardiogenic shock. Bilirubin elevations typically are minimal, and they usually peak several days after enzyme activity reaches its greatest point. Laboratory findings are similar to those seen in toxic hepatitis, and acute renal failure is a common complicating factor. Prognosis is primarily related to the underlying cause of hypotension. Individuals with prolonged elevation of bilirubin appear to have a poor prognosis.

AT A GLANCE

Assessment of Viral Hepatitis

- In all cases of viral hepatitis, it is prudent to test patients for each of the major bloodborne viruses: HBV, HCV, and human immunodeficiency virus.
- In viremic patients, testing should include measurement of viral nucleic acid (HBV DNA and HCV RNA).
- Hepatic inflammation is indicated by the extent of elevation of aminotransferases, but these are neither sensitive nor specific.
- The staging of severity of chronic viral hepatitis is determined by the severity of liver fibrosis. Liver fibrosis can be assessed using noninvasive blood tests, fibroelastography, imaging or liver biopsy, or any combination of these tests.

Chronic Hepatitis

Chronic hepatitis is defined as chronic inflammation of the liver that persists for at least 6 months or signs and symptoms of chronic liver disease in the presence of elevated cytosolic enzymes. Common causes of chronic hepatitis and tests used to make a specific etiologic diagnosis are listed in Table 37.3.

The clinical features of chronic hepatitis are highly variable. Most patients are asymptomatic, but nonspecific features, such

DIAGNOSTIC ALGORITHM OF VIRAL HEPATITIS

TABLE 37.3 Causes of Chronic Hepatitis and Diagnostic Strategies

Cause	Diagnosis
Hepatitis B	History, HBsAg, anti-HBs, anti-HBc, HBV DNA
Hepatitis C	Anti-HCV, HCV RNA by PCR
Autoimmune type 1	ANA, anti-smooth muscle antibody
Autoimmune type 2	SLA, anti-LKM1
Wilson disease	Ceruloplasmin
Drugs	History
AAT deficiency	AAT phenotype
Nonalcoholic fatty liver disease	Metabolic syndrome, liver ultrasound, liver biopsy
Idiopathic	Liver biopsy, absence of markers

AAT, Alpha₁-antitrypsin; ANA, antinuclear antibody; HB_c, hepatitis B core antigen; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; HCV, hepatitis C virus; LKM1, liver-kidney microsomal antigen type 1; PCR, polymerase chain reaction; SLA, soluble liver antigen.

as fatigue, lack of concentration, and weakness may be present. Most patients are diagnosed because of an unexplained abnormality in aminotransferase activities or detection of positive results on a screening test for a cause of chronic hepatitis. Moderate elevations in plasma aminotransferase activities are characteristic (an average of approximately twofold,

and in most cases, less than fivefold). Normal aminotransferase activities do not exclude chronic hepatitis, especially in the presence of chronic viral hepatitis or **nonalcoholic fatty liver disease (NAFLD)**. Characteristically, ALT is elevated to a greater degree than AST. Reversal of the AST/ALT activity ratio to more than 1 suggests coexisting alcohol abuse or cirrhosis. Although ALT is relatively specific for the liver, skeletal muscle sources for AST and ALT should always be considered, especially in physically active young individuals. Persistent elevation of aminotransferase activity should lead to an evaluation for chronic hepatitis using the tests outlined in **Table 37.3**. A liver biopsy may be helpful in determining the cause and in assessing disease severity. A specific etiologic diagnosis is essential to determine prognosis and treatment. The most common causes of chronic hepatitis are chronic HBV, HCV, and NAFLD, but a variety of other disease processes may cause chronic hepatitis.

Chronic Hepatitis B

Worldwide, HBV infection is the most important cause of chronic hepatitis. According to the WHO, approximately 350 million individuals worldwide have chronic HBV infection; most cases are found in Asia, Africa, and Southern Europe.

HBV is not cytopathic, rather injury results from an immune-mediated inflammatory attack against hepatocytes. Chronic hepatitis results when the virus is not eliminated

TABLE 37.4 Patterns of Chronic Hepatitis B Virus Infection

Type	AST/ALT	HBsAg	HBeAg	Anti-HBc	HBV DNA
Occult	Normal	Negative	Negative	Positive	Negative ^a
Immune control	Normal	Positive	Negative	Positive	Negative ^a
Immune tolerant	Normal	Positive	Positive/negative	Positive	Positive
Immune active	Increased	Positive	Positive/Negative	Positive	Positive, viral load >2000 IU/mL
HBeAg-negative chronic hepatitis	Increased	Positive	Negative	Positive	Positive, viral load usually >2000 IU/mL but <10 ⁶ IU/mL

^aMay have very low level (usually <10² IU/mL) in serum.

ALT, Alanine aminotransferase; AST, aspartate aminotransferase; HBc, hepatitis B core antigen; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus.

from infected cells resulting in a continuing cycle of viral replication, reinfection of regenerating hepatocytes, and immune damage to newly infected cells that is inadequate to clear infection.

The clinical presentation may be complicated by various extrahepatic complications (which occur in 1% to 10% of those with HBV), including polyarteritis, glomerulonephritis, polymyalgia rheumatica, cryoglobulinemia, myocarditis, and Guillain-Barré syndrome. These conditions are associated with circulating immune complexes containing HBsAg. Immunocompromised persons, such as HBV/HIV coinfecting individuals, typically have higher replication markers, less hepatic inflammation, and poorer survival than those with HIV alone. The natural history of chronic hepatitis B (defined by the persistence of HBsAg) varies. Features of the different stages of chronic HBV are given in Table 37.4. The evolution of HBV infection is best defined by the nature of the host immune response and inflammatory activity. The stages of chronic HBV infection can only be classified with reference to eAg and eAb status, HBV DNA concentrations, along with ALT activities and histology. HBV DNA levels are commonly very high (exceeding 10⁶ IU/mL) during the immune-tolerant phase of infection. In the immune active and immune control phases of HBV infection, viral DNA levels exceeding 2000 IU/mL are considered to be indicative of levels of replication associated with liver damage. All phases of chronic HBV are associated with the presence of HBsAg in serum. Occult HBV infection is not associated with inflammation in the liver or elevated aminotransferases.

In general, chronic HBV passes through stages in untreated persons. For those infected early in life, the immune tolerant phase is usually followed by an immune active phase that may vary in duration and may cause significant liver damage. This phase usually gives way to a protracted period of immune control, with HBsAg positivity or occult infection if HBsAg is cleared. For those infected individuals who go on to have chronic infection as older children or adults, the immune tolerant phase may be a short period or absent, leading straight into the immune active phase. Approximately 8% to 10% of persons per year will transition from the immune active to the immune control phase of chronic HBV. A variable, but low, proportion of those in the immune control phase will revert to the immune active phase that is manifest by levels of HBV DNA greater than 2000 IU/mL and elevated transaminases.

Approximately 0.5% to 1% of persons per year will convert from HBsAg positive to HBsAg negative, entering the occult phase of infection (or, in a minority, resolved HBV). Each of these transitions can be associated with an acute rise in aminotransferase activities and a clinical picture that mimics acute viral hepatitis.

Individuals who have chronic replicating infection are at risk of developing cirrhosis and HCC. An estimated 20% to 30% of individuals with chronic hepatitis B will develop cirrhosis over a 20-year follow-up period; the risk is directly related to the amount of HBV DNA, with risk progressively increasing at viral loads of more than 2000 IU/mL (10,000 copies/mL). Once cirrhosis has developed, the annual risk of HCC is 1.5% to 5%. Although the risk of HCC is lower in individuals with HBV infection who do not have cirrhosis, risk is directly related to viral load and rises at quantities greater than 2000 IU/mL. Even a person in the nonreplicating stage of infection have a 10-fold higher risk of HCC than unexposed individuals. Worldwide, hepatitis B infection is the most common cause of liver cancer.

Efficacy of treatment is typically measured by response of ALT and/or AST and HBV DNA; goals of treatment include normalization of ALT and suppression of HBV DNA to less than the limits of detection of assays, ideally using assays with detection limits of approximately 20 to 50 IU/mL. With polymerase inhibitors, approximately 70% to 80% of patients will achieve these goals within 1 year of treatment. Duration of treatment is largely dependent on HBeAg status before the start of therapy. For those who are HBeAg positive before treatment, loss of HBeAg and development of anti-HBe indicate a high likelihood of maintenance of HBV DNA control and normalization of ALT once treatment is stopped (after 6 to 12 months of further treatment once anti-HBe appears). For those who are HBeAg negative prior to treatment, suppression of HBV DNA for more than 3 years with HBsAg levels less than 1000 IU/mL is associated with good control after stopping treatment. Treatment should be maintained indefinitely in patients who do not achieve these goals. With interferon therapy, response rates to 1 year of treatment are somewhat lower than with polymerase inhibitors, but treatment requires only 6 to 12 months. Loss of HBsAg is uncommon; with most agents, the likelihood of loss of HBsAg usually is not higher than that in untreated persons, although it may be higher with interferon (IFN) and tenofovir.

Chronic Hepatitis C

Approximately 170 million individuals worldwide have been diagnosed with chronic HCV infection; most cases are found in North America, Northern Europe, and Japan. Chronic HCV infection develops in 75% to 85% of cases of acute hepatitis C. Clearance of acute HCV infection does not appear to confer lasting immunity. Once viremia becomes established beyond 6 months after initial exposure, infection never resolves spontaneously. It is estimated that approximately 20% to 30% of patients with hepatitis C will progress to cirrhosis over a period of 20 years. The frequency of progression appears to be increased by age older than 40 years at the time of infection, male sex, alcohol abuse, and immunosuppression, but it is less than 5% after 20 years of infection in those infected during the first 20 to 30 years of life. In those who develop recurrent HCV after liver transplantation, the rate of progression to cirrhosis is faster than in primary infection. The likelihood of progression to HCC is between 1.5% and 5% per year in those with cirrhosis.

Infection with HCV is characterized by fluctuating ALT activities over time. Only approximately one-third of those with chronic HCV have continually increased ALT, and many of these individuals show variation in ALT activity. A significant minority of individuals with chronic hepatitis C and normal transaminases have advanced fibrosis or cirrhosis.

Dramatic advances in the treatment of chronic hepatitis C have revolutionized outcomes for patients and changed the requirements for laboratory testing in the management of patients on treatment. Directly acting antiviral agents that target essential HCV proteins have been shown to cure infection in most patients. The critical tests required for the evaluation and monitoring of HCV infection are HCV genotype and viral load measurement, both of which depend on molecular tests. Although this remains a rapidly evolving field, it is highly likely that it will be possible to cure infection in almost all cases within the next decade in any patient capable of adhering to a full course of treatment. The assessment of HCV genotype, the presence of resistance associated sequences, and viral load may influence the choice of treatment and so access to molecular tests of HCV is mandatory in the treatment of hepatitis C. The extent to which liver fibrosis reverses in patients who attain clearance of HCV still needs to be established, but studies of patients who have been cured using INF-based therapies suggest that the long-term risks of liver cancer and bleeding **varices** are reduced even in cirrhotic patients who attain clearance of HCV.

Nonalcoholic Fatty Liver Disease and Nonalcoholic Steatohepatitis

NAFLD is now a major cause of chronic liver disease and is increasing in prevalence. NAFLD encompasses a range of pathology from simple steatosis to **nonalcoholic steatohepatitis (NASH)** characterized by an inflammatory response to hepatic fat. Fibrosis is a feature of NAFLD that is triggered by NASH and may culminate in cirrhosis. The histologic features of NASH are identical to those of alcoholic hepatitis (including hepatocyte ballooning, presence of Mallory hyaline, and

neutrophil infiltration) but can be attributed to fatty liver disease in those who have no history of heavy alcohol intake. Many individuals with NAFLD have features of the metabolic syndrome (obesity, hypertension, and dyslipidemia). As many as 20%–30% of the population in North America and Europe have NAFLD, making it far and away the most common form of liver disease and an extremely common condition in the developed world. Approximately 10% of those with NAFLD have NASH. Almost half of individuals who meet the criteria for metabolic syndrome have NAFLD. The frequency in obese or diabetic individuals is much higher, with NAFLD in 60% to 75% and NASH in 20% to 25%. Prospective studies of patients with liver disease have confirmed that NASH is a common cause of elevated liver enzymes in an unselected population of patients referred to gastroenterologists or seen in primary care settings. The frequency of cirrhosis in NASH is not well established, but it has been suggested that NASH may be a major cause of cryptogenic cirrhosis. Because weight loss develops with chronic illness, fat may disappear from the liver, leaving only fibrosis.

Current evidence suggests that accumulation of fat in NAFLD is a consequence of insulin resistance. However, the pathogenesis is likely to be more complicated because a variety of other factors lead to increased fat accumulation in the liver, including increased carbohydrate intake, certain drugs, and mutations in lipid synthesis, but they have not been associated with the development of NASH. Laboratory abnormalities may include raised ferritin levels, signs of diabetes, and dyslipidemia.

Autoimmune Hepatitis

AIH represents a rapidly progressive form of chronic hepatitis, with up to 40% 6-month mortality in untreated individuals; it is associated with the presence of autoimmune markers. It is relatively uncommon, with an annual incidence of 1.9 cases per 100,000 population in the United States, but it is responsible for 3% to 6% of all liver transplantations; the disease recurs in approximately 30% of patients after transplantation. As with most autoimmune diseases, there is a strong female predominance. Forms of AIH have been found in individuals of all ages, with no racial or ethnic predilection. It has been associated with specific human leukocyte antigen (HLA) haplotypes, notably DR3 and DR4, as is true for many other autoimmune diseases. For details on autoimmune chronic hepatitis, refer to the AASLD (American Association for the Study of Liver Diseases) practice guidelines.

AIH is associated with the presence of liver and non-liver autoantibodies in plasma. These are helpful in diagnosis but are not likely to be the cause of liver injury. The most important antibodies for diagnosis include antinuclear antibody (ANA), anti-smooth muscle (or anti-actin) antibody (ASMA), anti-liver-kidney microsomal antigen type 1, and anti-soluble liver antigen (SLA), which is insensitive but highly specific. A summary of the most common autoantibodies, their associations, and their molecular targets (when known) are given in [Table 37.5](#). Individuals who are negative

TABLE 37.5 Serologic Markers of Autoimmune Liver Disease

Antibody Name	Antigen Target	Associations
Antiactin	Actin	AIH type 1; more specific than ASMA, poor response to corticosteroids, early age of onset
Anti-asialoglycoprotein receptor	Transmembrane antigen-binding protein	AIH, correlate with activity, disappear with successful treatment
Anti-LKM1	Cytochrome P450 2D6	AIH type 2; seen in only 4% of US cases; usually in children
Anti-liver-specific cytosol	Enzyme (possibly formiminotransferase cyclodeaminase or argininosuccinate lyase)	AIH in younger patients, often with anti-LKM1, primary sclerosing cholangitis; vary with activity of disease
Antimitochondrial antibody	Dihydrolipoamide acyltransferase	Primary biliary cholangitis
Antineutrophil cytoplasmic antibodies	Bactericidal/permeability protein, cathepsin G, lactoferrin	PSC (50%–70%), ulcerative colitis (50%–70%), AIH; nonspecific
Antinuclear antibody	Multiple targets (centromere, ribonucleoproteins); may not be detected by ELISA	AIH type 1, some PSC cases
ASMA	Actin, tubulin, vimentin, desmin, keratin	AIH type 1, seen in other autoimmune diseases in lower titers
Antisoluble liver antigen/liver pancreas	UGA tRNA suppressor-associated transfer protein	AIH type 3; specific for AIH, correlate with relapse after corticosteroid withdrawal

AIH, Autoimmune hepatitis; ASMA, anti-smooth muscle antigen; ELISA, enzyme-linked immunosorbent assay; LKM1, liver-kidney microsome; PSC, primary sclerosing cholangitis.

for common autoantibodies, but who otherwise meet criteria for diagnosis, have a similar prognosis and response to treatment.

Inherited Liver Disease Presenting as Chronic Hepatitis

Inherited liver diseases that present as chronic hepatitis are relatively uncommon but important to recognize and include hemochromatosis, Wilson disease, and AAT deficiency.

Hemochromatosis. Hereditary hemochromatosis (HH) is an autosomal recessive disorder of iron metabolism that results in excessive iron absorption and accumulation in tissues, specifically in the parenchymal cells of the liver, heart, pancreas, and other organs HH is caused by mutations in the *HFE* gene that affect any of the proteins that control the entry of iron into the circulation. These proteins include **hepcidin**, HFE, transferrin receptor 2 (Tfr2), hemojuvelin (HJV) (these proteins all sense iron accumulation that hepcidin acts to correct) and the protein ferroportin (Fpn), which is a cellular transporter of iron down-regulated by hepcidin (for more detail refer to [Chapter 28](#)).

HH is primarily a disease in men and postmenopausal women with common clinical features, including lethargy and weakness, arthralgia, loss of libido, upper abdominal discomfort, hepatomegaly, grey/bronze skin pigmentation, testicular atrophy, and joint swelling and/or tenderness. Untreated, HH can lead to serious complications, including liver fibrosis and cirrhosis with HCC in approximately 30% of patients with cirrhosis, diabetes mellitus, and cardiomyopathy, and arrhythmias.

Liver disease due to hemochromatosis becomes more common after the age of 30 years. Liver function tests are frequently normal in asymptomatic patients. The most useful tests are fasting transferrin saturation and serum ferritin. A transferrin saturation value more than 45% is the most

sensitive marker of early iron overload, but neither a raised fasting transferrin saturation nor ferritin concentration is diagnostic of HH. Ferritin is also an acute-phase reactant and can be raised nonspecifically in the presence of alcohol consumption, NAFLD, other liver disease and any systemic inflammatory condition. Serum ferritin is considered to be abnormal when it is more than 250 µg/L in premenopausal women and more than 300 µg/L in men and postmenopausal women. *HFE* gene testing can be used to confirm that diagnosis of HH and to evaluate familial risks. Cirrhosis is unlikely if the ferritin is less than 1000 µg/L, plasma AST activities are normal, and there is no hepatomegaly. Cirrhotic patients rarely regress to normal and have a lifelong risk of HCC.

Wilson disease. **Wilson disease** is an autosomal recessive disorder of copper metabolism. It has a gene frequency of 1 in 200 and a disease frequency of 1 in 30,000. It is due to mutations in a gene on chromosome 13 that codes for a copper-transporting adenosine triphosphatase (ATP7B) found mainly in the liver and involved in movement of copper into bile; deficiency leads to accumulation of copper in the liver and eventually in other tissues.

Wilson disease usually manifests at age younger than 30 years. Patients usually present either with the hepatic or the neuropsychiatric form of the disease. Hepatic involvement tends to predominate in children, whereas in adolescents and adults, the neuropsychiatric form becomes more common. Patients presenting with neuropsychiatric manifestations commonly have advanced liver disease at presentation, whereas those presenting with liver disease may have little in the way of neurologic damage. An important presentation to recognize is antibody negative hemolytic anemia resulting from hepatic release of copper into the circulation. Several laboratory tests are available for the diagnosis of Wilson disease; ceruloplasmin (see [Chapter 18](#)) and copper

measurement (see [Chapter 27](#)). Classic findings of Wilson disease include decreased plasma ceruloplasmin, decreased total plasma copper, increased plasma-free (or non-ceruloplasmin) copper, increased urine copper excretion, and increased hepatic copper content. Ceruloplasmin is a ferroxidase that typically is measured by enzymatic activity or by immunoassay. Controversy is ongoing over which assay format is preferable, and guidelines have not specified one type. Molecular diagnosis is complicated by the numerous gene mutations known to cause Wilson disease.

α_1 -antitrypsin deficiency. AAT is the most important of the serine protease inhibitors (collectively termed serpins; see also [Chapter 18](#)). AAT inhibits trypsin and other proteolytic enzymes, including neutrophil-derived elastase, cathepsin G, and proteinase 3. The gene for AAT (*SERPINA1*) is located on chromosome 14. Several genetic variants of AAT (differing by a single amino acid) have been classified on the basis of their electrophoretic mobility; the slowest migrating of these was termed the Z variant. The most severe forms of disease have been associated with homozygosity for the Z variant, which is found in 1 in 1000 to 2000 individuals in Europe and North America. However, it is estimated that only approximately 10% of those with AAT deficiency develop clinical disease.

The effects of AAT deficiency on the liver are controversial. In neonates, AAT deficiency is often associated with hepatitis, with up to 25% 1-year mortality. However, in those who survive the first year, evidence of liver injury diminishes and usually resolves by age 12 years.

AAT is estimated by protein electrophoresis, in which it constitutes most of the α_1 -globulin band. It can also be quantified by a variety of other techniques. Determination of phenotype was typically accomplished by isoelectric focusing and had been recommended as the diagnostic test of choice in one guideline, but phenotyping cannot distinguish true homozygotes from heterozygotes who have a null genotype on the other *SERPINA1* gene. Molecular tests are now available to determine *SERPINA1* genotype. Because the prognosis may vary between those who are actually homozygous for the Z variant and those with null phenotype, molecular testing of the *SERPINA1* gene is considered preferable.

Drug-Induced Liver Injury

As discussed earlier, most cases of **drug-induced liver injury (DILI)** present as acute hepatitis. Less commonly, drugs have produced chronic liver injury in a pattern that mimics chronic hepatitis or other chronic liver injury (chronic cholestasis and hepatic granulomas). The drugs most commonly linked to chronic hepatitis are nitrofurantoin, methyldopa, and hydroxy-3-methylglutaryl-coenzyme-A (CoA) reductase inhibitors; however, a large number of drugs have been associated with liver injury, and herbal medications have been linked to chronic hepatitis. In individuals with increased activities of aminotransferases and no obvious cause, prescription drug use was significantly more likely to be present than in those with a known cause for elevated enzyme activities. As with acute drug reactions, establishing drugs as the

cause of chronic hepatitis is difficult; temporal relationships to drug ingestion are not as clear as with acute hepatitis, and reactions can be seen first in those who have been taking the medication for many months. Most chronic drug reactions resolve when administration of the drug is discontinued.

POINTS TO REMEMBER

Most Common Causes of Chronic Liver Disease

Alcohol
Fatty liver disease
Chronic viral hepatitis B or hepatitis C

AT A GLANCE

Causes of Chronic Liver Disease

Often the cause of chronic liver disease is not immediately obvious. In this situation, a systematic approach to differential diagnosis should be taken, gathering history, and the findings of clinical examination, and blood and urine tests, as well as imaging and biopsy.

The following etiologies of chronic liver disease should be considered:

Toxins: alcohol, drugs

Viruses: HBV, HCV

Metabolic liver diseases: fatty liver disease, hemochromatosis, AAT deficiency, Wilson disease

Immune-mediated liver diseases: AIH, PBC, primary sclerosing cholangitis

Infiltration of the liver

Tumors: benign and malignant (primary, secondary)

Cirrhosis

Cirrhosis, which is defined anatomically as diffuse fibrosis with nodular regeneration, represents the end stage of scar formation and regeneration in chronic liver injury. Fibrosis is the common response to all forms of liver injury. Common causes of cirrhosis and their therapies are listed in [Table 37.6](#). Virtually all chronic liver diseases are known to lead to cirrhosis (see [Fig. 37.6](#)).

In the early stages of cirrhosis when the functions of the damaged liver are sufficiently well preserved (termed compensated cirrhosis), no signs or symptoms of liver damage may be present. Laboratory abnormalities usually appear before clinical findings, such as **ascites**, gynecomastia, palmar erythema, and portal hypertension develop. The earliest laboratory abnormalities to develop in cirrhosis are a fall in platelet count, an increase in PT, a decrease in the plasma albumin-to-globulin concentration ratio to less than 1, and an increase in the AST/ALT activity ratio to more than 1. In general, cirrhosis progresses to decompensation slowly, at a rate of approximately 3% per year; 10-year survival with compensated cirrhosis is 90%. Once decompensation occurs, 10-year survival is only approximately 20%. However, prognosis varies with etiology and may be influenced dramatically by response to treatment (as is the case in viral hepatitis B and C) or by abstinence from alcohol in **alcoholic liver disease**. Jaundice is a late finding in decompensated cirrhosis. Plasma

TABLE 37.6 Causes and Treatment of Cirrhosis

Cause	Treatment
Viral	
Hepatitis B	Administration of nucleoside or nucleotide HBV DNA polymerase inhibitors or pegylated α -interferon
Hepatitis C	Directly acting antiviral inhibitors of HCV
Toxic	
Alcohol	Abstinence, liver transplantation
Metabolic	
Hemochromatosis	Phlebotomy
Wilson disease	Penicillamine, zinc trientine
α_1 -antitrypsin deficiency	Gene therapy, protein administration
Nonalcoholic fatty liver disease	Diet, exercise, insulin sensitizers
Biliary	
Primary biliary cholangitis	Ursodeoxycholic acid, obeticholic acid
Primary sclerosing cholangitis	Liver transplantation
Autoimmune hepatitis	Corticosteroids, azathioprine, other immunosuppressants
Idiopathic	Consider immunosuppression
Advanced cirrhosis, irrespective of cause	Liver transplantation

HBV, Hepatitis B virus; HCV, hepatitis C virus.

TABLE 37.7 Child-Pugh System for Classifying Severity of Cirrhosis

Feature	1 Point	2 Points	3 Points
Encephalopathy	None	Grade 1–2	Grade 3–4
Ascites	None	Slight	Moderate-severe
Albumin, g/dL	>3.5	2.8–3.5	<2.8
Prothrombin time, seconds prolonged	<4	4–6	>6
Bilirubin, mg/dL (μ mol/L)	<4 (<68)	4–10 (68–170)	>10 (>170)

Scoring: <7 points: class A; 7 to 9 points: class B; >9 points: class C.

activities of aminotransferases are variable in cirrhosis and reflect underlying necroinflammatory activity. Clinical scales for assessing cirrhosis in widespread use include the Child-Pugh system (Table 37.7). Current thinking advocates the concept of “acute on chronic” liver failure in which acute exacerbations of liver disease due to any one of a variety of causes may cause acute worsening of liver function in cirrhosis. Tests commonly used for the assessment of hepatic function are summarized in Table 37.8.

TABLE 37.8 Tests of Hepatic Function and Injury

Test	Utility
Bilirubin	Diagnosing jaundice, modest correlation with severity
Alkaline phosphatase	Diagnosing disorders of metabolism and disorders of the newborn
Bilirubin fractionation	Diagnosing cholestasis and space-occupying lesions
AST	Sensitive test of hepatocellular disease; AST > ALT in alcoholic disease
ALT	Sensitive and more specific test of hepatocellular disease
γ -Glutamyltransferase	Prognostic indicator for increased cardiovascular and all-cause mortality
Albumin	Indicator of chronicity and severity
Prothrombin time	Indicator of severity of cholestasis

ALT, Alanine aminotransferase; AST, aspartate aminotransferase.

Biomarkers of Fibrosis

Due to the limitations of liver biopsy, several noninvasive methods have been developed to detect progressive liver fibrosis and stage liver disease. Over the past two decades, numerous serum markers or biomarkers have been identified and described. In contrast to a liver biopsy, biomarkers are less invasive, with minimal associated procedural morbidity. Serum biomarkers of fibrosis can be categorized into direct serum markers (measuring parameters directly related to both the fibrolytic and fibrogenic processes involved in liver matrix turnover) and indirect serum markers (combinations of serum parameters that are related to liver function, including AST and ALT).

Direct Biomarkers

Direct biomarkers exhibit biologic plausibility because they represent alterations of extracellular matrix (ECM) composition that occur during hepatic fibrosis. Combinations of direct biomarkers can result in superior diagnostic performance for the detection of fibrosis compared with their constituent components. The Enhanced Liver Fibrosis (ELF) test is a combination of hyaluronic acid (HA), tissue inhibitor of matrix metalloproteinase 1, and the amino terminal fragment of procollagen III that has been validated for the detection of fibrosis in a variety of liver diseases, including viral hepatitis B and C, NAFLD in children and adults, and PBC and **primary sclerosing cholangitis (PSC)**.

Indirect biomarkers. By contrast, indirect biomarkers reflect parameters that are altered because of changes in hepatic function that arise in the context of a particular stage of liver fibrosis. Indirect biomarkers include biochemical or hematologic variables that are synthesized or regulated by the liver (e.g., clotting factors, cholesterol, and bilirubin), or indicate inflammation (e.g., aminotransferases). Hitherto, the AST-to-platelet ratio index (APRI) has been one of the most

studied indirect biomarkers of liver fibrosis. The AST-to-platelet ratio is calculated by dividing AST by the URL of AST (for the sex of the patient) and the platelet count and multiplying by 100. Another indirect biomarker is Fib-4, which is a combination of AST, ALT, age, and platelet count.

Hybrid biomarkers. Indirect biomarkers can also be combined with direct biomarkers to form combination or hybrid biomarkers. Fibrometer is a hybrid biomarker that uses age, platelets, prothrombin index, AST, α_2 -macroglobulin, HA, and urea. Hepascore is a combination of bilirubin, GGT, HA, α_2 -macroglobulin, age, and sex. Fibrotest is a combination of GGT, bilirubin, haptoglobin, α_2 -macroglobulin, apolipoprotein A1, age, and sex.

Hepatic Glycogenoses

The glycogenoses are a group of rare inherited disorders that are characterized by excessive and/or aberrant glycogen storage in various tissues. All are transmitted as autosomal recessive traits, except for type IV, which is sex linked. The hepatic glycogen storage diseases and their enzyme defects are discussed in more detail in [Chapter 22](#).

Cholestatic Liver Disease

Cholestasis (stoppage or suppression of the flow of bile) is characterized by retention of bile within the excretory system. The term obstruction is often used inappropriately, because cholestasis frequently occurs without mechanical obstruction to the biliary tract, as with many drug reactions. Mechanical obstruction must always be excluded with imaging in the first instance before other causes are considered. The major cholestatic diseases include mechanical obstruction of the bile ducts, PBC, and PSC. There are specific types of cholestasis that can occur in pregnancy; these are discussed in [Chapter 44](#).

Mechanical Bile Duct Obstruction

The most common cause of cholestasis is biliary tract obstruction by space-occupying lesions. Extrahepatic bile duct obstruction occurs most commonly as the result of gallstones in the common bile duct or because of tumors in the head of the pancreas or duodenum. Other causes of extrahepatic obstruction include (1) bile duct strictures, (2) extrinsic compression of the bile ducts by enlarged lymph nodes, (3) congenital biliary atresia, and (4) PSC. Extrahepatic obstruction is commonly associated with jaundice, especially when obstruction is complete. Transient increases in aminotransferases are more common with choledocholithiasis than with other causes of extrahepatic obstruction. Transient increases in carbohydrate antigen (CA) 19-9 occur with bile duct obstruction; this is an important consideration because CA 19-9 is often used as a diagnostic test for pancreatic and bile duct carcinoma (for more details see [Chapter 20](#) on tumor markers).

Intrahepatic cholestasis caused by mechanical obstruction is also common but is rarely associated with jaundice or with visibly dilated ducts on imaging studies, although it may be

associated with increased direct bilirubin. The commonest cause is drug-induced cholestasis, but viral infections can also cause intrahepatic cholestasis. Obstructive intrahepatic cholestasis leads to jaundice with lesions that are large or are located near the porta hepatis, where they may obstruct both hepatic ducts. Common causes of intrahepatic obstruction include tumors (particularly metastases), granulomatous diseases (such as sarcoidosis and tuberculosis), and infiltrative processes (such as lymphoma, leukemia, and extramedullary hematopoiesis).

Primary Biliary Cholangitis (PBC, Formerly Primary Biliary Cirrhosis)

PBC, or nonsuppurative destructive cholangitis, is an uncommon autoimmune disorder that targets intrahepatic bile ducts. Its prevalence is approximately 2 to 8 per 100,000 population in the developed world but is much lower in developing areas. The median age at onset is 50 years, and the female-to-male ratio is approximately 6:1. An association with HLA class II antigen DR8 has been noted in some populations. A family history of PBC is seen in 1% to 4% of cases. In up to 80% of cases, the condition is associated with other autoimmune processes, most commonly [Sjögren syndrome](#) and hypothyroidism (which often develops before the onset of PBC).

The pathogenesis of PBC is not well understood. However, it is known that destruction of the bile duct is mediated by T cells in the presence of upregulation of HLA class I antigens on hepatocytes and HLA class II antigens on biliary epithelial cells. At least 95% of patients have antimitochondrial antibodies that react against the dihydrolipoamide acyltransferase component of the pyruvate decarboxylase complex. Part of this complex is found on the apical surface of biliary epithelial cells, suggesting a role for this antigen as an immune target. In individuals with coexisting Sjögren syndrome, the antigen is also expressed on the surface of salivary gland cells.

Biochemical tests and direct markers of liver fibrosis have been studied as surrogate markers of disease severity and prognostic markers of survival in PBC. Of these, the ELF test (see earlier section on direct biomarkers of liver fibrosis) has been shown to be the most accurate in determining prognosis.

Primary Sclerosing Cholangitis

PSC is a chronic inflammatory disease of the biliary tree that most commonly affects the extrahepatic bile ducts; involvement of intrahepatic ducts, with extrahepatic involvement or as an isolated finding, is also possible. In contrast to PBC, PSC has a male predominance (60% to 70%) and a younger median age at onset (30 years). In 70% to 90% of patients, PSC is associated with ulcerative colitis, which usually (but not always) precedes onset of PSC; conversely, only approximately 2% to 4% of patients with ulcerative colitis develop PSC. This has led to speculation that bacterial antigens in portal blood might be involved in the pathogenesis of PSC.

An autoimmune component is likely because 97% of patients with PSC have one or more autoantibodies present in their plasma. The prevalence of PSC is similar to that of PBC, but it is most common in Northern Europe, where PSC is the most common indication for liver transplantation. A markedly increased prevalence of HLA antigens B8 and DR3 has been noted.

Drug-Induced Cholestasis

Drugs are a common cause of cholestasis, causing approximately 15% of cases. Drug reactions are especially common in older individuals, among whom up to 50% of individuals have increased enzymes because of medications. Nonmedicinal drugs are also increasingly recognized as a cause of cholestasis. Drugs can cause a cholestatic picture by two major mechanisms. In some cases, only conjugated bilirubin is increased, whereas canalicular enzymes are not elevated. This picture, which is often seen with estrogen and anabolic steroids, appears to be due to inhibition of production of the multidrug resistance protein-2, an ATP-binding cassette (ABC) transporter that transports drug-conjugates and divalent bile salt conjugates into bile. More commonly, drugs induce a cholestatic hepatitis, as discussed earlier. The National Institutes of Health website, <http://livertox.nih.gov>, and reviews provide further information and excellent support in the investigation of suspected drug-induced liver toxicity.

Gallstones

Gallstones are solid formations in the gallbladder that are composed of cholesterol and bile salts. Although they vary in chemical composition, they generally contain a mixture of cholesterol, bilirubin, calcium, and mucoproteins. In the United States, 70% to 85% of all gallstones are predominantly cholesterol, and more than 10% of the adult population is affected.

Three major types of gallstones are cholesterol, pigmented, and, the most common, mixed. These stones form whenever bile is supersaturated with cholesterol or unconjugated bilirubin. Whenever an increase in cholesterol or a decrease in bile acids or lecithin occurs, bile becomes lithogenic and cholesterol may precipitate. Factors that predispose to cholesterol hypersecretion include obesity, aging, certain drugs such as clofibrate and nicotine, and certain hormones such as estrogen. Factors that decrease bile acid secretion include terminal ileal disease and cholestatic diseases, such as PBC, PSC, and cystic fibrosis. Genetic factors also appear to be involved. Within racial groups, women are more frequently affected than men. Diet may play a role because it appears that people who ingest diets high in polyunsaturated fats have a higher incidence, whereas those with a diet high in fiber have a decreased incidence.

Pigmented gallstones are associated with conditions in which the bilirubin concentration is increased, such as hemolytic anemia, or when bilirubin becomes insoluble (i.e., deconjugated), such as occurs in cholestasis or chronic biliary infection.

Hepatic Tumors

The liver is host to a wide variety of benign and malignant primary tumors. It is the second most common site of metastases; metastatic tumors account for 90% to 95% of all hepatic malignancies. Primary tumors may arise from many cell lines in the liver, but they arise most commonly from parenchymal and biliary epithelial cells and from mesenchymal cells. The two most important primary liver tumors are HCC and cholangiocarcinoma.

Hepatocellular Carcinoma

HCC is the fifth most common cancer worldwide and a leading cause of cancer death; more than 500,000 cases occur annually, with a similar number of deaths. Wide geographic and ethnic variations are noted in the incidence, suggesting that both host and environmental factors are involved in its origin. Seventy-five percent of HCC cases occur in Asia, with an annual incidence of HCC in China of approximately 30 cases per 100,000 males. Worldwide, the incidence is twofold to threefold higher among men than among women. The incidence of HCC has been increasing in the United States and much of Europe because of the increasing frequency of cirrhosis caused by HCV; however, incidence has declined in many parts of the world because of the success in prevention of infection by HBV. Although cirrhosis is present in most patients with HCC, it is absent in approximately 25% to 30% of cases, often in association with HBV. More importantly, the presence of cirrhosis had been recognized before diagnosis of HCC in only one-third of cases. The incidence of HCC in cirrhosis varies greatly with the cause of cirrhosis, but viral hepatitis B and/or C is the commonest cause worldwide.

The tumor marker most widely used for screening purposes is alpha-fetoprotein (AFP); it is typically quantified using assays that measure its total concentration. Although it appears to be relatively sensitive, elevation of AFP is common in individuals with chronic hepatitis and cirrhosis, which is the group at highest risk for HCC.

LIVER TRANSPLANTATION

Clinical biochemistry, as part of the multidisciplinary transplant team, plays an important role in the management of patients before and after transplantation. Algorithms incorporating biochemical and other clinical parameters have been developed for the assessment of the need for transplantation in patients with acute and chronic liver disease. These include the Child-Pugh-Turcotte, **Model for End-Stage Liver Disease (MELD) Score**, and United Kingdom End-stage Liver Disease Score classifications. Post transplantation, the main focus of management is on detecting graft failure, organ rejection, and monitoring the efficacy of immunosuppression. Laboratories are closely involved in monitoring liver enzymes, tests of hepatic synthetic function, therapeutic drug monitoring, and monitoring for viruses, including recurrence of HBV or HCV and CMV, which may complicate the course of recovery in immune-suppressed patients.

REVIEW QUESTIONS

- In the liver, bilirubin is conjugated to:
 - vinyl groups.
 - methyl groups.
 - hydroxyl groups.
 - glucuronide.
- Functions of the liver include the synthesis of all of the following *except*:
 - albumin.
 - immunoglobulins.
 - glycogen.
 - coagulation factors.
- In the liver, the small grooves between adjacent hepatocytes that carry bile to the gallbladder are the:
 - cords.
 - canaliculi.
 - lobules.
 - sinusoids.
- Hepatocellular carcinoma (HCC) can be directly related to:
 - an acute viral hepatitis infection.
 - cholestasis.
 - a chronic hepatitis B infection.
 - the synthetic function of the liver.
- Which type of viral hepatitis is usually spread parenterally by transfusion, shared needles, or dialysis and is considered the most common chronic viral infection in North America?
 - Hepatitis B
 - Hepatitis C
 - Hepatitis A
 - Cirrhosis
- Laboratory tests that are initially run to determine the presence of any liver disease include:
 - liver enzymes only.
 - viral antigens and antibodies, serum cholesterol.
 - hepatitis antigens and antibodies, coagulation times, and serum proteins.
 - bilirubin, liver enzymes, prothrombin time (PT), and albumin.
- Blockage of the bile ducts or blockage of bile flow from within the liver due to inflammation will stop normal bile flow. This is referred to as:
 - hepatitis.
 - hepatocellular carcinoma (HCC).
 - cholestasis.
 - cirrhosis.
- A genetic disorder that is associated with elevated amounts of copper in the liver and other tissues and leads to decreased ceruloplasmin concentration in blood is:
 - Wilson disease.
 - Reye syndrome.
 - cholestasis.
 - autoimmune hepatitis.
- A woman visits her physician with symptoms of jaundice, hepatic pain, and chalky-appearing stools. Lab values indicate elevated conjugated bilirubin, alkaline phosphatase (ALP) and γ -glutamyltransferase (GGT). These findings are most likely due to:
 - hemolytic anemia.
 - ineffective erythropoiesis.
 - cholestasis due to gallstones.
 - Reye syndrome.
- The type of portal hypertension seen in the majority of cases is sinusoidal hypertension, which is most commonly caused by:
 - blockage of the portal veins.
 - hepatic vein occlusion.
 - congestive heart failure.
 - cirrhosis.

Gastric, Pancreatic, and Intestinal Function

Roy A. Sherwood, Natalie E. Walsham, Ingvar Bjarnason

OBJECTIVES

1. Define the following terms:
 - Digestion
 - Absorption
 - *Helicobacter pylori*
 - Celiac disease
 - Steatorrhea
 - Diarrhea
2. List and describe the three phases of digestion.
3. Describe the structure and function of the stomach, intestinal tract, and pancreas.
4. List the main enzymes involved in the digestion of carbohydrates, fats, and proteins.
5. List the tests used to investigate possible celiac disease, lactase deficiency, and bacterial overgrowth and describe the test principles.
6. State the use of the following tests:
 - Serum gastrin
 - Fecal elastase
 - Antibodies against tissue transglutaminase
 - Fecal calprotectin

KEY WORDS AND DEFINITIONS

Acute pancreatitis An acute episode of destruction of the pancreas due to the release of active pancreatic enzymes into pancreatic tissue.

Breath tests Tests that detect products of bacterial metabolism in the gut or products of human metabolism by measuring compounds in breath.

Celiac disease A disease caused by the destructive interaction of gluten with intestinal mucosa causing malabsorption.

Chronic pancreatitis An inflammatory disease characterized by persistent and progressive destruction of the pancreas.

Crohn disease A chronic inflammatory bowel disease that may affect any part of the digestive tract.

Cystic fibrosis An inherited disease caused by genetic alteration of a transmembrane conductance regulator protein (CFTR) that can lead to chronic pancreatitis and pulmonary disease.

Diarrhea The passage of liquid stools more than three times daily and/or a stool weight greater than 200 g/day.

Digestion The conversion of food in the intestines into compounds capable of being absorbed.

Gastrin A group of peptide hormones secreted by gastrointestinal mucosal cells that stimulates the production of acid.

Gastritis Inflammation of the mucosa of the stomach.

Helicobacter pylori A bacterium found in the stomach that can be associated with inflammation.

Lactose intolerance A condition due to lactase deficiency leading to the malabsorption of lactose resulting in symptoms following consumption of foods containing lactose.

Malabsorption An abnormality in the absorption of nutrients.

Maldigestion An abnormality of the digestive process due to dysfunction of the pancreas or small intestine.

Steatorrhea A condition of excessive fat in feces.

Ulcerative colitis An inflammatory bowel disease predominantly localized to the large intestine.

INTRODUCTION TO THE ANATOMY AND PHYSIOLOGY OF THE GASTROINTESTINAL TRACT

The major organs of the gastrointestinal (GI) tract include the stomach, small and large intestines, pancreas, liver (see [Chapter 37](#)), and gallbladder, all of which are involved in the digestive processes that commence with the ingestion of food and water and culminate with the excretion of waste products as feces.

Anatomy

The GI tract is a hollow tube approximately 8 m in length beginning with the mouth and ending with the anus. The esophagus, which is approximately 25 cm in length, is a muscular tube connecting the pharynx to the stomach. The laboratory has little role in the investigation of disorders of the esophagus.

Stomach

The stomach consists of three major zones: the cardiac zone, the body, and the pyloric zone (Fig. 38.1). The upper cardiac zone includes the fundus and contains mucus and pepsinogen II-secreting surface epithelial cells and endocrine secreting cells. The body of the stomach contains cells of many different types: surface epithelial cells that secrete mucus, parietal cells that secrete hydrochloric acid and intrinsic factor, chief cells that secrete groups I and II pepsinogens, enterochromaffin cells that secrete serotonin, and other endocrine cells. The pyloric zone is subdivided into the antrum (approximately the distal third of the stomach), the pyloric canal, and the sphincter. The cells of the pyloric zone secrete mucus, group II pepsinogens, serotonin, and **gastrin**, but not hydrochloric acid. In the stomach, food is converted into a semifluid, homogeneous material (chyme) that passes through the pyloric sphincter into the small intestine.

Small Intestine

The small intestine consists of three parts: the duodenum, jejunum, and ileum. In adults, the small intestine is approximately 6 m in length and its cross section decreases as it proceeds distally. The duodenum is approximately 25 cm long and is the shortest part of the small intestine. The jejunum and ileum make up the remainder of the small intestine, with the ileum constituting the distal 3.5 m.

The wall of the small intestine consists of four layers: mucosa, submucosa, muscular layer, and serosa/adventitia. The internal surface of the upper part of the small intestine contains valve-like circular folds (valvulae conniventes or plicae circulares) that project 3 to 10 mm into the lumen. Covering the entire mucous surface are small (1-mm) finger-like projections (villi). The luminal surface of each epithelial cell consists of some 1700 microvilli projecting approximately 1 μ m from

the cell. The folds, villi, and microvilli increase the absorptive surface area 600-fold to approximately 250 m², comparable to the area of a doubles lawn tennis court.

Large Intestine

The large intestine is approximately 1.5 m in length, extending from the ileum to the anus and including the cecum, appendix, colon, rectum, and anal canal. The cecum is a blind pouch that begins the large intestine; it is connected to the terminal ileum via the ileocecal sphincter (or valve). The colon is approximately 1 m long and is divided into the ascending, transverse, descending, and sigmoid sections. The sigmoid colon connects to the rectum, which is approximately 15 cm long and connects to the anal canal.

Pancreas

The pancreas is 12 to 15 cm long and lies across the posterior wall of the abdominal cavity. The head is located in the duodenal curve, with the body and tail extending to the left to the spleen (Fig. 38.2). The pancreas secretes a juice containing digestive enzymes and bicarbonate; this enters the duodenum through the ampulla of Vater and the sphincter of Oddi to mix with the bolus of food coming from the stomach.

Phases of Digestion

The processes of **digestion** can be divided into neurogenic, gastric, and intestinal phases.

Neurogenic Phase

The neurogenic, or cephalic, phase is initiated by the intake of food into the mouth; the sight, smell, and taste of food stimulates the cerebral cortex and subsequently the vagal nuclei.

Fig. 38.1 Schematic drawing of the stomach with major zones.

Fig. 38.2 Cross section through the pancreas.

Gastric Phase

When food enters the stomach, the resulting distention initiates the gastric phase of digestion, which is mediated by local and vagal reflexes. Hydrochloric acid release is caused by direct vagal stimulation of the parietal cells, local distention of the antrum, and vagal stimulation of antral cells to secrete gastrin, which in turn stimulates the release of hydrochloric acid from parietal cells and release of gastrin stimulated by the near neutralization (pH 5.0 to 7.0) of the stomach contents entering the pyloric zone. Gastrin also stimulates antral motility, the secretion of pepsinogens and of pancreatic fluid rich in enzymes, and the release of hormones such as secretin, insulin, acetylcholine, somatostatin, and pancreatic polypeptide. As a result of the acid environment, pepsinogen is rapidly converted to the active proteolytic enzyme pepsin. Food is mixed by contractions of the stomach and is partially degraded into chyme by the chemical secretions of the stomach. The pylorus plays a role in emptying chyme into the duodenum by virtue of its strong musculature.

Intestinal Phase

The intestinal phase of digestion begins when the weakly acidic digestive products of proteins enter the duodenum. Many hormones and other regulatory peptides are released by both neural and local stimulation and act within the GI tract to regulate digestion and absorption. Digestion, absorption, and storage functions are stimulated or inhibited by different hormones, creating a control system that regulates the action of intestinal hormones and provides for the secretion of bile acids, bicarbonate, and numerous enzymes involved in the digestion of food.

During the intestinal phase, carbohydrates, proteins, and fats are broken down and absorbed. Most nutrients, including vitamins and minerals, have been absorbed by the time the food passes from the jejunum and ileum into the large intestine. In the large intestine, water is actively absorbed, electrolyte balance is regulated, and bacterial actions take place. These processes result in the formation of feces.

Processes of Digestion and Absorption

The total quantity of fluid absorbed each day by the gut is estimated to be approximately 9 L, which is composed of 2 L oral intake, 1.5 L saliva, 2.5 L gastric juice, 0.5 L bile, 1.5 L pancreatic juice, and 1 L intestinal secretions. More than 90% of this fluid is absorbed in the small intestine. The maximal absorptive capacity for fluid is probably at least 20 L. Several hundred grams of carbohydrates, 100 g of fat, and 50 to 100 g of amino acids are absorbed daily in the small gut, but the maximal absorptive capacity may be 10 times higher. This considerable reserve capacity may explain the lack of symptoms from mild disease processes. The efficiency of absorption is due to the unique features of the absorptive surface of the bowel and the relationship of the epithelial cells to the underlying rich vascular plexus and the lymphatic vessels.

Digestion of food starts in the mouth through the action of salivary amylase and lingual lipase, but it principally takes place both within the lumen of the small intestine and at the

mucosal (brush-border) surface. Defects of digestion may occur at one or more stages of this process. The terms **mal-digestion** and **malabsorption** refer to different functional abnormalities. *Maldigestion* is a dysfunction of the digestive process that may occur at various sites in the GI tract. For example, a reduction in the acidity in the stomach will reduce peptic digestion of protein, whereas hyperacidity of the duodenum can inactivate pancreatic enzymes; loss of brush-border enzymes in the small intestine can prevent oligosaccharides and disaccharides from being further hydrolyzed; and pancreatic insufficiency will reduce intraluminal enzyme activity in the small gut, causing maldigestion of fats and proteins. Inherited disorders of the exocrine pancreas can cause maldigestion by causing pancreatic insufficiency secondary to chronic pancreatic inflammation. In contrast, malabsorption is strictly a dysfunction of the absorptive process in the small gut resulting from a reduction in the size of the absorptive surface caused by responses to factors including gluten, inflammation, infection, surgical resection, and infiltration. Various transport defects also lead to malabsorption of specific substances (e.g., glucose-galactose malabsorption, and zinc deficiency in the congenital disorder acrodermatitis enteropathica). In clinical practice, however, the term *malabsorption* is often used to encompass all aspects of impaired digestion and absorption.

In the following sections, the digestion and absorption of carbohydrates, fats, and proteins is discussed separately. It must be remembered, however, that a complex interplay takes place among nutrients, regulatory peptides, enzymes, gallbladder and pancreatic function, and bowel motility, leading to an integrated absorptive process that commences with the ingestion of food and culminates in the excretion of feces.

Digestion and Absorption of Carbohydrates

After the salivary and pancreatic α -amylases have acted on dietary starch and glycogen, the carbohydrate content of the small intestine will consist of newly formed maltose; ingested monosaccharides; dietary disaccharides such as lactose, sucrose, maltose, and trehalose; oligosaccharides such as dextrans and maltotriose; and indigestible oligosaccharides and polysaccharides such as cellulose, agar, and other dietary fibers.

The brush-border enzymes with disaccharidase and oligosaccharidase activity are listed in [Table 38.1](#). The sucrase-isomaltase complex comprises most (80%) of the sucrase, isomaltase, and maltase activity of the small intestine. It hydrolyzes sucrose to its constituent monosaccharides, cleaves glucose from α -limit dextrans with 1,6 bonds, and hydrolyzes maltose. The activity of the complex is four- to fivefold greater in the jejunum than the ileum. Changes in diet have a marked effect on the expression of the complex; starvation leads to a rapid decline in activity that is quickly restored on refeeding. Secretion of all small intestinal saccharidases may decrease with infection or inflammation of the small bowel to the extent that carbohydrate malabsorption occurs, leading to **diarrhea**, flatulence, and weight loss.

TABLE 38.1 Brush-Border Oligosaccharidases

Enzyme	Principal Substrate	Products
Lactase (EC 3.2.1.23)	Lactose	Glucose + galactose
Sucrase (EC 3.2.1.48)	Maltose/sucrose	Glucose or fructose + glucose
Isomaltase (EC 3.2.1.10)	1,6- α -linkages in Isomaltose and α -dextrins	Glucose
	Maltose	Glucose
Trehalase (EC 3.2.1.28)	Trehalose	Glucose
Glucoamylase complex (EC 3.2.1.20)		
Glucoamylase (maltase)-1 and glucoamylase (maltase)-2 (have similar substrate specificities)	1,4- α -linkages at nonreducing ends of amylose, amylopectin, glycogen, and straight-chain 1,4- α -glucopyranosyl oligomers, including maltose	Glucose

From Semenza, G., Auricchio, S., & Mantei, N. (2001). Small-intestinal disaccharidases. In C. R. Scriver, A. L. Beaudet, W. S. Sly, & D. Valle (Eds.), *The metabolic and molecular bases of inherited disease* (8th ed., pp. 1623–1650). New York: McGraw-Hill.

The lactase–phlorizin hydrolase complex is the only brush-border enzyme able to hydrolyze lactose and is therefore essential for the survival of mammals early in life. Infectious and inflammatory diseases greatly reduce lactase–phlorizin hydrolase activity, leading to symptomatic intolerance to milk (bloating, abdominal pain, diarrhea, and flatulence). The developmental regulation of lactase is discussed later, in the section on disaccharidase deficiencies. Also present in the brush-border is the α -glucosidase maltase-glucoamylase, which removes individual glucose molecules from the nonreducing end of α (1,4)-oligosaccharides and disaccharides. This enzyme accounts for approximately 20% of the total maltase activity of the small intestine. Trehalase is also found in the brush-border of the small intestine and hydrolyzes trehalose, an α (1,1)-disaccharide of glucose found in yeast and mushrooms. The developmental pattern of trehalase appears to follow that of sucrase-isomaltase.

In addition to their actions on disaccharides, the brush-border enzymes further hydrolyze the products of amylase action, including maltose, maltotriose, and α -limit dextrins. The brush-border enzymes appear to act in an integrated manner in that a flow of substrate occurs from glucoamylase and isomaltase to sucrose, producing the monosaccharides glucose, galactose, and fructose. These monosaccharides are transported into enterocytes by the sodium-dependent glucose (and galactose) transporter (SGLT1) and the GLUT5 transporter, which transports fructose across the apical membrane of the enterocyte. Absorbed glucose and fructose are transported across the basolateral membrane, out of the enterocyte, and into the portal system by the GLUT2 transporter.

Carbohydrate digestion in the small intestine is not always complete. Up to 10% of ingested starch and sucrose can pass undigested and unabsorbed into the colon. It has been estimated that colonic bacteria require 70 g of carbohydrate per day. Much of this is derived from endogenous sources, such as glycoproteins from GI secretions, with the remainder coming from unabsorbed dietary carbohydrate and dietary fiber. Bacterial action creates short-chain fatty acids that are rapidly absorbed by the colonic mucosa and are thought to provide fuel for the colonocytes. Starch and oligosaccharides are osmotically active; they draw water into the gut and retain

luminal fluidity. The colon, however, can absorb up to four times the normal colonic water load; for this reason diarrhea is not always present in oligosaccharide malabsorption.

Digestion and Absorption of Lipids

The recommended daily fat intake in Europe and North America is 70 to 85 g. Less than 5 g/24 h is recoverable in feces, indicating the overall efficiency of the normal processes of fat digestion and absorption. Most dietary fat is in the form of long-chain triacylglycerols (triglycerides). Pancreatic lipase is quantitatively the most important hydrolytic enzyme, but the contribution of gastric lipase to overall hydrolysis should not be underestimated. Gastric lipase is secreted by the gastric mucosa and normally accounts for up to 17.5% of fatty acids released from triglycerides following a meal. Lipase has a wide pH optimum and is active in both the stomach and duodenum. This nonpancreatic lipase may have a significant role in lipid digestion when pancreatic function is impaired and in the neonatal period before pancreatic lipase activity is fully developed. A lingual lipase is also produced but is thought to be of little significance in humans.

Fats are first emulsified in the stomach by its churning action and are stabilized by interaction with luminal lecithin and protein fragments. The lingual and gastric lipases do not require bile salts or cofactors for their action; they have a pH optimum of 3 to 6, and their action produces 1,2-diacylglycerols and fatty acids. These products further stabilize the surface of the triglyceride emulsion and in the duodenum promote the binding of pancreatic colipase. In addition, the liberated fatty acids stimulate release of cholecystokinin (CCK) from the duodenal mucosa.

In the presence of bile salts and colipase, pancreatic lipase acts at the oil-water interface of the triglyceride emulsion to produce fatty acids and 2-monoacylglycerols. Colipase is secreted by the pancreas as an inactive proenzyme and is then activated by trypsin. Other significant enzymes involved in the breakdown of fats are cholesterol ester hydrolase, phospholipase A2, and a nonspecific bile salt-activated lipase.

Only a small proportion of ingested triacylglycerol is completely hydrolyzed to glycerol and fatty acids. These products form micelles with bile salts and lysophosphoglycerides; the micelles convey the nonpolar lipid molecules from the lumen

Fig. 38.3 Summary of the processes involved in fat absorption and malabsorption. (From Clark, M. L., & Silk, D. B. [2005]. Gastrointestinal disease. In P. Kumar, & M. Clark [Eds.], *Clinical medicine* [6th ed., pp. 265–345]. Edinburgh: Saunders.)

to the epithelial cell surface and dissociate there to produce a high concentration of monoglycerols, lysophosphoglycerides, and fatty acids, which partition into the mucosal cell. Absorption involves both passive and active transport processes and is facilitated by a fatty acid-binding protein in the cytosol of the cell that has a high affinity for fatty acids. Within the cell, triacylglycerols are resynthesized from the absorbed 2-monoacylglycerols and fatty acids. The triacylglycerols— together with phospholipids, cholesterol and its ester, fat-soluble vitamins, and apolipoprotein B-48—are formed into chylomicrons that are then released by exocytosis into the lymphatic system of the small bowel. The absorption of long-chain fatty acids is facilitated by transmembrane fatty acid transport proteins.

From the lymphatic system, chylomicrons enter the bloodstream via the thoracic duct and are distributed to the liver, adipose tissue, and other organs. Medium- and short-chain fatty acids (chain length <12 carbon atoms) in mixed triglycerides are preferentially split by lipases and pass into the aqueous phase, from which they are rapidly absorbed. Medium-chain triglycerides can be absorbed without complete lipolysis and in the absence of bile. They do not require micellar solubilization and are transported from the intestinal epithelial cells predominantly via the hepatic portal vein. Fig. 38.3 summarizes the processes involved in fat absorption and conditions that compromise the efficiency of one or more stages in these processes that can result in fat malabsorption.

Digestion and Absorption of Proteins

The average daily intake of protein in developed countries is approximately 100 g, compared with an estimated requirement for adults of 50 to 70 g. Another 50 to 60 g of protein

enters the intestinal tract daily in GI secretions and from desquamated mucosal cells. Normal daily fecal loss of protein is about 10 g.

Protein digestion is initiated in the stomach by the action of pepsin in a highly acidic medium. The acidity also helps denature dietary proteins, unfolding the polypeptide chains for better access by the gastric, pancreatic, and intestinal proteolytic enzymes. The polypeptides and amino acids produced in the stomach by the action of pepsin are potent secretagogues for hormones that stimulate the pancreas and intestine. Stimulated pancreatic secretion contains proenzyme forms of the proteolytic enzymes trypsin, chymotrypsin, elastase, exopeptidases, and carboxypeptidases. Proteolytic enzymes may be endopeptidases (e.g., pepsin, trypsin, chymotrypsin, elastase), which hydrolyze peptide bonds within the polypeptide chain, or exopeptidases, which hydrolyze peptide bonds of the terminal amino acids (e.g., carboxypeptidase, aminopeptidase). Stimulation of the intestine by GI hormones liberates several proteolytic enzymes from the brush-border. One of them, enterokinase, selectively cleaves a hexapeptide from the N-terminus of trypsinogen to form trypsin. Trypsin then activates more trypsin (autocatalysis) and also converts other pancreatic proenzymes into their active forms. The action of the pancreatic enzymes on partially digested proteins within the lumen produces peptides that are 2 to 6 amino acid residues in length as well as single amino acids. The peptides are largely hydrolyzed to single amino acids by the aminopeptidases and dipeptidases of the brush-border before absorption, although some dipeptides and tripeptides are absorbed and hydrolyzed to amino acids by cytosolic peptidases within the enterocytes. Multiple carrier systems with overlapping specificities for the 20 essential amino acids are involved in the transport of amino acids into cells. Absorption of amino acids

by these transport systems is faster in the jejunum than the ileum. The amino acids pass across the enterocyte basolateral membrane by passive diffusion as well as by active transport systems, which are distinct from those at the brush-border membrane. The rich vascular plexus is drained by the portal circulation, and it is by this route that absorbed amino acids reach the liver and then the systemic circulation.

Mucosal diseases may affect protein assimilation through a number of mechanisms. Reduction in the number of mucosal cells decreases peptidase activity in the intestine and the absorptive capacity for amino acids. Disease may increase the turnover of intestinal cells and their rate of desquamation. This cell loss, together with increased losses of plasma proteins from the damaged intestinal surface, can cause a negative nitrogen balance. Surgical resection of the intestine not only reduces the total absorptive surface area but may also remove a segment of the gut that is specialized for the absorption of certain nutrients (e.g., resection of the distal ileum removes the active transport system for vitamin B₁₂-intrinsic factor complex). Resection may also alter intestinal motility, leading to stasis and bacterial overgrowth, which can intensify a negative nitrogen balance. Also, rare hereditary defects in amino acid transporters (e.g., Hartnup disease) may produce distinct syndromes.

STOMACH: DISEASES AND LABORATORY INVESTIGATIONS

Growth in endoscopic procedures, with direct visualization of the interior of the stomach, has largely removed the need for the laboratory to carry out investigation of gastric contents. Situations remain, however, in which the laboratory continues to play a role in diagnosing gastric diseases and in monitoring the effectiveness of treatment.

Helicobacter pylori

In 1985, an association was made between the presence of a spiral-shaped bacterium, *Helicobacter pylori*, and peptic ulcer diseases. *H. pylori* is now accepted to be the predominant cause of gastric and duodenal ulcers, the remainder being associated with the long-term use of nonsteroidal antiinflammatory drugs (NSAIDs) and, rarely, gastrinomas. Estimates suggest that *H. pylori* is present in the mucus layer of the stomach in half the world's population. Some 30% to 50% of adults in Europe and at least 20% of adults in the United States are infected with the bacterium. Chronic infection produces an inflammatory response (**gastritis**) and carries an increased risk for developing a peptic ulcer (3- to 10-fold) and/or adenocarcinoma (2- to 10-fold). Up to 90% of gastric cancer patients are infected with *H. pylori*, compared with 40% to 60% of age-matched controls. *H. pylori* may cause dyspepsia in the absence of an ulcer, and current recommendations suggest a low threshold for testing for *H. pylori*; some advocate treatment without testing.

The mode of transmission of *H. pylori* is unclear. In many cases the infection appears to originate in childhood, presumably by the fecal-oral route, because the prevalence is higher in

developing countries and is inversely related to food hygiene. Almost all individuals infected with *H. pylori* develop chronic gastritis, but only 10% of cases manifest as peptic ulcers. *H. pylori* infection predominantly affects the gastric mucosa, with the antrum usually the most densely colonized area. At least 95% of patients with duodenal ulcers have *H. pylori* infection, and eradication of the organism results in healing of the ulcer and a reduction in relapse rates.

H. pylori produces urease, and hydrolysis of this endogenously produced urea to bicarbonate and ammonia may create a more hospitable environment for the survival of the organism in the stomach. This ability of *H. pylori* to hydrolyze urea forms the basis of urea **breath tests** and direct urease tests on gastric biopsy samples.

Diagnostic Tests for *Helicobacter pylori*

In theory it would be possible to carry out endoscopy on all patients who have symptoms that could be associated with *H. pylori* infection, but in the real world this is not practical, nor would it be acceptable to the patient population. Numerous invasive and noninvasive diagnostic tests for *H. pylori* have been described (**Box 38.1**) and many have been reviewed.

At gastroduodenoscopy, biopsies can be taken from the gastric mucosa in the antrum or body of the stomach from which the organism can be visually detected or cultured. False-negative results may also occur when biopsies are taken during treatment with proton pump inhibitors (PPIs) or within 2 weeks of stopping PPI therapy, because these drugs alter the intragastric distribution of *H. pylori* and suppress its activity. PPIs can also lead to false-negative urea breath test results. Histamine (H₂)-receptor antagonists should be stopped at least 24 hours before a breath test. Antacids do not affect the test results. Commercially available kits can be used to identify *H. pylori* in gastric biopsy samples. These are based on a gel that incorporates urea and an indicator that changes color at an alkaline pH. The action of urease present in *H. pylori* cleaves the urea to bicarbonate and ammonia, raising the pH and inducing a color change in the indicator.

BOX 38.1 Diagnostic Tests for *Helicobacter pylori*

Invasive Tests: Using Gastric Mucosal Biopsy Samples

- Histology: microscopy after Giemsa or silver staining
- Histology: microscopy after immunohistochemical staining
- Direct urease test: biopsy included in urea/indicator solution—visual end point
- Culture: incubation in suitable media for 4 to 10 days
- Polymerase chain reaction: amplification of specific DNA sequences

Noninvasive Tests: Using Breath, Blood, Saliva, or Feces

- Breath tests: rise in ¹⁴CO₂ or ¹³CO₂ after ingestion of ¹⁴C- or ¹³C-labeled urea
- Serum, saliva, or feces tests: detection of IgG antibody or *H. pylori* antigen

Tests for *H. pylori* are required for the diagnosis of infection and in some situations to ascertain whether eradication therapy has been successful. High sensitivity is required to ensure that positive findings are not missed; similarly, high specificity is essential to prevent inappropriate use of eradication therapy. The Maastricht III Consensus Guidelines recommend a “test and treat” strategy, using a breath test or stool antigen test, in adults with appropriate dyspeptic symptoms who are younger than 45 years of age. The age limit may vary depending on local prevalence and the age distribution of gastric cancer. Successful eradication of *H. pylori* should be confirmed with the urea breath test or by a monoclonal antibody–based stool antigen test if urea breath tests are not available. Testing to confirm eradication should be done at least 4 weeks after completion of the course of treatment.

The urea breath test for *H. pylori* is currently the most widely used method for the noninvasive diagnosis of infection. Urea labeled with carbon-13 is given orally as a drink or a capsule. *H. pylori* rapidly hydrolyzes the urea to produce labeled bicarbonate, which is absorbed into the bloodstream and broken down to be exhaled as $^{13}\text{CO}_2$. In the absence of urease, the urea is absorbed intact and excreted by the kidney. Breath samples are collected before and 45 to 60 minutes after drinking the labeled urea. The detection of labeled carbon, which is not radioactive, is usually carried out by mass spectrometry. The breath test has sensitivity and specificity for *H. pylori* in excess of 95% and can be used both for diagnosis and to assess the success of eradication therapy.

Serologic methods are available to detect *H. pylori*–specific antibodies (immunoglobulin G [IgG] or IgA), but they have some drawbacks compared with the urea breath test. The systemic antibody response is variable, with equivocal results often occurring in subjects above 50 years of age. The sensitivity (92%) and specificity (83%) are also lower than those for the breath test. Serologic tests cannot be used to confirm eradication of the bacterium because of the persistence of the antibodies for variable periods after completion of treatment. Point-of-care devices exist to detect *H. pylori* antibodies, but current evidence is that these perform poorly in terms of both sensitivity and specificity and cannot be recommended. These tests may be useful in specific situations, such as when PPI therapy cannot be withheld because of ulcers that are bleeding.

H. pylori is shed in feces, and several tests have been described that can detect the organism. Polyclonal or monoclonal antibodies to *H. pylori* can be configured into various immunoassay formats, although sensitivity and specificity are lower than for breath tests. Commercial kits are available that use the polymerase chain reaction to amplify nuclear sequences specific for *H. pylori* in feces (or saliva); they have a sensitivity and specificity of 95% and 94%, respectively. In time, stool tests for *H. pylori* may replace the urea breath test, particularly in assessing whether eradication has been successful.

POINTS TO REMEMBER

Helicobacter pylori

- *H. pylori* is the predominant cause of gastric and duodenal ulcers.
- There is an increased risk for gastric cancer with *H. pylori* infection.
- The urea breath test is useful in the diagnosis of *H. pylori* infection.
- Tests based on serologic/molecular techniques are available to detect *H. pylori* in blood or feces.

Gastric Acid Secretion and Gastrinomas

Before the discovery of the role of *H. pylori*, patients with gastric or duodenal ulcers were often tested for hyperacidity of the stomach, either in the basal state or after stimulation. Patients with duodenal ulcers are typically hypersecretors of acid, whereas those with peptic ulcers are more often normal or low secretors, but there was significant overlap between the two groups of patients. Collection of gastric juice and analysis of acid output was at one time extensively carried out in the investigation of possible gastrinomas. This invasive technique has now been replaced by the greater availability of plasma gastrin measurements, endoscopy, and imaging modalities, including computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET), and octreotide scanning.

Gastrin

Three molecular forms of gastrin occur in blood and tissues: G-34, G-17, and G-14. Gastrins originate from the cleavage of a single precursor, preprogastrin—a peptide consisting of 101 amino acids. The smallest peptide sequence of gastrin possessing biologic activity is the carboxy-terminal tetrapeptide (G-4), but it is only 10% to 20% as potent as G-17. A synthetic pentapeptide (pentagastrin) was used in the past to stimulate acid secretion for collection and analysis, but it is rarely used now.

Gastrin is produced and stored mainly by endocrine cells (G cells) of the antral mucosa and to a lesser extent by G cells of the proximal duodenum and Δ cells of the pancreatic islets. After secretion, gastrin is transported by the blood through the liver to the parietal cells of the fundus of the stomach, where it stimulates the secretion of gastric acid. Gastrin also stimulates secretion of gastric pepsinogens and intrinsic factor by the gastric mucosa, release of secretin from the small intestinal mucosa, and secretion of pancreatic bicarbonate and enzymes and hepatic bile; it increases gastric and intestinal motility, mucosal growth, and blood flow to the stomach. It is secreted in response to antral distention from food and by the presence of amino acids, peptides, and polypeptides in the stomach from partially digested proteins. Other stimuli of gastrin include alcohol, caffeine, insulin-induced hypoglycemia, and calcium.

Maximal secretion of gastrin occurs at an antral pH of 5 to 7. At pH 2.5, the secretion of gastrin is reduced by approximately 80%, with maximal suppression occurring at pH 1.

Secretion is inhibited by the direct action of acid on the G cells. This negative feedback prevents excess acid production regardless of the stimulant.

Gastrinoma and the Zollinger-Ellison Syndrome

In 1955, Zollinger and Ellison described a syndrome consisting of multiple peptic ulcers, gastric hypersecretion, and non- β islet cell tumors of the pancreas secreting gastrin. Gastrinomas are a rare cause (<0.5%) of gastroduodenal ulcers. The persistently high circulating gastrin concentrations lead to the hypersecretion of gastric acid and increased parietal cell mass, as the hormone is trophic to parietal cells. Most cases occur between the ages of 30 and 50 years, although the condition has been reported in patients as young as 7 and as old as 90 years of age. It is more common in men (60% of cases) than in women.

Symptoms may be those of *H. pylori* peptic ulcer disease, but they can also include diarrhea (secondary to inactivation of pancreatic enzymes in the acidic environment). Duodenal ulceration and ulcers resistant to standard therapies must be considered suspicious. Gastrinomas are most often sporadic, but they may also be associated with multiple endocrine neoplasia type 1 (MEN1, Wermer syndrome—see Chapter 20), a syndrome characterized by the presence of two or more tumors sited in the pituitary, parathyroid glands, or pancreas.

Gastrinomas are commonly located in the pancreas, but they can arise from the stomach, duodenum, or other tissues. They are more often (60%) malignant than benign, with metastases frequently present at the time of diagnosis. Measurement of plasma gastrin in a fasting sample is the initial step in aiding the differential diagnosis. A mildly elevated plasma gastrin concentration may be observed in long-term PPI therapy, hypochlorhydria, pernicious anemia, and G-cell hyperplasia. *H. pylori* infection can also lead to increased plasma gastrin and in some cases atrophic gastritis. Increases in plasma gastrin in chronic renal failure appear to be related to the severity of renal impairment.

Fasting plasma gastrin concentrations in the Zollinger-Ellison syndrome are usually markedly increased, and a concentration of more than 10 times the upper reference limit in the presence of gastric acid hypersecretion is virtually diagnostic of a gastrinoma. No correlation has been observed between the severity of symptoms and the extent of plasma gastrin elevation. However, the fasting plasma gastrin concentration at presentation in sporadic gastrinomas is related to the extent of tumor burden and the presence of hepatic metastases; it is therefore of prognostic value.

Measurement of Plasma Gastrin

In plasma from healthy subjects, the predominant forms of gastrin are amidated G-34 and G-17. In patients with gastrinomas, the gastrins found in the circulation display unpredictable heterogeneity with a shift toward larger peptides. For the detection of gastrinomas, the assay should detect all secreted forms of gastrin to prevent false-negative findings. Gastrin is unstable in serum or plasma, and samples may lose up to 50% of their immunoreactivity over 48 hours at 2°C to

8°C because of the action of proteolytic enzymes. Blood samples should be collected in tubes containing an anticoagulant and a protease inhibitor (e.g., aprotinin) to prevent degradation. Samples should be processed rapidly and the plasma stored at -20°C until assayed.

INTESTINAL DISORDERS AND THEIR LABORATORY INVESTIGATION

This section includes discussion of celiac disease, disaccharidase deficiency, bacterial overgrowth, bile salt malabsorption, inflammatory bowel disease (IBD), and protein-losing enteropathy and the main laboratory investigations associated with the diagnosis and monitoring of these disorders.

Celiac Disease

Pathophysiology of Celiac Disease

Celiac disease occurs in genetically predisposed subjects as a consequence of an inappropriate T cell-mediated immune response to ingestion of gluten from wheat and to similar proteins in barley and rye. The external trigger to the development of celiac disease in genetically susceptible individuals is found in gluten, which is the complex group of proteins found in wheat and other grains.

The identification in 1997 of small bowel tissue transglutaminase as the autoantigen of celiac disease has led to a greater understanding of the pathogenesis of the condition. The tissue transglutaminases are a family of calcium-dependent enzymes released from cells during wound healing. They catalyze the cross-linking or deamidation of proteins leading to stabilization of the wound area. Deamidation of gliadin peptides enhances their binding to HLA DQ2/DQ8 and increases recognition of these peptides by gut-derived T cells from subjects with celiac disease. The characteristic enteropathy is then induced by the release of interferon- γ and other proinflammatory cytokines.

A 33-amino acid peptide of gluten appears to be the primary initiator of the inflammatory response. It is resistant to breakdown by all gastric, pancreatic, and brush-border membrane proteases, thus allowing it to reach the small intestine intact. The peptide can be detoxified by exposure to a bacterial prolyl endopeptidase, suggesting a therapeutic strategy for celiac disease.

Increased intestinal permeability in untreated celiac disease that is reversible on withdrawal of gluten from the diet has been recognized since the early 1980s. Evidence suggests that this increase in paracellular permeability may be mediated by increased expression of zonulin, a protein that opens small intestinal tight junctions, or by decreased expression of intercellular epithelial cell adhesion molecules such as ZO-1, catenin, and cadherin. The zonulin pathway is now thought to play a significant role in the entry of allergens into cells and hence in the autoimmune response.

Clinical Considerations

Celiac disease is a common disorder in Caucasian populations with a prevalence of approximately 1%, but it also occurs

in northern Indian and North African populations. It is rare among people of Chinese, Japanese, and African Caribbean origin.

A wide spectrum of clinical manifestations of celiac disease is seen, with most diagnoses being made in adult life. Classic celiac disease—manifesting in infancy with failure to thrive, abdominal distention, and diarrhea—is now uncommon in developed countries. Most adults present with non-specific symptoms; the condition may be picked up during the investigation of patients suspected of having irritable bowel syndrome (IBS). Mild iron deficiency is common. The initial presentation may be to a wide range of clinical specialties (Table 38.2). A strong association with other autoimmune diseases, especially type 1 diabetes and autoimmune thyroid disease, has been reported. In type 1 diabetes, the prevalence of celiac disease is approximately 5% and serologic screening to detect these cases has been advocated.

Tests for Celiac Disease

Appropriately standardized serologic tests have high clinical sensitivity and specificity for diagnosis and monitoring of compliance with a gluten-free diet. Table 38.3 compares the sensitivity and specificity of the serologic tests commonly used for the diagnosis of celiac disease.

Historically serologic testing for celiac disease involved testing for antigliadin antibodies and antiendomysial antibodies by indirect immunofluorescence. The sensitivity and specificity of these tests was poor; they have largely been superseded by measurement of antibodies against tissue transglutaminase (TGA) and deaminated gliadin peptide (DGP). Both IgG

and IgA tests are available for these antibodies as quantitative enzyme-linked immunosorbent assays (ELISAs). The diagnostic accuracy of DGP-IgA is similar to that of TGA-IgA, with sensitivities of 85% to 90% and a specificity of approximately 95%. Sensitivity for DGP-IgG is not as good as that for DGP-IgA but has a specificity approaching 99%. Subjects with selective IgA deficiency (plasma IgA concentration <0.05 g/L, incidence ~1 in 600) are at greater risk for celiac disease. The tests directed at the IgA antibodies to TGA and DGP may produce false-negative results in patients with IgA deficiency; total IgA measurement should be considered in requesting serologic tests for celiac disease. When IgA deficiency is identified, the IgG-based tests should be used to confirm or exclude a diagnosis of celiac disease. No current recommendations suggest that DGP-based tests should replace tests based on TGA antibodies, but their use is increasingly supported in both adult and pediatric populations. The response to gluten withdrawal can be assessed clinically, by serologic tests, or by endoscopic or wireless capsule techniques. Endoscopic biopsies are considered the gold standard but are invasive and expensive, and they are now less frequently used for this purpose.

Strict adherence to a gluten-free diet leads to mucosal healing in celiac disease and reduces the risk for bowel malignancy (small bowel lymphoma). TGA can be used as a marker for monitoring dietary adherence in addition to its diagnostic role. Failure of symptoms to respond to a prescribed gluten-free diet may indicate nonadherence to the diet, other coexisting conditions such as small bowel overgrowth, **lactose intolerance**, microscopic colitis, or the presence of refractory celiac disease. This last is characterized by persistent villous atrophy with an increase in intraepithelial lymphocytes in the small bowel while the patient is on a strict long-term gluten-free diet. In both responsive and refractory celiac disease, antibody titers are typically decreased with dietary therapy and remain within reference intervals unless individuals are reexposed to gluten.

Disaccharidase Deficiencies

The presence of the brush-border disaccharidases is essential for carbohydrate absorption; a reduction in their activity leads to carbohydrate malabsorption and intolerance. Carbohydrate malabsorption can result in osmotic diarrhea with abdominal pain and distention and flatulence resembling the symptoms of IBS. Inherited disorders of sucrase-isomaltase and of transport proteins causing glucose-galactose malabsorption and fructose malabsorption have been described but are rare. Adult lactase deficiency is common in humans; in many Asian populations it is the normal state.

TABLE 38.2 Sample of Clinical Specialties to Which a Child or Adult With Celiac Disease May Present

Clinical Specialty	Symptoms/Manifestations
General medicine	Tired all the time
Gastroenterology	Diarrhea, flatulence, weight loss
Hematology	Anemia
Obstetrics/gynecology	Infertility
Orthopedics	Fracture, osteopenia
Dermatology	Dermatitis herpetiformis, hyperkeratosis
Neurology	Peripheral neuropathy
Rheumatology	Arthropathy
Endocrinology	Short stature, thyroid disease
Diabetes	Diarrhea, anemia

TABLE 38.3 Comparison of Serologic Tests for Celiac Disease

Antibody	Method	Sensitivity (%)	Specificity (%)
IgA-endomysial antibody	Immunofluorescence on monkey esophagus or human umbilical cord	80–100	>99
IgA-antigliadin antibody	Quantitative ELISA	75–95	95
IgA-antitissue transglutaminase antibody	Quantitative ELISA	>90	>99
IgA-deamidated gliadin peptide antibody	Quantitative ELISA	90	90

ELISA, Enzyme-linked immunosorbent assay; IgA, immunoglobulin A.

TABLE 38.4 Prevalence of Hypolactasia in Adults

Racial Group	Prevalence (%)
Chinese	>90
African Americans	54–81
Asians	60–90
Greeks	60–78
North Europeans	5–30

BOX 38.2 Methods for Detecting Lactase Deficiency

- Lactase in mucosal biopsy
- Oral lactose tolerance
 - Measure increase in plasma glucose or galactose
 - Measure increase in breath H_2 or $^{13}CO_2$
 - Measure urinary excretion of lactose after oral load

Lactase Deficiency

Lactase activity has its highest prevalence in the earliest months of life and declines after weaning. The prevalence of lactase deficiency varies widely with ethnic origin; although only 5% to 15% of northern Europeans are lactase-deficient, hypolactasia or alactasia can be found in more than 70% of individuals of African and Asian origin (Table 38.4). Congenital lactase deficiency is a very rare disorder that becomes apparent once the infant has been exposed to milk feeds. Stools have a low pH and contain large amounts of lactose and glucose, the latter being produced by bacterial degradation of undigested lactose. Secondary lactase deficiency is common in celiac disease owing to villous atrophy, but it may also occur in tropical sprue, small bowel Crohn disease (CD), radiation enteritis, giardiasis and other bowel infections, chronic alcoholism with malnutrition, and the enteropathy associated with acquired immunodeficiency syndrome (AIDS).

Tests for Lactase Deficiency

Many methods have been proposed for the diagnosis of lactase deficiency (Box 38.2). Disaccharidase activities can be measured in jejunal biopsies, although this is rare in routine practice. The xylose absorption test was first introduced as a test for carbohydrate malabsorption in the 1930s. In humans, D-xylose, a pentose sugar of plant origin, is absorbed by a passive mechanism in the jejunum. After an oral dose of D-xylose, it can be measured in blood or urine samples. It is now accepted that the amount of xylose excreted is affected not just by reduced absorption in the gut but also by renal, hepatic, and cardiac disease, and the test has largely been superseded by the hydrogen breath test. Oral lactose tolerance tests, measuring the increase in plasma glucose after ingestion of lactose, have been used to diagnose lactase deficiency. The usual dose of lactose is 50 g, but lower doses should be used in children (2 g/kg up to a maximum of 50 g). Blood samples are taken over a 2-hour period and the peak increment in glucose

is recorded; a rise greater than 1.1 mmol/L (20 mg/dL) for capillary samples or greater than 1.4 mmol/L (>25 mg/dL) for venous plasma excludes lactase deficiency.

Hydrogen Breath Tests

Hydrogen is not a normal end product of mammalian metabolism, and hydrogen in breath is derived from bacterial metabolism in the intestinal tract. After lactose ingestion, the disaccharide is normally broken down into its constituent monosaccharides, which are absorbed. In the presence of lactase deficiency, unabsorbed disaccharide passes into the large bowel, where bacteria act, producing hydrogen that is absorbed into the systemic circulation and subsequently exhaled. Breath hydrogen can be measured by a variety of techniques based on the electrochemical detection of hydrogen; both laboratory and handheld point-of-care devices are available. Fasting breath hydrogen is normally less than 5 ppm (5 μ L/L), and concentrations greater than 20 ppm (20 μ L/L) at 2 hours after oral administration of 50 g lactose in adults (2 g/kg up to a maximum of 50 g in children) are suggestive of malabsorption or bacterial overgrowth. A lower cutoff of 10 ppm (10 μ L/L) has been suggested that can improve diagnostic sensitivity without altering specificity. In some individuals (estimated at 2% to 13%), the large bowel bacteria do not produce hydrogen and fasting breath hydrogen will be low; in such individuals a normal result cannot exclude lactase deficiency. A positive breath hydrogen result after ingestion of lactose also may occur in glucose-galactose malabsorption; this can be confirmed or excluded by repeating the test substituting 25 g each of glucose and galactose for the lactose. An increase in breath hydrogen confirms the diagnosis. Lactose intolerance or malabsorption has become a very topical issue with clinicians as well as dieticians and nutritionists. Many of these have abandoned any measurements to confirm malabsorption-maldigestion and simply rely on exacerbation of symptoms with the ingestion of a pint of milk. Alternatively, the diagnosis is based on symptomatic improvement when patients are placed on a dairy-free diet.

Bacterial Overgrowth

The proximal small intestine (duodenum and jejunum) normally contains few bacteria. Most ingested bacteria do not survive the acidic environment of the stomach; therefore few live organisms enter the small bowel. The motility of the jejunum prevents fecal-type organisms from progressing up into the jejunum from the cecum. The ileum normally contains some fecal-type bacteria. Colonization of the upper small bowel is described as bacterial overgrowth and usually occurs as a consequence of other abnormalities (structural or motility disorders) of the small intestine. Gastric hypochlorhydria (associated with the use of PPIs) may contribute to bacterial overgrowth. Abnormalities in the systemic immune system (e.g., isolated IgA deficiency, hypogammaglobulinemia, combined immunodeficiency, infection with the human immunodeficiency virus [HIV]) can result in bacterial overgrowth. Impaired motility, pancreatic insufficiency, intrinsic small bowel disease, or surgically induced blind loops are often associated with bacterial overgrowth.

Small bowel bacterial overgrowth can be asymptomatic or associated with nonspecific symptoms that include abdominal distention, flatulence, and diarrhea resembling IBS. Bacteria colonizing the small bowel (e.g., *Escherichia coli* and *Bacteroides* species) deconjugate and dehydroxylate bile salts, resulting in conjugated bile salt deficiency and mild fat malabsorption. Bacterial metabolism of vitamin B₁₂ can occur, leading to deficiency, whereas plasma folate concentration may be increased owing to production by the bacteria.

The gold standard diagnostic procedure is microbiologic examination of small bowel contents, but this is seldom practical. Noninvasive procedures based on oral administration of substances metabolized by bacteria to yield products that can be detected in breath are now the most common tests for bacterial overgrowth, but there is controversy as to which test to use and their sensitivity/specificity.

The ¹⁴C-glycocholate breath test was one of the first tests to be used for noninvasive diagnosis of bacterial overgrowth, but it has been superseded by tests that avoid the use of radioactive isotopes. Small bowel bacterial breath tests in routine use involve test substances labeled with ¹³C and the breath hydrogen tests. Lactulose is not normally absorbed from the small bowel and is therefore available for metabolism by bacteria throughout the gut; alternatively, labeled glucose can be used. In a normal subject, breath hydrogen does not increase until the substrate reaches the large intestine; the time from ingestion to a rise in breath hydrogen is an indicator of small bowel transit time. In bacterial overgrowth, an early rise in breath hydrogen of at least 20 ppm (20 μL/L) is observed within 30 minutes of ingestion. The early increase is diagnostic when it can be distinguished clearly from the later colonic phase. Frequent measurements are essential (e.g., at 5-minute intervals) for the first 30 minutes. The finding of an increased breath hydrogen output has high specificity for bacterial overgrowth but poor sensitivity. Variations in gastric emptying rate and small bowel transit times limit the diagnostic accuracy of the breath tests.

Bile Acid Malabsorption

Bile acids are synthesized in the liver and pass into the lumen of the small bowel via the gallbladder. Bile acids are present in bile as taurine or glycine conjugates; because the pH of bile is slightly alkaline and contains significant amounts of sodium and potassium, most of the bile acids and their conjugates exist as salts (i.e., bile salts). In practice, the terms *bile acids* and *bile salts* are frequently used synonymously. Their major function is to act as surface-active agents, forming micelles and facilitating the digestion of triglycerides and the absorption of cholesterol and fat-soluble vitamins. Little reabsorption of bile acids occurs in the proximal small bowel, but normally more than 90% is reabsorbed in the terminal ileum. The bile acids return to the liver via the portal circulation and can be resecreted into bile (enterohepatic circulation). Less than 10% of secreted bile acid is lost in the feces (~0.2 to 0.6 g/24 h).

Bile acid malabsorption leading to chronic diarrhea occurs when ileal disease is present or after resection of the terminal ileum; it may also occur after cholecystectomy and is present

in some patients with IBS. Malabsorption of bile salts produces diarrhea by two different mechanisms. When significant bile salt depletion occurs, the deficiency of intraluminal bile salts leads to fat malabsorption and **steatorrhea**. More commonly, malabsorption of bile salts in the ileum leads to increased concentrations of bile salts in the colon, where they alter water and electrolyte absorption. This leads to net secretion of water into the lumen and diarrhea.

The most widely used test for bile acid malabsorption involves oral administration of the synthetic radiolabeled bile acid selenohomocholytaurine (SeHCAT). Whole-body gamma counting is used to determine the basal level at 1 hour and then repeated at 7 days when in normal subjects more than 15% of the dose is retained. Retention of less than 10% of SeHCAT at 7 days can predict a good response to bile acid sequestrants.

Two blood tests have been proposed as alternatives to SeHCAT to avoid administration of a radioactive substance: fibroblast growth factor-19 (FGF-19) and 7α-hydroxy-4-cholesten-3-one (C4). C4 is the intermediary step between cholesterol and taurocholic acid and reflects the activity of hepatic cholesterol 7α-hydroxylase and therefore, because this is the rate-limiting enzyme, the rate of bile acid synthesis. Bile acid malabsorption is associated with increased plasma concentrations of C4 as hepatic synthesis is upregulated to maintain the pool of circulating bile acids. The presence of bile acids in the ileum has been shown to stimulate the production of FGF-19. Good correlation has been demonstrated between both serum C4 and FGF-19 and SeHCAT.

With growing awareness of the role of bile salt malabsorption in chronic diarrhea in a proportion of patients with IBS or IBD and the therapeutic effectiveness of cholestyramine, measurement of C4 and/or FGF-19 may become routine.

POINTS TO REMEMBER

Malabsorption

- Carbohydrate malabsorption can occur in disaccharidase deficiency.
- Celiac disease causes malabsorption by reduction in the villous surface area.
- Fat malabsorption is associated with exocrine pancreatic insufficiency.
- Fecal elastase is a useful test for exocrine pancreatic insufficiency.

Inflammatory Bowel Disease and Irritable Bowel Syndrome

Intestinal symptoms including abdominal pain or discomfort with diarrhea or constipation are common to both IBD and IBS. IBD includes **ulcerative colitis** (UC) and CD. IBS is a functional bowel disorder for which there is no identifiable pathologic process or known cause. Although IBS may produce symptoms that are sufficient to interfere with daily life, it is seldom associated with serious morbidity. IBS may affect up to 10% to 20% of the adult population in the developed world, with a typical age at presentation of 20 to 30 years and

a female preponderance. The prevalence of UC is approximately 100 to 200 per 100,000 people and of CD approximately 50 to 100 per 100,000 people, with no significant difference between genders. There is, however, a difference in prevalence with ethnic origin, with IBD being more common among Caucasians than individuals of Asian or African origin. Up to 20% of cases of IBD manifest in childhood, although the most common age at presentation is between 15 and 30 years of age. Both UC and CD are chronic conditions that tend to follow a remitting and relapsing course. The prognosis of patients with CD tends to be worse than that of those with UC, although in the latter it is estimated that up to 10% of patients will require surgical intervention within 10 years of diagnosis.

The cause of IBD is not fully understood, but both genetic and environmental factors have been implicated. Genome-wide association studies have identified over 160 susceptibility loci/genes that are significantly associated with IBD. Studies in monozygotic twins, however, have shown a lower than expected concordance rate (15% to 19% for UC, 27% to 50% for CD) if IBD were simply an inherited disorder. It is thought that individuals with a genetic predisposition to IBD need to be exposed to a range of environmental triggers that affect the host's immunity. Tissue damage is a consequence of neutrophil activation and the production of proinflammatory cytokines/chemokines. The success of treatments based on immunosuppressive agents or tumor necrosis factor- α (TNF- α) inhibitors appears to support an immune basis for the development of IBD. Environmental factors implicated in triggering the development of active disease include a protective effect of breast-feeding and an increased risk in patients who have recurrent GI infections or exposure to drug therapy (antibiotics, oral contraceptives, NSAIDs) along with socioeconomic factors, stress, smoking, and diet.

The conventional diagnostic pathway includes a full blood count to detect/exclude anemia, markers of generalized inflammation (erythrocyte sedimentation rate [ESR] and C-reactive protein [CRP]), and serologic testing for celiac disease (see earlier section on tests for celiac disease). In the past 20 years, there have been significant advances in biomarkers that can aid in differentiating IBD from IBS and in monitoring disease activity or response to treatment. Most of these are fecal markers.

Calprotectin

Calprotectin is a member of the S100 family of zinc- and calcium-binding proteins and is a heterodimer of S100A8/9. First discovered in 1980, it accounts for approximately 60% of cytosolic protein in neutrophils. It is also present in monocytes and macrophages at lower concentrations than in neutrophils and may have antimicrobial properties. Any disruption to the mucosal architecture of the GI tract allows neutrophils that accumulate at sites of active inflammation to be released into the lumen and subsequently shed in feces. The fecal concentration of calprotectin has been

shown to correlate well with the gold standard indium-111-labeled granulocyte test and is directly related to the extent of inflammation. Calprotectin appears to be evenly distributed in fecal samples and has reasonable stability at room temperature.

The initial studies of fecal calprotectin were on its ability to differentiate between IBS and IBD. In a study of 602 consecutive referrals from primary care to gastroenterology clinics at King's College Hospital (London, UK) patients had fecal calprotectin measured and were assessed for IBS using the Rome questionnaire. The sensitivity and specificity for calprotectin for the detection of organic disease were 89% and 79%, respectively. Combining calprotectin with the Rome questionnaire had a predictive value approaching 100%.

Several meta-analyses have investigated the value of fecal calprotectin for distinguishing IBD from IBS. The studies included in these meta-analyses may have been biased by preselection of patients in primary care before referral to secondary or tertiary care. A retrospective analysis of data from 946 patients from 48 primary care practices found a sensitivity of 82% and a specificity of 77%. Nevertheless, the (UK) National Institute for Health and Care Excellence (NICE) has recommended the widespread use of calprotectin in general practice to select patients at high risk for having IBD for referral to gastroenterologists, with the vast majority of the rest with IBS (normal calprotectin) remaining in primary care and treated appropriately. The cost savings of this approach are substantial.

Calprotectin has been found to differentiate between active and inactive IBD. The aim of treatment of IBD is currently to secure and maintain remission, with the ultimate aim of achieving mucosal healing. Assessment of treatment efficacy until recently has been based on clinical scores, including the Crohn Disease Activity Index (CDAI) and the Ulcerative Colitis Disease Activity Index (UCDAI), and by changes in ESR and CRP. However, many patients in clinical remission have increased fecal calprotectin concentrations, and it is perhaps these who would benefit from escalation of treatment to achieve mucosal healing. Several studies have demonstrated that a fall in the fecal calprotectin concentration indicates a good response to treatment and that this can precede any clinical response. It has been recommended that fecal calprotectin should be included in the range of tests before consideration of initiating or changing IBD therapy. Various studies have provided data on the use of fecal calprotectin in predicting relapse or recurrence of IBD, and these have been reviewed. Treating the inflammatory component of IBD regardless of symptoms promises to alter the natural history of the disease in a way similar to that seen in rheumatoid arthritis.

Fecal calprotectin is not, however, specific to IBD and is increased in patients with colorectal carcinoma, the chronic use of NSAIDs, bacterial infections, and diverticular disease. Other fecal markers that are undergoing active research include M2-PK, lactoferrin, S100A12, and cationic eosinophilic protein.

ALGORITHM FOR THE USE OF FECAL CALPROTECTIN IN DIFFERENTIATING IRRITABLE BOWEL SYNDROME AND INFLAMMATORY BOWEL DISEASE

Therapeutic Drug Monitoring in Patients With Inflammatory Bowel Disease

The increasing use of thiopurine analogs (azathioprine [AZA] and mercaptopurine [MP]) and the introduction of the anti-tissue necrosis factor (anti-TNF) drugs infliximab (IFX) and adalimumab (ADA) have led to the introduction of the concept of therapeutic drug monitoring (TDM) to gastroenterology. The metabolism of AZA (a prodrug) is complex, involving a number of enzymatic pathways that result in active, inactive, and potentially toxic metabolites. Measurement of red cell thiopurine methyltransferase (TPMT) activity has become a prerequisite before starting patients on AZA therapy because the presence of the low metabolic activity phenotype is a relative contraindication to the use of thiopurine analogs, and those who are heterozygous require a reduced dose. Measurement of the plasma concentration of 6-thioguanine (6-TG) can be used to assess adherence or the adequacy of dosage.

The anti-TNF drugs, particularly IFX and ADA, have proved effective in inducing and maintaining remission in patients with IBD. However, because these drugs are

themselves humanized antibodies against TNF, many patients develop antibodies against them. Simultaneous measurement of the plasma drug concentrations and the antibodies against these drugs has meant that a failure to sustain a beneficial response to anti-TNF therapy can be correctly ascribed to either subtherapeutic drug concentrations or the presence of antidrug antibodies and alternative therapies can be devised and initiated.

Assessment of Functional Small Bowel Length

The amino acid citrulline, which is involved in the urea cycle, is predominantly synthesized in the enterocytes of the small intestine. The short bowel syndrome can be present after major surgical resection of the gut in the treatment of Crohn disease or necrosis. The remaining small bowel length can be estimated at surgery, but this is unreliable at lengths over 50 to 80 cm. Plasma citrulline concentrations have been shown to correlate well with small bowel length and absorption of xylose ($P < .001$), but not with CRP, CDAI, or ESR. Plasma citrulline measurements therefore appear to be a noninvasive

means of assessing small bowel absorptive capacity that is not influenced by intestinal inflammation.

Protein-Losing Enteropathy

Loss of significant quantities of plasma proteins into the bowel lumen and their subsequent excretion in feces is associated with a range of GI disorders. These include IBD, diseases in which the intestinal lymphatics are obstructed (e.g., lymphoma, Whipple disease), and disorders of immune status such as systemic lupus erythematosus and some food allergies.

In the healthy bowel, fecal protein is largely derived from enterocytes shed from the mucosal surface and from intestinal secretions. The normal GI loss of albumin is less than 10% of albumin catabolism, representing a daily loss of less than 1% to 2% of the circulating protein pool. In protein-losing enteropathy, this may increase to 40%, resulting in hypoalbuminemia and edema.

The diagnosis of protein-losing enteropathy should be considered in the investigation of patients with hypoalbuminemia in whom renal loss, liver disease, and malnutrition have been excluded. Methods using the administration of radioactive albumin or dextran are the gold standards but are seldom used now.

Fecal excretion of α_1 -antiprotease inhibitor (AAT) can be used as a marker of GI protein loss. AAT is a 54-kDa glycoprotein (formerly called α_1 -antitrypsin) present in plasma at a concentration of approximately 1.0 to 2.0 g/L that is resistant to degradation in the GI tract. Increased AAT excretion can be found in both small and large bowel disease both in adults and children. Interpretation must be made with knowledge of the plasma AAT concentration because the test is invalid in the presence of low plasma AAT concentrations (e.g., in AAT deficiency or impaired hepatic synthesis).

POINTS TO REMEMBER

Inflammatory Bowel Disease

- Crohn disease and ulcerative colitis are the most common IBDs.
- Fecal calprotectin can help distinguish IBD from IBS.
- Fecal calprotectin is related to disease activity and can predict relapse in IBD.
- Therapeutic drug monitoring is valuable in treating IBD with anti-TNF- α agents

PANCREAS: DISEASE AND ASSESSMENT OF EXOCRINE PANCREATIC FUNCTION

The pancreas plays a central role in the absorptive process for carbohydrates, fats, and proteins. Disorders of the exocrine pancreas therefore are frequently associated with symptoms of malabsorption such as diarrhea or steatorrhea. In this section, pediatric and adult exocrine pancreatic disorders are briefly discussed and tests that can be used to assess exocrine pancreatic function are described. Information on neuroendocrine tumors of the pancreas is

also provided. Textbooks on gastroenterology or medicine provide much greater detail on the clinical aspects of exocrine pancreatic disorder.

Pediatric Disorders of the Exocrine Pancreas

Pancreatic disorders of childhood have been reviewed and are summarized in [Box 38.3](#).

Cystic fibrosis (CF) is the most common severe autosomal recessive disease, with an estimated gene frequency in Western Europe and the United States of between 1:25 and 1:35 and a disease incidence of approximately 1 in 2500 to 1 in 3200. The pathogenesis and diagnosis of CF are described in [Chapter 24](#). Pancreatic insufficiency is present in the neonatal period in 65% of infants with CF, and a further 15% develop it during infancy and early childhood. The 20% who do not develop pancreatic insufficiency have a better prognosis and develop fewer complications.

Measurement of pancreatic elastase-1 in feces (see the following section on noninvasive tests of exocrine function) is considered to be a reliable test for pancreatic insufficiency in infants over the age of 2 weeks with CF and in older children at the time of diagnosis. This test can also be used to detect the onset of pancreatic insufficiency in those previously sufficient.

Recurrent bouts of acute pancreatitis in childhood should arouse a suspicion of a hereditary cause. Two gene defects have been shown to be associated with pancreatitis manifesting in childhood: the cationic trypsinogen gene (*PRSS1*) and the serine protease inhibitor Kazal type 1 (*SPINK1*) gene. The majority of patients with *PRSS1*-related hereditary pancreatitis have a pathogenic mutation in exons 2 or 3 of the *PRSS1* gene. Duplication or triplication of the *PRSS1* gene has been reported

BOX 38.3 Spectrum of Pancreatic Disease in Childhood

Disorders of Morphogenesis

- Annular pancreas, pancreas divisum, pancreatic hypoplasia and agenesis, heterotopic pancreas

Inherited Syndromes Affecting the Pancreas

- Cystic fibrosis
- Schwachman-Diamond syndrome, Johnson-Blizzard syndrome, Pearson bone marrow pancreas syndrome

Gene Mutations Leading to Pancreatic Disease

- Hereditary pancreatitis, cationic trypsinogen gene mutations, trypsin inhibitor gene mutations

Pancreatic Insufficiency Syndrome

- Isolated enzyme deficiencies: lipase, colipase, enterokinase
- Pancreatic insufficiency secondary to other disorders
- Celiac disease

Acquired Pancreatitis in Childhood

- Idiopathic, traumatic, drugs, viral, metabolic, collagen vascular disease, autoimmune, fibrosing, nutritional (trophic)

to cause hereditary pancreatitis. The mechanism is assumed to be inappropriate activation of trypsin with consequent proteolytic action causing cell damage. Approximately 22% of patients with idiopathic pancreatitis have been reported to have at least one copy of the c.101A>G (p.Asn34Ser) mutation in the *SPINK1* gene, compared with approximately 2.5% of the general population. This protease inhibitor is believed to be the principal inhibitor of trypsin and chymotrypsin within the pancreas, and the mutation results in a loss of its inhibitory capacity.

Adult Disorders of the Exocrine Pancreas

The major exocrine pancreatic disorders manifesting in adult life are acute pancreatitis, chronic pancreatitis, and carcinoma of the pancreas. The use of enzyme tests in the diagnosis of acute pancreatitis is discussed in [Chapter 19](#). The causes of pancreatitis are given in [Box 38.4](#).

Chronic pancreatitis is defined by irreversible pancreatic damage, with histologic evidence of inflammation and fibrosis leading to destruction of cells and loss of endocrine and exocrine function. In developed nations, the most common cause is alcohol (60% to 90% of all cases of chronic pancreatitis),

although because only 5% to 15% of heavy drinkers develop the disease, other predisposing factors must be present (e.g., smoking, diet high in fat and protein).

Tests of Exocrine Function of the Pancreas

The predominant exocrine function of the pancreas is the production and secretion of pancreatic juice, which is rich in enzymes and bicarbonate. Normal pancreatic juice is colorless and odorless; it has a pH of 8.0 to 8.3 and a specific gravity of 1.007 to 1.042. The total 24-hour volume secreted may be as high as 3000 mL.

Laboratory tests used to assess exocrine pancreatic function can be divided into invasive and noninvasive categories. Invasive tests require GI tract intubation to allow the collection of pancreatic secretions. Noninvasive tests were developed to avoid the need for intubation, which is uncomfortable for the patient, time-consuming, and therefore expensive. Noninvasive (“tubeless”) tests are simpler to perform but in general lack the sensitivity and specificity of invasive tests, particularly for the diagnosis of mild pancreatic insufficiency.

Invasive Tests of Exocrine Pancreatic Function

In these tests the total volume of pancreatic juice, the concentration of bicarbonate, and activities of the pancreatic enzymes amylase, lipase, and trypsin are measured in duodenal fluid.

The secretin-cholecystokinin test is based on the principle that secretion of pancreatic juice and bicarbonate output are related to the functional mass of the pancreas. After an overnight fast, a tube is sited in the duodenum to permit the collection of pancreatic juices. Secretin (1 U/kg body weight) is given intravenously, and the duodenal fluid is collected at 15-minute intervals for at least 1 hour. Secretin stimulates the secretion of pancreatic juice and bicarbonate. CCK (or the synthetic equivalent, ceruletide, the C-terminal octapeptide sequence of the intact hormone, where the functional activity resides, [Fig. 38.4](#)) can then be given to stimulate the secretion of pancreatic enzymes, allowing a more complete assessment of pancreatic reserve than can be obtained with secretin alone. The secretin-cholecystokinin and secretin-ceruletide tests are considered the gold standard for assessing pancreatic exocrine function. Although seldom used in adults, this test is still used in infants with pancreatic insufficiency to distinguish between CF and Schwachman-Diamond syndrome (pancreatic α -cell aplasia). In the former, mucous plugs reduce pancreatic secretion, but the enzyme concentrations increase in a normal physiologic response to cholecystokinin, whereas in the latter enzyme secretion is absent or minimal.

BOX 38.4 Causes of Pancreatitis in Adults

Acute

- Gallstones
- Alcohol
- Infection (e.g., mumps, Coxsackie B)
- Pancreatic tumors
- Drugs (e.g., azathioprine, estrogens, corticosteroids, didanosine)
- Iatrogenic (e.g., postsurgical, endoscopic retrograde cholangiopancreatography)
- Hyperlipidemias
- Miscellaneous (e.g., trauma, scorpion bite, cardiac surgery)
- Idiopathic

Chronic

- Alcohol
- Tropical (nutritional)
- Hereditary (trypsinogen and inhibitory gene defects, cystic fibrosis)
- Idiopathic
- Trauma
- Hypercalcemia

From Burroughs, A. K., & Westaby, D. (2009). Liver, biliary tract disease and pancreatic disease. In P. Kumar, & M. Clark (Eds.), *Clinical medicine* (7th ed., pp. 319–385). Edinburgh: Saunders.

Noninvasive Tests of Exocrine Pancreatic Function

A range of tubeless tests has been proposed, but none has adequate sensitivity for reliably detecting early pancreatic disease. When malabsorption is present, such tests are of value in confirming or excluding pancreatic disease. Considerable overlap often occurs between results observed in normal individuals and those found in patients with pancreatic disease; this is due mainly to the large functional reserve of the pancreas. It has been estimated that pancreatic insufficiency cannot clearly be demonstrated until at least 50% of the acinar cells have been destroyed. Clinical signs of pancreatic insufficiency often do not appear until 90% of acinar tissue has been destroyed.

The noninvasive tests are based on the reduction in secretion of pancreatic enzymes with measurement of the enzymes in feces (chymotrypsin or elastase) or detection of products of their catalytic reactions after oral administration of synthetic substrates in urine (*N*-benzoyl-L-tyrosine-*p*-aminobenzoic acid [NBT-PABA] or pancreolauryl test) or in breath (^{13}C mixed-chain triglyceride breath test). The NBT-PABA and pancreolauryl substrates are no longer commercially available.

Pancreatic chymotrypsin is almost completely digested in its passage through the gut in adults, but the residual activity of the enzyme in feces is stable for several days at room temperature. Its output in stool correlates poorly with chymotrypsin secretion in duodenal contents when both are measured after stimulation with secretin-CCK. In patients without pancreatic disease, the incidence of falsely low results is approximately 10% to 15% and may be due to voluminous stools ($>300\text{ g}/24\text{ h}$), thus less enzyme per gram of feces; inadequate food intake; partial gastrectomy or mucosal disease (e.g., celiac disease), which causes inadequate stimulation of pancreatic secretion; or obstruction of the common bile duct. Falsely normal results in patients with mild pancreatic insufficiency may be as high as 50%. In a collaborative study in children, both fecal chymotrypsin and elastase showed 100% sensitivity for detecting pancreatic insufficiency in CF; but the specificity of chymotrypsin was lower than that of elastase in a control group of children with small intestinal disease.

Pancreatic elastase-1 is a pancreas-specific protease present in pancreatic juice. It is not degraded during passage through the gut, and concentrations in feces are five- to six-fold greater than those in pancreatic juice. Elastase-1 can be measured by ELISA with two monoclonal antibodies specific to the human enzyme. Treatment of patients with pancreatic enzyme supplements therefore does not interfere with the test. Fecal elastase-1 has been evaluated extensively in both CF and adult pancreatic insufficiency, and its use is recommended in both groups. Fecal elastase is often undetectable ($<15\text{ }\mu\text{g/g}$) in children with CF, and values below $200\text{ }\mu\text{g/g}$ after 4 weeks of age are indicative of pancreatic insufficiency.

Using random fecal samples, specificities of 98% and 100% have been reported in healthy controls and specificities of 90% to 97% in patients with nonpancreatic GI disease. Positive results (i.e., $<200\text{ }\mu\text{g/g}$) have been reported in patients with clinical or laboratory evidence of malnutrition who also have IBD or chronic diarrhea (nonpancreatic).

Measurement of pancreatic elastase-1 in feces has high sensitivity for the detection of severe and moderate chronic pancreatitis in adults. It has better sensitivity than other tests for detecting mild chronic pancreatitis and high sensitivity and high negative predictive value for discriminating between diarrhea of pancreatic and nonpancreatic origin. The test is not specific for pancreatitis and detects moderate to severe impairment of pancreatic exocrine secretion from any cause. It is considered to be the most suitable test to confirm pancreatic insufficiency in CF infants older than 2 weeks. A negative test does not exclude mild disease and false-positive results in some nonpancreatic diseases and in very watery samples limit its diagnostic accuracy.

Gastrointestinal Regulatory Peptides

The gut is the largest endocrine organ in the body but is also a major target for many hormones released locally or from other organs. GI regulatory peptides are released from the pancreatic islets (e.g., somatostatin) or from endocrine cells spread throughout the gut mucosa and collectively known as the diffuse endocrine system. Many of these peptides (such as vasoactive inhibitory peptide [VIP] and somatostatin) are present in the enteric nerves. They are also found in the central nervous system (CNS) and have important roles in the neuroendocrine control of the gut. Although many of them fulfill the classic criteria for a hormone by acting on distant cells, others function as neurotransmitters or have local (paracrine) effects on adjacent cells. Collectively they influence motility, secretion, digestion, and absorption in the gut. They regulate bile flow and the secretion of pancreatic hormones and affect the tonicity of the vascular walls, blood pressure, and cardiac output.

Table 38.5 summarizes the basic chemical characteristics of four of the major GI regulatory peptides and indicates their site of origin and main functions. More detailed descriptions of these peptides are given in the following paragraphs. A list of other regulatory peptides of the GI tract is presented in Table 38.6.

Gastrointestinal Neuroendocrine Tumors and Tumor Markers

GI neuroendocrine tumors may be endocrine pancreatic tumors or carcinoid tumors arising from enterochromaffin cells that occur throughout the GI tract. Carcinoid tumors are described in Chapter 26. Approximately two-thirds of patients with tumors arising from pancreatic islet cells present with excessive hormone production. This group of tumors includes insulinomas, gastrinomas, VIPomas, glucagonomas, and somatostatinomas. Insulinomas and glucagonomas are not usually associated with GI symptoms. Gastrinomas were discussed earlier. The somatostatinoma syndrome is associated with steatorrhea, gallstones, and hypoglycemia.

The watery diarrhea hypokalemic achlorhydria syndrome (WDHA syndrome, Werner-Morrison syndrome) is a consequence of a tumor producing excessive amounts of VIP. The WDHA syndrome may be suspected in a patient who

TABLE 38.5 Characteristics of Prominent Forms of Principal Gut Regulatory Peptides

Hormone/Peptide	Molecular Weight (Da)	No. of Amino Acids	Main Gut Localization	Principal Physiologic Action
Gastrin Family				
Cholecystokinin	3918	33	Duodenum and jejunum	Stimulates gallbladder contraction and intestinal motility; stimulates secretion of pancreatic enzymes, insulin, glucagon, and pancreatic polypeptides; has a role in indicating satiety; the C-terminal 8-amino acid peptide (CCK-8) retains full activity
Gastrin-17	2098	17	Gastric	Stimulates the secretion of gastric acid pepsinogen, intrinsic factor, and secretin; stimulates intestinal mucosal growth; increase gastric and intestinal motility
Gastrin	3839	34	antrum and duodenum	
Secretin-Glucagon Family				
Secretin	3056	27	Duodenum	Stimulates pancreatic and jejunal secretion of bicarbonate, enzymes, and insulin; reduces gastric and intestinal motility, inhibits gastrin release and gastric acid secretion
VIP	3326	28	Enteric nerves	Relaxes smooth muscle of gut, blood, and genitourinary system; increases water and electrolyte secretion from the pancreas and gut; releases hormones from the pancreas, gut, and hypothalamus
GIP	4976	42	Duodenum and jejunum	Stimulates insulin release; reduces gastric and intestinal motility; increases fluid and electrolyte secretion from the small intestine

GIP, Glucose-dependent insulintropic peptide; VIP, vasoactive intestinal polypeptide.

TABLE 38.6 Brief Description of Other Gastrointestinal Regulatory Peptides

Hormone/Peptide	Major Tissue Location	Principal Known Actions
Bombesin	Throughout the gut and pancreas	Stimulates release of CCK and gastrin
Calcitonin gene-related peptide	Enteric nerves	Unclear
Chromogranin A	Neuroendocrine cells	Secretory protein
Enkephalins	Stomach, duodenum	Opiate-like actions
Enteroglucagon	Small intestine, pancreas	Inhibits insulin secretion
Ghrelin	Stomach	Stimulates appetite, increases gastric emptying
GLP-1	Pancreas, ileum	Increases insulin secretion
GLP-2	Ileum, colon	Enterocyte-specific growth hormone
Leptin	Stomach	Appetite control
Motilin	Throughout the gut	Increases gastric emptying and small bowel motility
Neuropeptide Y	Enteric nerves	Regulation of intestinal blood flow
Neurotensin	Ileum	Affects gut motility; increases jejunal and ileal fluid secretion
Pancreastatin	Pancreas	Inhibits pancreatic endocrine and exocrine secretion
Pancreatic polypeptide	Pancreas	Inhibits pancreatic and biliary secretion
PYY	Colon	Inhibits food intake
Somatostatin	Stomach, pancreas	Inhibits secretion and action of many hormones

CCK, Cholecystokinin; GLP, glucagon-like peptide; PYY, peptide tyrosine tyrosine.

produces large volumes (>1 L/24 h) of secretory diarrhea with dehydration and hypokalemia. The diagnosis is confirmed by the finding of high plasma VIP concentrations and demonstration of somatostatin-receptor uptake on imaging.

The remaining one-third of patients with neuroendocrine tumors have no specific clinical symptoms associated with the tumors, which are described as nonfunctional.

The pattern of hormonal and precursor production by neuroendocrine tumors is complex. Most secrete several tumor markers. Chromogranin A, a member of a family of secretory proteins, has a diagnostic sensitivity of more than 90% for neuroendocrine tumors. Plasma chromogranin A concentration is elevated in most tumors and is an alternative to more specific markers in monitoring the effectiveness

of therapy. Although chromogranin A has high sensitivity, false-positive findings have been observed in several nonendocrine tumors, including prostate cancer.

Chromogranin A has been reported to be slightly increased in IBD and also in other malignancies, including lung, prostate, breast, and uterine. It is increased by the use of PPIs and hydrogen receptor blockers, which can be problematic because many patients suspected of having a neuroendocrine tumor may have started on these in primary care. Chromogranin A is renally excreted, so significant renal dysfunction increases the concentration. For these reasons, chromogranin A is usually considered to be a marker of prognosis and for monitoring response to therapy rather than a diagnostic tool.

TABLE 38.7 Summary of Disorders Leading to Malabsorption**Disorders of Intraluminal Digestion**

- | | |
|-----------------------------|---|
| 1. Altered gastric function | Postgastrectomy syndrome, Zollinger-Ellison syndrome |
| 2. Pancreatic insufficiency | Chronic pancreatitis, cystic fibrosis, pancreatic cancer |
| 3. Bile acid deficiency | Disease/resection of terminal ileum, small bowel overgrowth |

Disorders of Transport Into the Mucosal Cell

- | | |
|--|--|
| 1. Generalized disorders due to reduction in absorptive surface area | Celiac disease, tropical sprue |
| 2. Specific disorders | Hypolactasia, vitamin B ₁₂ in pernicious anemia, zinc in acrodermatitis enteropathica |

Disorders of Transport Out of the Mucosal Cell

- | | |
|-------------------------------|--|
| 1. Blockage of the lymphatics | Primary lymphangiectasia, Abdominal lymphoma |
| 2. Inherited disorders | Abetalipoproteinemia |

Investigation of Maldigestion and Malabsorption

This section summarizes causes of malabsorption and suggests a general laboratory approach to these disorders. [Table 38.7](#) summarizes the main causes of malabsorption under the three categories of intraluminal disorders and malabsorption secondary to disorders of either transport into the mucosal cells or transport out of the mucosal cells.

The clinical presentation of a patient with malabsorption or maldigestion classically includes the following features:

Evidence of general ill health. Anorexia, weight loss, fatigue after minor effort, and dyspnea may be seen. Edema (due to hypoalbuminemia), tetany (low plasma calcium concentration), and dehydration secondary to electrolyte imbalance and water loss may be present. In exocrine pancreatic insufficiency, however, hyperphagia is the rule: patients may often report a very high (5000 kcal/day, 21,000 kJ/day) food intake without weight gain.

Isolated nutrient deficiencies. Iron, folate, or vitamin B₁₂ deficiency may manifest as anemia, which may be mild; vitamin K deficiency as a bleeding tendency; and vitamin D deficiency as bone disease (see [Chapter 27](#) for more details on vitamins). They are reflected by a variety of signs and symptoms (glossitis, pallor, dermatitis, petechiae, bruising, hematuria, muscle or bone pain, or neurologic abnormalities).

Abdominal symptoms. These include discomfort, distention, flatulence, and borborygmi (rumbling and gurgling sounds resulting from movement of gas in the intestine).

Watery diarrhea and possible steatorrhea. In severe cases of steatorrhea the stool is typically loose, bulky, offensive, greasy, light-colored, and difficult to flush away. Alternatively, the stools may appear normal but may be more bulky or be passed more frequently.

Early manifestation of malabsorption will, however, be more subtle than this list might indicate. The alteration in volume or consistency of the stool may be slight, and only mild symptoms may be attributable to the GI tract. The patient may report only anorexia, fatigue, and lack of interest in daily activities. It is in these cases that the astute physician who suspects malabsorption on clinical grounds will rely on the laboratory to assist in the diagnosis. Initial laboratory investigations consist of routine tests, with abnormalities that may indicate the possibility of malabsorption (e.g., blood hemoglobin concentration, mean red cell volume, serum concentrations of folate, ferritin, calcium, albumin, liver enzyme activities, and tests for antibodies in celiac disease).

Evaluation of Fat Absorption

The evaluation of fat absorption or malabsorption is required in only a small minority of patients undergoing investigation for GI disorders, because a firm diagnosis can often be made on clinical grounds alone.

Historically the assessment of fat malabsorption was carried out by measurement of fecal fat excretion in a timed (2 to 3 days) fecal collection. This had many limitations and is seldom performed today. A range of alternative tests have been proposed, but most had similar limitations to those for fecal fat measurement in either their sensitivity and specificity or analytic constraints. Currently, investigation of fat malabsorption is limited to the measurement of fecal elastase and the ¹³C mixed-chain triglyceride breath test to identify exocrine pancreatic insufficiency with consequent reduction in secretion of lipase.

The ¹³C mixed-chain triglyceride breath test uses ¹³C-labeled medium- and long-chain fatty acids as a means of assessing intraluminal pancreatic lipase activity. The labeled substrate is administered orally with a standard meal of toast and butter. Breath samples are collected over a 5-hour period and exhaled ¹³CO₂ is expressed as a percentage of the administered dose, with normal excretion in the range of 25% to 40%. The sensitivity and specificity of the test for identifying pancreatic insufficiency has been reported as 89% and 81%, respectively. Similar results have been reported for the ¹⁴C-triolein test using a variety of fat loads and procedures. The disadvantage of this test is the need to measure the ¹⁴C-labeled CO₂ immediately, which requires the availability of a scintillation counter and facilities for the administration of radioisotopes.

Investigation of Chronic Diarrhea

Although diarrhea is a common problem, no clear definition has existed to distinguish it from the range of stool weight, frequency, consistency, or volume that occurs in the normal population. A 2003 proposal that sought to encompass these different elements suggests that for a Western diet, diarrhea may be defined as “the abnormal passage of loose or liquid stools more than three times daily and/or a volume of stool greater than 200 g/day.” Guidelines suggest that diarrhea may

BOX 38.5 Causes of Chronic Diarrhea**Colonic**

- Ulcerative colitis
- Crohn disease
- Microscopic colitis

Small Bowel

- Celiac disease
- Small bowel enteropathies (e.g., Crohn disease, Whipple disease, tropical sprue, amyloidosis, intestinal lymphangiectasia)
- Bile salt malabsorption
- Disaccharidase deficiency
- Small bowel bacterial overgrowth
- Lymphoma
- Giardiasis (and other chronic infections)
- Irritable bowel syndrome

Endocrine

- Hyperthyroidism
- Diabetes
- Hypoparathyroidism
- Addison disease
- Neuroendocrine tumors (e.g., VIPoma, carcinoid tumors)

Other

- Chronic laxative abuse (e.g., bulimia nervosa)
- Surgical causes (e.g., small bowel resection, internal fistulas)
- Drugs and alcohol
- Autonomic neuropathy

Modified from Thomas, P. D., Forbes, A., Green, J., Howdle, P., Long, R., Playford, R., et al. (2003). Guidelines for the investigation of chronic diarrhoea. 2nd edition. *Gut*, 52(suppl V), 1–15.

be defined as chronic when it has continued for 4 weeks or more; such persistence indicates the likelihood of a noninfectious cause requiring further investigation.

Several quite different mechanisms can lead to diarrhea. In carbohydrate malabsorption, the presence of unabsorbed solutes in the bowel causes osmotic diarrhea as water enters the bowel from tissue. By contrast, the diarrhea of most cases of laxative abuse or VIPomas is due to active secretion of water and electrolytes into the bowel, which is described as secondary diarrhea. IBD causes diarrhea as a consequence of the inflammatory process.

Many diseases more commonly thought to cause “diarrhea” in fact lead to more frequent passage of stools but not usually to an increased stool weight (or volume). Such disorders (e.g., IBS) generally fall outside the scope of the definition of chronic diarrhea. Guidelines for the management of IBS are available, and the best results are achieved with an integrated approach to the problem, involving clinicians with a special interest, dietitians, a psychiatric-psychological approach, etc.

Box 38.5 describes the many causes of chronic diarrhea; most are due to disease of the colon, in which laboratory diagnostic tests are of little value with the exception of fecal calprotectin for the differentiation of IBS from IBD.

BOX 38.6 Causes of the Acute Abdomen**Common Causes**

- Acute appendicitis
- Acute cholecystitis, ascending cholangitis
- Small and large bowel obstruction
- Intussusception, volvulus, and strangulated hernias
- Renal/ureteric colic
- Perforated peptic/duodenal ulcer
- Acute pancreatitis
- Acute diverticulitis
- Gynecologic conditions (e.g., ectopic pregnancy, salpingitis)
- Ruptured aortic aneurysm
- Mesenteric lymphadenitis

Less Common Causes

- Gastroenteritis including *Salmonella*, *Shigella*, *Yersinia*, measles virus, etc.
- Crohn disease
- Pyelonephritis
- Meckel diverticulitis
- Acute intermittent porphyria

Conditions That May Simulate the Acute Abdomen

- Myocardial infarction or myocarditis

Laxative Abuse

Surreptitious laxative abuse is an important cause of diarrhea that is often overlooked. It may be as common as 20% of cases in secondary or tertiary referral centers. In Munchausen syndrome by proxy, adults have administered laxatives surreptitiously to young children. A clinical diagnosis rarely can be made; no single clinical feature reliably predicts a positive test. When there is a high index of clinical suspicion, urine screens for laxatives may be helpful.

The Acute Abdomen

The acute abdomen is defined as undiagnosed intense abdominal pain lasting less than 1 week. Many of the diseases that present in this way have a high mortality if not treated surgically, but others may have high morbidity and mortality if surgical intervention is carried out. The clinical diagnosis is based primarily on the nature of the pain. Common causes of the acute abdomen are detailed in Box 38.6. Nonabdominal conditions may simulate an acute abdomen. History and examination often yield a likely diagnosis, but laboratory investigations may help in establishing this (e.g., pregnancy test in suspected ectopic pregnancy, serum amylase, or lipase in acute pancreatitis). A full blood count may reveal a raised neutrophil count suggestive of infection or anemia secondary to blood loss from the GI tract. Knowledge of renal function and acid-base status is important if surgery is being considered.

Acute Pancreatitis

Acute pancreatitis is an inflammatory condition of the pancreas that may have a self-limiting short course but can be fatal. Almost all patients with acute pancreatitis have severe

epigastric pain, usually of sudden onset and often radiating to the back. In more severe cases, there is nausea and vomiting, fever, hypotension, shock, and multiorgan failure that may lead to death. Biochemical features of acute pancreatitis include uremia, hypoalbuminemia, hypokalemia, hyperglycemia, metabolic acidosis, hypoxemia, and abnormal liver tests. None of these are invariably present or diagnostic for pancreatitis. In acute necrotizing pancreatitis, methemalbuminemia may be detectable. The use of enzyme measurements in the diagnosis of acute pancreatitis is explained in Chapter 19.

AT A GLANCE

Causes of Acute Pancreatitis

- Gallstones
- Alcohol excess
- Drugs
- Hypertriglyceridemia
- Hypercalcemia
- Trauma
- Infections
- Rare causes including tumors

REVIEW QUESTIONS

1. Gastrin
 - a. is secreted by the liver and stomach.
 - b. is secreted when stomach pH is low.
 - c. stimulates gastric acid secretion.
 - d. inhibits secretion of intrinsic factor.
2. The hydrogen breath test using glucose or lactulose as a substrate assesses
 - a. intestinal bacterial overgrowth.
 - b. celiac disease.
 - c. the presence of *H. pylori*.
 - d. bile acid malabsorption.
3. A peptide neurotransmitter that relaxes smooth muscle in the gut and increases water and electrolyte secretion is
 - a. cholecystokinin (CCK).
 - b. secretin.
 - c. vasoactive intestinal polypeptide (VIP).
 - d. gastric inhibitory polypeptide.
4. The three phases of the digestive process include the neurogenic, gastric, and the intestinal phases. The intestinal phase is initiated
 - a. by distention of the stomach.
 - b. by the sight, smell, and taste of food.
 - c. upon stimulation of the cerebral cortex in the brain.
 - d. when weakly acidic digestive products of proteins and lipids enter the duodenum.
5. An example of an invasive test for detection of *H. pylori* in peptic ulcer disease would be
 - a. breath testing following ingestion of ^{14}C -labeled urea.
 - b. microbiologic culture of a gastric biopsy sample.
 - c. lab measurement of a specific IgG antibody.
 - d. detection of a specific fecal antigen.
6. Which one of the following is considered to be a disease of the intestine?
 - a. Zollinger-Ellison syndrome
 - b. Peptic ulcer disease
 - c. Celiac disease
 - d. Cystic fibrosis (CF)
7. In Western countries, the most common cause of chronic pancreatitis in adults is
 - a. gallstones.
 - b. infections.
 - c. pancreatic tumors.
 - d. alcohol consumption.
8. Which one of the following peptides stimulates increased pancreatic secretion of bicarbonate?
 - a. Glucose-dependent insulinotropic peptide (GIP)
 - b. Gluten
 - c. Secretin
 - d. Vasoactive intestinal polypeptide (VIP)
9. A tumor of the pancreatic islet cells that produces in part massive gastric hypersecretion, diarrhea, and steatorrhea causes
 - a. the Zollinger-Ellison syndrome.
 - b. celiac disease.
 - c. lactose intolerance.
 - d. cystic fibrosis (CF).

Bone and Mineral Metabolism

William D. Fraser

OBJECTIVES

- Define the following:
 - Bone marker
 - Matrix
 - Osteoblast
 - Osteoclast
 - Osteomalacia
 - Osteopenia
 - Osteoporosis
 - Rickets
 - Type I collagen
 - Magnesium
 - PTH
 - Total/free calcium
 - Vitamin D and metabolites
 - State the effect each of the following disorders has on total and free calcium, phosphate, albumin, and PTH:
 - Primary and secondary hyperparathyroidism
 - Primary and secondary hypoparathyroidism
 - Pseudohypoparathyroidism
 - Discuss 1,25-dihydroxyvitamin D, including its metabolism, physiology, and roles in bone health, mineral metabolism, and disease.
 - List and describe five markers of bone formation and resorption.
 - For the following disorders, state the cause(s), symptoms, laboratory analyses, and lab results used to diagnose:
 - Osteoporosis
 - Paget disease of bone
 - Rickets
- Describe the structure and function of bone.
 - Detail the physiology and regulation of calcium and phosphate.
 - List causes, symptoms, and laboratory analyses used in the differential diagnosis of the following:
 - Hypercalcemia
 - Hypermagnesemia
 - Hyperphosphatemia
 - Hypocalcemia
 - Hypomagnesemia
 - Hypophosphatemia
 - List and describe commonly used methods in the measurement of the following analytes:
 - Bone alkaline phosphatase (Bone ALP)
 - Parathyroid-related protein
 - Phosphate

KEY WORDS AND DEFINITIONS

Adynamic bone disease (ABD) A type of renal osteodystrophy characterized by reduced osteoblasts and osteoclasts, and low bone turnover.

Bone alkaline phosphatase An isoenzyme of alkaline phosphatase and a biochemical marker of bone formation.

Calcitonin A 32-amino-acid polypeptide hormone elaborated by the parafollicular cells of the thyroid gland in response to hypercalcemia.

CTX An antigen produced when type I collagen is digested by the proteinase cathepsin K yielding crosslinked carboxy-terminal telopeptide of type I collagen; a plasma marker for bone resorption.

Deoxypyridinoline (DPD) A crosslink of type I collagen present in bone that is excreted, free or protein-bound, in serum or urine and serves as a marker of bone resorption.

Humoral hypercalcemia of malignancy (HHM) A malignancy caused by bone resorption mediated by circulating factors released from distant tumor cells.

Hypercalcemia Increased concentration of calcium in plasma; manifestations include fatigability, muscle weakness, depression, anorexia, nausea, and constipation; most commonly caused by primary hyperparathyroidism or malignancy.

Hypercalcemia-associated malignancy (HCM) Hypercalcemia caused by the presence of malignancy.

Hypermagnesemia A condition characterized by abnormally high concentrations of magnesium in plasma.

Hyperphosphatemia A condition characterized by abnormally high concentrations of phosphates in plasma.

Hypocalcemia A condition characterized by a low concentration of calcium in plasma.

Hypomagnesemia A condition characterized by a low concentration of magnesium in plasma.

Hypoparathyroidism The condition produced by greatly reduced function of the parathyroid glands.

Hypophosphatemia A condition characterized by a low concentration of phosphate in plasma.

Mineralization The process by which the body uses minerals to build bone structure.

N-telopeptide (NTX) A biochemical marker of bone resorption.

Osteitis fibrosa A complication of hyperparathyroidism in which the bones are soft and often deformed; also called *osteitis fibrosa cystica*.

Osteoblasts Cells responsible for formation of bone, including synthesis of type I collagen and noncollagenous proteins and mineralization of osteoid.

Osteocalcin (OC) A protein found in the extracellular matrix of bone and dentin and involved in regulating mineralization in the bones and teeth.

Osteoclasts Large, multinuclear cells responsible for resorption of bone.

Osteomalacia Inadequate or delayed mineralization of osteoid; the adult equivalent of rickets (interruption in the development and mineralization of the growth plate in children).

Osteopenia A condition characterized by decreased bone mineral density. Often a predecessor to osteoporosis. It is diagnosed with a bone mineral density test.

Osteoporosis A condition characterized by reduction in bone mass, leading to fractures with minimal trauma; postmenopausal osteoporosis occurs in women after menopause; senile osteoporosis occurs in both men and women later in life.

Paget disease of bone A localized, bone disease characterized by osteoclastic bone resorption followed by replacement of bone in a chaotic fashion. Prevalence varies markedly between countries.

Parathyroid hormone (PTH) A peptide hormone secreted by parathyroid glands in response to decreased free calcium that increases calcium in blood by increasing bone resorption, increasing renal reabsorption of calcium, and increasing the synthesis of 1,25-hydroxyvitamin D [25(OH)D]; the

latter increases intestinal absorption of calcium and phosphate.

Parathyroid hormone-related protein (PTHrP) A protein that mimics many actions of PTH, but is a product of a different gene that is expressed in many normal tissues and overexpressed by some tumors in cases of humoral hypercalcemia of malignancy (HHM).

Procollagen type I carboxy-terminal propeptide (PICP) A biochemical marker of bone formation.

Procollagen type I N-terminal propeptide (PINP) A biochemical marker of bone formation.

Pyridium crosslinks A family of molecules that links collagen molecules to each other; the breakdown products of collagen are excreted into blood then urine with attached crosslinks including pyridinoline (PYD) and deoxypyridinoline (DPD).

Renal osteodystrophy Bone diseases associated with chronic renal failure, including high turnover (osteitis fibrosa or secondary hyperparathyroidism) and low turnover (osteomalacia and adynamic bone) diseases.

Rickets A disorder in children caused by a lack of vitamin D, calcium, or phosphate that leads to softening and weakening of the bones. In adults it is known as osteomalacia.

Tartrate-resistant acid phosphatase 5b (TRACP5b) An enzyme derived from osteoclasts; it is a marker of bone resorption.

Vitamin D Fat-soluble vitamin produced by skin upon exposure to sunlight (vitamin D₃, also called cholecalciferol) or adsorbed from foods that contain it (vitamin D₂ or ergocalciferol); deficiency causes rickets in children and osteomalacia in adults. Related tests with clinical utility include assays for 25(OH)D and 1,25-dihydroxyvitamin D (calcitriol).

This chapter provides an overview of skeletal metabolism then details the clinical chemistry of calcium and other ions, including phosphate and magnesium.

OVERVIEW OF SKELETAL METABOLISM

Bone is composed primarily of an extracellular mineralized matrix with a smaller cellular fraction. It is a dynamic tissue under continuous turnover or *remodeling*. **Osteoclasts** and **osteoblasts** are located on bone surfaces and are responsible for bone resorption and formation, *Osteocytes*, the most abundant cells in mature bone, are located in lacunae within the bone matrix. Osteoclasts resorb bone, osteoblasts lay down new bone at a site of previous bone resorption, and osteocytes nourish the skeleton and regulate bone cell activity (Fig. 39.1). The remodeling cycle can be divided into

activation, resorption, reversal, formation, and termination/resting phases.

Giant multinucleate osteoclasts resorb bone by producing hydrogen ions to mobilize minerals and lysosomal enzymes to digest the organic matrix. Osteoblasts form bone by synthesizing the organic matrix, including type I collagen, and participating in the **mineralization** of newly synthesized matrix. The development of the osteoblast phenotype has been divided into three phases (Fig. 39.2).

The organic matrix of bone is 90% type I collagen combined with a large number of noncollagenous proteins. The organic matrix is mineralized by the deposition of inorganic calcium and phosphate in small crystals with carbonate, magnesium, sodium, and potassium. Bone contains 99% of the body's calcium, most of the phosphate (85%), and much of the magnesium (55%).

Fig. 39.1 Bone remodeling is shown in two dimensions, in vivo. It occurs in three dimensions, with osteoclasts continuing to enlarge the cavity at one end and osteoblasts beginning to fill in at the other end. (From Riggs, B. L., & Parfitt, A. M. [2005]. Drugs used to treat osteoporosis: the critical need for a uniform nomenclature based on their action on bone remodeling. *J Bone Miner Res*, 20, 177–184.)

Fig. 39.2 Development of the osteoblast phenotype. The reciprocal relationship between cell growth and differentiation is shown, arrows depict expression of cell cycle and cell growth-related genes (proliferation arrow) and that of genes related to maturation of the osteoblast phenotype and production of the extracellular matrix (differentiation arrow). The three principal periods in the developmental sequence are designated by vertical broken lines. AP, Alkaline phosphate; COL, type I collagen; MGP, matrix Gla protein; OC, osteocalcin; OP, osteopontin. (Modified from Lian, J. B., & Stein, G. S. [1995]. Development of the osteoblast phenotype: molecular mechanisms mediating osteoblast growth and differentiation. *Iowa Orthop J*, 15, 118–140.)

Bone Remodeling

From 10% to 30% of the skeleton is remodeled yearly. Bone growth and turnover are influenced by the metabolism of calcium, phosphate, magnesium, PTH, and 1,25-dihydroxyvitamin D (1,25(OH)₂D). Bone formation and resorption are affected by thyroid hormones, estrogens, androgens, cortisol, insulin, growth hormone, insulin-like growth factors (IGF-I and IGF-II), transforming growth factor-β (TGF-β), fibroblast growth factor 23 (FGF23), and platelet-derived growth factor (PDGF). Numerous cytokines alter bone remodeling

by stimulating resorption; these include interleukins (IL)-1, -4, -6, and -11; macrophage and granulocyte/macrophage colony-stimulating factors (MCSF, GCSF), and TNF-α.

During childhood and adolescence, bone formation markedly exceeds bone resorption (bone modeling)—a process that ends with epiphyseal closure at the end of puberty and is followed, in women, by a period of consolidation for the next 5 to 10 years, when the bone becomes fully mineralized. In healthy individuals, resorption and formation remain in balance for several decades. After the menopause, the decline in estrogen in women triggers an increase in bone resorption that exceeds the capacity of formation and results in a decrease in bone mass. Men do not experience this phase of rapid bone loss unless they develop altered physiology, such as hypogonadism, but they do experience longer-term age-related loss at a rate similar to that in women. **Osteoporosis** results from remodeling imbalance.

BIOCHEMICAL MEASUREMENTS IN METABOLIC BONE DISEASE

CALCIUM

Calcium is the fifth most common element in the body and the most prevalent cation. An average human (70 kg) contains 1 kg, or 25 mol, of calcium predominantly as extracellular crystals in hydroxyapatite (Ca₁₀(PO₄)₆(OH)₂).

Biochemistry and Physiology

In blood virtually all calcium is found in plasma, which has a mean calcium concentration of 9.5 mg/dL (2.38 mmol/L). Calcium exists in three physicochemical states in plasma (Table 39.1).

The free (ionized) fraction is the biologically active form. Its concentration is tightly regulated by PTH and $1,25(\text{OH})_2\text{D}$. Synthesis and secretion of PTH by the parathyroid glands is controlled via a calcium-sensing receptor (CaSR). A decrease in circulating free calcium is detected at the CaSR, resulting in the chief cells releasing PTH to act via the kidneys (reabsorption), the gut (absorption), and the skeleton (bone resorption) to increase free calcium (Fig. 39.3). In a classic feedback loop an increase in free calcium interacts with the CaSR, switching off PTH synthesis and release.

There is 80% of protein-bound calcium associated with albumin, with the remaining 20% associated with globulins. Because calcium binds to negatively charged sites on proteins, its binding is pH dependent. For each 0.1 unit change in pH, 0.2 mg/dL (0.05 mmol/L) of inverse change occurs in free calcium.

Calcium can be redistributed among the three plasma pools.

Calcium is classified as intracellular or extracellular. Intracellular calcium has key roles including muscle contraction, hormone secretion, glycogen metabolism, and cell division. The intracellular concentration of calcium in the cytosol of unstimulated cells is around $0.1 \mu\text{mol/L}$, less than $1/20,000$ of that in extracellular fluid.

Extracellular calcium provides calcium ion for the maintenance of intracellular calcium, bone mineralization, blood

coagulation, and plasma membrane potential. Calcium stabilizes the plasma membranes and influences permeability and excitability. A decrease in the plasma-free calcium concentration causes increased neuromuscular excitability and can lead to tetany.

Clinical Significance

Hypocalcemia

Low total plasma calcium (**hypocalcemia**) may be due to a reduction in albumin-bound calcium, the free fraction of calcium, or both. Hypoalbuminemia is the most common cause of apparent hypocalcemia, particularly in hospitalized patients. Low plasma albumin is seen in chronic liver disease, nephrotic syndrome, congestive heart failure, malignancy, malnutrition, and post-surgical volume replacement with saline or colloidal. Causes of hypocalcemia include preanalytical interference such as presence of ethylenediaminetetraacetic acid (EDTA), chronic kidney disease (CKD), malignancies, drugs, and hypoparathyroidism.

Hypoparathyroidism is mainly caused by parathyroid gland destruction or removal during neck surgery (90%). In pseudohypoparathyroidism resistance to PTH results in increased circulating PTH.

Symptoms and signs of hypocalcemia include paresthesia, increased neuromuscular irritability, central nervous system abnormalities, and fatigue. The severity of symptoms is related to the rate of decrease in free calcium. This can occur during transfusion when large quantities of citrated blood are infused; citrate complexes calcium, leading to lower free calcium concentration without decreasing the total calcium. It is also observed in hysterical over-breathing where an increase in respiratory rate results in respiratory alkalosis, with the increased pH causing protein binding of free calcium. Treatment of symptomatic hypocalcemia may require intravenous calcium, if secondary to hypoparathyroidism or pseudohypoparathyroidism, **vitamin D** or vitamin D analogs plus oral calcium are administered. PTH therapy by intramuscular injection is available to treat hypoparathyroidism. In hypomagnesemic hypoparathyroidism, intravenous magnesium will normalize magnesium, which restores control

TABLE 39.1 Physicochemical States of Calcium, Phosphate, and Magnesium in Human Plasma

State	APPROXIMATE PERCENT OF TOTAL		
	Calcium	Phosphate	Magnesium
Free (ionized)	50	55	55
Protein-bound	40	10	30
Complexed	10	35	15
Total, mg/dL	8.6–10.3	2.5–4.5	1.7–2.4
Total mmol/L	2.15–2.57	0.81–1.45	0.70–0.99

Modified from Marshall, R. W. (1976). Plasma fractions. In B. E. C. Nordin (Ed.), *Calcium, phosphate and magnesium metabolism* (pp. 162–185). London: Churchill Livingstone.

Fig. 39.3 Regulation of calcium via parathyroid hormone (PTH) secretion and its direct and indirect action at the kidneys, intestine, and bone. (Modified from Fraser, W. D. [2009]. Hyperparathyroidism. *Lancet*, 374, 145–158.)

over PTH synthesis and secretion, and results in normocalcemia with calcium supplementation. An important exception to symptomatic hypocalcemia occurs in CKD when marked acidosis is present. Hypocalcemia triggers muscle contraction, but acidosis impairs muscle contraction.

Hypercalcemia

The major causes of **hypercalcemia** in clinical practice include primary hyperparathyroidism (PHPT), malignancies, renal failure, drugs, and vitamins D or A overdose. Hypercalcemia results when the influx of calcium into the extracellular fluid compartment from the skeleton, intestine, or kidney is greater than the efflux. When the kidney's capacity to excrete filtered calcium is exceeded, hypercalcemia develops; where renal failure is present and calcium excretion is decreased, hypocalciuria may paradoxically be present.

PHPT is the most common pathologic cause in outpatients, whereas malignancy is common in hospitalized patients. Vitamin D or analog therapy has become a common cause of hypercalcemia. These account for 90% to 95% of all cases.

In developed countries 80% of PHPT patients are free of overt symptoms on presentation because of detection through chemistry panels, including calcium. The most common signs and symptoms of hypercalcemia are nonspecific and include nausea, vomiting, constipation, weakness, kidney stone formation, depression, polyuria, and tissue calcification.

Measurement of intact PTH with contemporaneous calcium is the most sensitive and specific test for parathyroid function and is central to the differential diagnosis of hypercalcemia. If intact PTH is within the upper half of the reference interval, it is inappropriate for the prevailing calcium concentration. Serum $1,25(\text{OH})_2\text{D}$ is often in the upper half of the reference interval or increased in PHPT, PTH stimulates production from $25(\text{OH})\text{D}$. Nonparathyroid causes of hypercalcemia are associated with very low or suppressed PTH. $1,25(\text{OH})_2\text{D}$ is low-normal or suppressed in nonparathyroid hypercalcemia, except in sarcoidosis or other granulomatous diseases and certain lymphomas, in which pathologic tissues contain the $25\text{-hydroxyvitamin D-}1\alpha\text{-hydroxylase}$ which produces $1,25(\text{OH})_2\text{D}$.

Hypercalcemia occurs in 5% to 30% of individuals with cancer. Solid tissue malignancies, particularly squamous cell carcinomas, commonly produce **parathyroid hormone-related peptide (PTHrP)**, which stimulates bone resorption. Skeletal metastases from cancer can also produce hypercalcemia.

Samples must be obtained prior to initiating treatment for hypercalcemia as lowering the calcium in **hypercalcemia-associated malignancy (HCM)** will stimulate PTH secretion and can cause diagnostic confusion (hypercalcemia with detectable PTH).

Therapies are directed toward treating the malignancy, decreasing the plasma calcium by saline diuresis, and decreasing osteoclastic resorption (bisphosphonates, denosumab, calcitonin). Corticosteroids can be useful in reducing intestinal absorption of calcium in $1,25(\text{OH})_2\text{D}$ -mediated hypercalcemia.

Familial benign hypocalciuric hypercalcemia (FBHH) is characterized by the presence of hypercalcemia and hypocalciuria (low fractional calcium excretion).

Measurement of Calcium

Methods for quantifying calcium in blood can measure free Ca^{2+} or the total concentration of calcium and the subsequent calculation of albumin adjusted calcium. The term *ionized calcium*, although widely used, is a misnomer; all calcium in plasma or serum is ionized.

Free calcium is the biologically active fraction of blood calcium; it is tightly regulated by PTH and $1,25(\text{OH})_2\text{D}$, and thus is the best indicator of calcium status. Methods for total, albumin adjusted, and free calcium are currently in use and have their own sources of error. Adjustment of total calcium for the prevailing albumin concentration is often performed to correlate the total calcium concentration to the free calcium. Free calcium measurements and adjusted calcium calculations have been recommended because of the consequences of delayed treatment and the cost of working-up patients with misleading total calcium results.

Measurement of Total Calcium

Only photometric, ion selective electrode (ISE), and atomic absorption spectrophotometry are used in clinical laboratories for measuring serum and urine total calcium.

The specimen is acidified to convert protein-bound and complexed calcium to free calcium before measurement by ISE (for additional information see [Chapter 10](#)).

Photometric methods. Total calcium is most frequently measured by spectrophotometry using metallochromic indicators or dyes. Of the metallochromic indicators that change color on selectively binding calcium, *o*-cresolphthalein complexone (CPC) [3',3''-bis(bis-[carboxymethyl]amino)-methyl)-5',5''-dimethylphenolphthalein] and arsenazo III are most widely used.

***o*-Cresolphthalein complexone.** In alkaline solution, the metal-complexing dye CPC forms a red chromophore with calcium; the color is measured between 570 and 580 nm. The sample is diluted with acid to release protein-bound and complexed calcium. Organic base, most often diethylamine, 2-amino-2-methyl-1-propanol, or 2-ethylaminoethanol, is added to buffer the reaction and to produce an alkaline pH. Interference by magnesium is reduced: by adding 8-hydroxyquinoline, by buffering the reaction mixture to near pH 12, and by measuring the absorbance near 580 nm. Urea reduces the turbidity of lipemic specimens and enhances complex formation. Adding ethanol or other organic solvents reduces blank absorbance. Calcium forms 1:1 and 2:1 complexes with CPC, the former predominating at lower concentrations. The calibration curves are nonlinear at low concentrations. Multipoint calibration has been recommended. Sodium acetate may improve linearity.

Arsenazo III. Arsenazo III [1,8-dihydroxynaphthalene-3,6-disulfonic acid-2,7-bis(azo-2)-phenylarsonic acid], at mildly acidic pH, has higher affinity for calcium than magnesium and produces an intense, purple complex. A reaction pH of 6 is used; imidazole buffers the reaction. The

spectral properties of arsenazo III are dependent on pH. Interference from most biological pigments is reduced by measuring the calcium–dye complex near 650 nm. Citrate can cause negative interference, particularly with dry-slide techniques. Clinically significant interference may be noted in patients receiving citrated blood or blood products. Unlike CPC, which has limited stability, the arsenazo III reagent is stable.

Atomic absorption spectrometry methods. The Clinical Laboratory and Standards Institute (CLSI) has approved an atomic absorption spectrophotometry (AAS) method as a reference method for measuring total serum calcium. The reference method is reported to have an accuracy of $100 \pm 2\%$, compared with $100 \pm 0.2\%$ for isotope dilution–mass spectrometry (ID–MS) the definitive method developed by the National Institute of Standards and Technology.

Total calcium adjusted for albumin (adjusted or corrected calcium). Wide variation in the concentrations of compounds that bind calcium in blood may be noted; this variation will affect the measured total calcium concentration without changing the free calcium. Several types of calculation have been suggested to adjust the total calcium concentration. The goal is to produce an adjusted result that would have been found if the concentrations of all compounds that bind calcium had been within their respective reference intervals. Only adjustments based on albumin are commonly used. The term *adjusted* is preferable to *corrected calcium*.

Adjusted calcium is calculated from total calcium and albumin by calculating a correction factor by multiplying the deviation of plasma albumin from the mean of its reference interval by the slope of the regression of total calcium against albumin. Two equations are frequently used with results expressed as mg/dL and mmol/L:

$$\begin{aligned} \text{Adjusted total calcium (mg/dL)} \\ = \text{Total calcium (mg/dL)} + 0.8 [4 - \text{Albumin (g/dL)}] \end{aligned}$$

$$\begin{aligned} \text{Adjusted total calcium (mmol/L)} \\ = \text{Total calcium (mmol/L)} + 0.02 [40 - \text{Albumin (g/dL)}] \end{aligned}$$

These are simplistic calculations and in practice it is recommended that laboratories should establish equations for their reference populations that incorporate linear regression for the different methods used to measure the total calcium and albumin concentrations. Many factors affect the distribution of calcium among the fractions (Box 39.1). The reliability of adjustment for serum albumin deteriorates in patients with very low or high albumin concentrations and in patients with severe disease and multiple organ failure as seen in intensive care units. Direct determination of free calcium by ISE is preferable to adjusted calcium but it should be remembered that ISE methods are also subject to effects due to prevailing albumin concentrations.

Specimen requirements. Serum and heparinized plasma are the preferred specimens. Citrate, oxalate, and EDTA

BOX 39.1 Factors Altering the Distribution Between Protein-Bound, Complexed, and Free Calcium and Compounding the Interpretation of Total Calcium

Factors Altering Protein Binding of Calcium

Altered concentration of albumin or globulins
Abnormal proteins
Heparin
pH
Free fatty acids
Bilirubin
Drugs
Temperature

Factors Altering Complex Formation

Citrate
Bicarbonate
Lactate
Phosphate
Pyruvate and α -hydroxybutyrate
Sulfate
Anion gap

anticoagulants should not be used for spectrophotometric methods as they form complexes with calcium. Acidification of urine is recommended to ensure complete dissociation of calcium from complexes that can be formed at high pH seen in some samples.

Interferences. Hemolysis, icterus, lipemia, paraproteins, and magnesium have been reported to interfere with photometric methods. Many methods use bichromatic analysis, multiwavelength corrections, or blanking to reduce interference. Lipemic specimens should be ultracentrifuged before analysis, or treated to remove the lipid fraction.

Although hemolysis can cause a negative error because red cells contain lower concentrations of calcium than plasma, more significant errors may be caused by the spectral interference of hemoglobin. If hemolyzed specimens must be analyzed, blanking with ethylene glycol-O,O'-bis(2-aminoethyl)-N,N,N',N'-tetraacetic acid (EGTA) is recommended.

Individual instruments and methods should be evaluated for their susceptibility to effects of interferences. Care should be taken to prevent sample contamination with calcium. How the patient is prepared and how the specimen is obtained can have a significant effect on both free and total calcium measurements (see Chapter 3 and Box 39.2).

Measurement of Free (Ionized) Calcium

See also Chapters 10 and 24.

Blood gas analyzers, using ISEs, provide rapid whole blood determinations of plasma free calcium and electrolytes, as well as blood gases. Sensitive potentiometers measure the voltage difference between the calcium or pH and reference electrodes for calibrating solutions or samples. A microprocessor

BOX 39.2 Preanalytical Factors Affecting Measurement of Serum Total or Free Calcium

In Vivo

Tourniquet use and venous occlusion
 Changes in posture: 10%–12% increase in total calcium and 5%–6% increase in free calcium on standing
 Exercise
 Hyperventilation
 Fist clenching
 Alimentary status
 Alterations in protein binding
 Alterations in complex formation

In Vitro

Inappropriate anticoagulants
 Dilution with liquid heparin
 Interfering levels of heparin
 Contamination with calcium
 Bungs, glassware, tubes
 Specimen handling
 Alterations in pH (free calcium)
 Adsorption or precipitation of calcium
 Spectrophotometric interference
 Hemolysis, icterus, lipemia

calibrates the system and calculates calcium concentration and pH. Most instruments simultaneously measure free calcium and pH at 37°C.

Calcium ISEs contain a calcium-selective membrane, which encloses an inner reference solution of calcium chloride often containing saturated AgCl and physiologic concentrations of NaCl, KCl, and an internal reference electrode. The reference electrode, usually Ag/AgCl, is immersed in this inner reference solution. Modern calcium ISEs use liquid membranes containing the ion-selective calcium sensor dissolved in an organic liquid trapped in a polymeric matrix. The Ca^{2+} ionophores may be based on a polyvinyl chloride matrix and contain ETH1001 or ETH129 as a carrier. Instead of these two neutral carriers, ion exchangers, such as organophosphate sensors have been used. Neutral carrier membranes contain an uncharged calcium-selective organic molecule, such as ETH1001, dissolved in a plasticizer and trapped in a polyvinyl chloride membrane. These molecules have a favorable steric and electrostatic pocket or site for selectively binding calcium. Ion exchangers or negatively charged carrier membranes are calcium salts, such as calcium bis(di-*n*-octylphenyl) phosphate, dissolved in di-*n*-octylphenyl phosphonate, and trapped in a polyvinyl chloride membrane. The electrochemical cell is completed by the external reference electrode, an Ag/AgCl or calomel electrode, which is in contact with the specimen through a liquid/liquid junction or a salt bridge of potassium chloride or sodium formate. The potential difference across the cell is logarithmically related to the activity of free calcium ions in the sample by the Nernst equation. By convention, free calcium is converted from activity to concentration using

its activity coefficient, which is itself dependent on ionic strength.

Most free calcium analyzers adjust and maintain samples at 37°C, thereby ensuring that results are physiologically relevant.

Interferences. Because ISEs measure ion activity, they are affected by the ionic strength of a specimen (see [Chapter 10](#)). Free calcium analyzers (and the associated calibrators) are optimized for serum, plasma, or whole blood. Modern electrodes have high selectivity for calcium over Na^+ , K^+ , Mg^{2+} , H^+ , and Li^+ ions. At normal concentrations, these cations have little effect on the accuracy of free calcium measurements. Wide variations in the concentration of Na^+ and high concentrations of Mg^{2+} and Li^+ may influence the concentration of free calcium. Electrodes are insensitive to H^+ , with insignificant interference noted between pH 5 and 9.

Many anions including protein, phosphate, citrate, lactate, sulfate, and oxalate form complexes with calcium ions. Although these anions reduce the concentration of free calcium by complex formation, they do not directly interfere with measurement of the calcium that is free. Protein deposits on the electrode may act as a divalent cation exchanger, resulting in positive interference with high concentrations of Mg^{2+} ions. Newer electrodes use a dialysis membrane or a neutral carrier to reduce or eliminate this protein effect, which typically is less than +0.02 mmol/L (0.08 mg/dL) for 1 g/dL (10 g/L) of protein. The type of dialysis technology or protein exclusion technology can result in different effects of protein concentration on free calcium measurement, especially at extremes of albumin concentration.

Effect of pH. Albumin, with up to 30 binding sites for calcium, accounts for 80% of the protein-bound calcium. Increasing the pH of a specimen in vitro increases the ionization and negative charge on albumin leading to an increase in protein-bound calcium and decrease in free calcium. Decreasing pH decreases ionization and negative charge, decreasing protein-bound calcium and increasing free calcium. Free calcium changes by 5% for each 0.1 unit change in pH ([Fig. 39.4](#)).

Because of this inverse relationship between free calcium and pH, specimens must be analyzed at the patient's pH.

Specimen requirements. Specimens for free calcium must be collected and handled to minimize alterations in pH and free calcium caused by loss of CO_2 and blood cell metabolism. Free calcium may be measured in heparinized whole blood, heparinized plasma, or serum. Where specimens are analyzed rapidly, heparinized whole blood is preferred because it reduces processing time, uses smaller specimen volume, and avoids alteration in pH associated with centrifugation. All syringes and evacuated tubes should be filled completely, kept tightly sealed, and handled anaerobically to prevent loss of CO_2 and the increase in pH that may occur when specimens are exposed to air. It is best that the sample for free calcium is collected in a separate container to minimize the likelihood that the specimen may be analyzed aerobically.

Whole blood specimens should be analyzed within 15 to 30 minutes of sampling. Free calcium is reported to be stable in

Fig. 39.4 Effect of pH on free and protein-bound calcium.

whole blood for at least 1 hour at room temperature and for 4 hours at 4°C. If specimens cannot be analyzed promptly, they can be collected in an ice-water slurry to minimize metabolism. For delayed analysis, serum may be the optimal sample type because of elimination of the anticoagulant and reduction in the occurrence of microclots. Once centrifuged, specimens are stable for hours at 25°C and for days at 4°C in a sealed tube.

The use of aerobic specimens for the measurement of free calcium with correction to pH 7.4 has been criticized and is not recommended. Free calcium at pH 7.4 may be misleading in patients with respiratory and metabolic alkalosis or acidosis.

Effects of anticoagulants. Heparin is the only acceptable anticoagulant for free calcium determinations. Heparin, a polyanion, significantly lowers free calcium at the concentrations (≥ 30 to 100 U/mL) found in many conventional blood gas syringes. Several commercial syringes containing lyophilized heparin are suitable for free calcium determinations. Most evacuated collection tubes, when filled completely, contain concentrations of heparin (15 U/mL) that only slightly decrease free calcium. It is important that all syringes and tubes be filled completely to minimize dilution and/or heparin effects.

Calibrators and quality controls. Various calibration solutions are used for free calcium analyzers. The buffers in which these calibrators are prepared may affect the liquid junction potential and calcium binding; this is usually corrected by the instrument software.

Aqueous quality control materials are available for free calcium. Because simple aqueous controls may not reliably detect changes in performance with patient specimens, the use of serum-based quality control materials is recommended.

Patient Preparation and Sources of Pre-analytical Error for Total and Free Calcium Measurements

Patient preparation and the manner of specimen collection can significantly affect the results of total and free calcium determinations (see Box 39.2).

A common source of pre-analytical error is the increase in total, but not free, calcium concentration associated with tourniquet use and venous occlusion during sampling. Errors of 0.5 to 1.0 mg/dL (0.12 to 0.25 mmol/L) in total calcium may result from the increase in protein-bound calcium caused by the vascular efflux of water during stasis.

Fist clenching or other forearm exercise should be avoided before phlebotomy, this causes a decrease in pH and an increase in free calcium.

Changes in posture cause fluid shifts within 10 minutes and thus alter the concentrations of cells and large molecules, including albumin and total calcium. Standing decreases intravascular water and increases the total calcium concentration by 0.2 to 0.8 mg/dL (0.05 to 0.20 mmol/L) while recumbency has the opposite effect.

Reference Intervals for Total and Free Calcium in Serum and Plasma

Total Calcium

The reference interval for serum/plasma calcium is usually defined by an upper limit of 10.1 to 10.5 mg/dL (2.52 to 2.62 mmol/L) and a lower limit between 8.5 and 8.8 mg/dL (2.12 to 2.20 mmol/L). Pediatric reference intervals have been established as part of the CALIPER study (see Appendix).

An analytical goal, for between-day imprecision, the coefficient of variation (CV), is 0.9% or less based on within-person biological variation. Current methods achieve between day CVs of 1.5% or less within laboratories.

Free Calcium

The reference interval of free calcium (in adults) is 4.6 to 5.3 mg/dL (1.15 to 1.33 mmol/L). Whole blood specimens develop a liquid junction potential different from that of serum or plasma because of the presence of erythrocytes. A positive bias that is directly proportional to the hematocrit has been reported. Free calcium values differ among capillary blood, venous blood, and serum samples because of pH

differences. Reference intervals should be determined using the local instrument, specimen type, and collection protocol, and reference subjects representative of the population served.

Physiologic Variation in Calcium

Plasma calcium concentration varies with age, gender, season, during pregnancy, and throughout 24 hours. Total and free calcium decrease in the elderly. During pregnancy, total calcium and adjusted calcium decline in parallel with plasma albumin, free calcium is unchanged. The fetal circulation is relatively hypercalcemic, with higher total and free calcium in cord blood than in maternal plasma. Calcium concentrations decline after birth in healthy term neonates during the first few days, but soon increase to concentrations slightly greater than in adults.

Interpretation of Total and Free Calcium Results

Calcium status is best determined by measuring free calcium. Interpretation of total serum calcium is complicated by its association with protein and inorganic and organic ions. Disagreement between free and total calcium occurs in a high percentage of specimens. One study reported disagreement between free and total or adjusted calcium values in 18% and 31% of patients, respectively.

Free calcium is more useful than total calcium determination in hospital patients who have received citrated blood or platelets, heparin, bicarbonate, intravenous solutions, or calcium, and in intensive care because of abnormal protein concentrations and circulating factors that alter calcium binding to albumin. Abnormally low free calcium is frequently found in critically ill patients.

The calcium metabolism of patients with renal disease is best evaluated by the determination of free calcium because of alterations in protein, pH, protein binding of calcium, and calcium complexes with organic and inorganic anions.

Free calcium may be useful in the diagnosis of hypercalcemia. Patients with surgically proven PHPT often have increases in free calcium greater than total calcium. Free calcium is more sensitive than total calcium in detecting HCM, as patients frequently have decreased plasma albumin concentrations. Less commonly, paraproteins produced in myeloma may bind calcium, complicating the interpretation of total or adjusted calcium measurements.

In neonates, free rather than total calcium is recommended because of its speed of analysis and ability to use small skin-puncture specimens, its greater validity in the presence of hyperphosphatemia, alterations in pH, and persistence of α -fetoprotein after birth.

Urinary Calcium

Urinary calcium excretion reflects calcium intake, intestinal absorption, skeletal resorption, renal tubular filtration, and reabsorption. Healthy men and women excrete up to 300 mg (7.5 mmol) of calcium per day on a diet with unrestricted calcium content, and up to 200 mg (5 mmol) per day on a calcium-restricted diet (500 mg or 12.5 mmol calcium per day or less).

The reference interval for urinary calcium for spot fasting or timed specimens collected after an overnight fast is less than 0.16 mg/100 mL (<0.04 mmol/L) of glomerular filtrate (GF), as calculated by the equation:

$$\text{UCa (mg/100 mL GF)} = \frac{[\text{UCa (mg/dL)}] \times [\text{Serum creatinine (mg/dL)}]}{\text{Urinary creatinine (mg/dL)}}$$

An important, but under-recognized contributor to urine calcium excretion, is urinary sodium. Patients with hypercalciuria and normal sodium excretion have renal leak hypercalciuria, which can result in increased secretion of PTH and can be corrected by a thiazide. Hypercalciuria with increased urinary sodium excretion responds rapidly to a reduced sodium intake.

Under fasting conditions, the intestinal and renal components are relatively fixed, and calcium excretion (mg/100 mL [mmol/L] of GF) in the fasting state is used to assess the skeletal component. A value greater than 0.16 mg/100 mL (>0.04 mmol/L) of GF implies an increase in osteoclastic bone resorption.

Specimens may be collected in a container containing acid to prevent calcium salt precipitation. HCl (6 mol/L) is commonly used. Specimens collected without acid should be acidified and allowed to stand for 1 hour before thorough remixing and aliquoting. The ability of postcollection acidification to redissolve all calcium salts has been questioned.

POINTS TO REMEMBER

Calcium

- The skeleton is the major store of calcium.
- The free calcium is the physiologically important ion and is tightly regulated.
- PTH and vitamin D metabolites combine to regulate calcium via the kidney, intestine, and bone.
- Calcium adjusted for albumin can supply important information regarding an individual's calcium status.
- A calcium sensing receptor is present on the chief cells of the parathyroid gland that is responsive to changes in circulating free calcium.

PHOSPHATE

An adult has 600 g or approximately 20 mol of phosphorus in inorganic and organic phosphates, 85% is in the skeleton, and the rest is in soft tissue.

Biochemistry and Physiology

Plasma contains both inorganic and organic phosphate, but only inorganic phosphate is measured. Inorganic phosphate exists as both monovalent (H_2PO_4^-) and divalent (HPO_4^{2-}) phosphate anions. The ratio of H_2PO_4^- to HPO_4^{2-} is pH dependent and varies from 1:1 in acidosis to 1:4 at pH 7.4 and 1:9 in alkalosis. Only 10% of phosphate in serum is protein-bound; 35% is complexed with sodium, calcium, and magnesium; the remainder, 55%, is free.

Inorganic phosphate is a major component of hydroxyapatite in bone; thus it plays an important role in the structural support of the body and provides phosphate for the extracellular and intracellular pool.

In soft tissue, phosphate is mainly intracellular. In cells, most is organic and is incorporated into nucleic acids, phospholipids, phosphoproteins, and high-energy compounds. Adenosine triphosphate (ATP) and other phosphates, such as creatine phosphate, are involved in many energy-intensive processes, such as muscle contractility, neurologic function, and electrolyte transport. Phosphate is an essential element of cyclic nucleotides and cofactors such as nicotinamide adenine dinucleotide phosphate (NADP). It is important for the activity of several enzymes, including adenylate cyclase, 25-hydroxyvitamin D-1 α -hydroxylase, and in the production of 2,3-diphosphoglycerate, the key compound regulating oxygen affinity of hemoglobin. Intracellular phosphate is involved in the regulation of intermediary metabolism of proteins, fats, carbohydrates, and in gene transcription and cell growth.

The regulation of phosphate involves the kidneys, intestine, and skeleton. Plasma phosphate in adults is maintained between 0.7 and 1.4 mmol/L. Plasma phosphate concentration demonstrates a diurnal variation with a significant increase after the evening meal to a peak in the early hours of the morning, decreasing to a nadir early morning. This circadian rhythm is blunted by fasting. 1,25(OH)₂D can promote phosphate and calcium absorption via the intestine and can increase phosphate mobilization through osteoclastic resorption of bone. PTH can have effects on phosphate via the kidneys by increasing expression of the type IIa sodium-phosphate co-transporter (NPT2a). PTH promotes phosphaturia and lowers circulating phosphate. PTH can stimulate both bone resorption and bone formation depending on the fluctuation in PTH and so can either release or deposit phosphate in bone. Variations observed in PTH and 1,25(OH)₂D in health and disease do not fully explain the changes in phosphate homeostasis and so the existence of “phosphatonin(s)” such as fibroblast growth factor (FGF)23 had long been suspected.

FGF23 is a mid to long-term modulator of phosphate homeostasis. FGF23 increases kidney fractional excretion of phosphate. It decreases production of 1,25(OH)₂D, by decreasing 25-hydroxyvitamin D 1-hydroxylase activity. These key effects lead to decreased plasma phosphate. FGF23 is secreted by bone cells (osteocytes, osteoblasts, and osteoclasts) in response to sustained increased plasma phosphate or increased plasma 1,25(OH)₂D. In CKD, FGF23 increases in a compensatory mechanism to counter increasing plasma phosphate. As kidney function deteriorates, responsiveness to FGF23 declines reducing FGF23's ability to lower plasma phosphate.

Clinical Significance

Hypophosphatemia

Hypophosphatemia, a concentration of inorganic phosphate in serum below the reference interval (<2.5 mg/dL [<0.81 mmol/L]), is common in hospitalized patients (2%).

Hypophosphatemia or phosphate depletion in blood may be caused by a shift of phosphate from extracellular to intracellular spaces; renal phosphate wasting; decreased intestinal absorption, intracellular phosphate loss. Major causes of hypophosphatemia and phosphate depletion include intracellular shift, such as that in alcoholism; carbohydrate induced-insulin secretion; vomiting; diarrhea; inadequate intestinal phosphate absorption, such as in patients taking aluminum- or magnesium-containing antacids; renal phosphate wasting; ketoacidosis; genetic causes; and certain drugs such as anticonvulsants and diuretics.

Treatment of hypophosphatemia depends on phosphate concentrations and on symptoms. Patients with moderate hypophosphatemia often require only treatment of the underlying disorder and, possibly, oral phosphate. In patients with marked symptoms of hypophosphatemia, particularly if respiratory muscle weakness is present, parenteral administration of phosphate is indicated.

Hyperphosphatemia

The most common cause is inability of the kidneys to excrete phosphate. Hyperphosphatemia is a major clinical problem in CKD (see [Chapter 35](#)). In acute kidney injury and CKD, a decrease in glomerular filtration rate (GFR) reduces the renal excretion of phosphate, resulting in hyperphosphatemia. Moderate increases in plasma phosphate occur in individuals with low PTH, PTH resistance, or acromegaly.

The clinical manifestations of hyperphosphatemia depend on its rate of onset. A rapid increase in plasma phosphate may be associated with hypocalcemia. Symptoms may include tetany, seizures, and hypotension.

Therapy for hyperphosphatemia is directed toward correcting the cause. In renal failure and in hypoparathyroidism, dietary restriction of phosphate and agents that bind phosphate in the intestine are useful in lowering phosphate.

Measurement of Phosphate

Most methods used to measure serum inorganic phosphate are based on the reaction of phosphate ions with ammonium molybdate forming a phosphomolybdate complex measured by a spectrophotometer.

The colorless phosphomolybdate complex may be measured directly by ultraviolet (UV) absorption (340 nm) or reduced to molybdenum blue and measured at 600 to 700 nm. An acidic pH is necessary for the formation of complexes. A higher pH can result in spontaneous reduction of molybdate. Solubilizing agents such as Tween 80 prevent protein precipitation. Measurement of unreduced complexes has several advantages, including simplicity, speed, and reagent stability. Disadvantages include greater interference by hemolysis, icterus, and lipemia when 340 nm wavelength is used.

Specimen Requirements

Serum and heparinized plasma are preferred specimens. Inorganic phosphate concentrations are 0.2 to 0.3 mg/dL (0.06 to 0.10 mmol/L) lower in heparinized plasma than in serum. Anticoagulants such as citrate, oxalate, and EDTA interfere with formation of the phosphomolybdate complex.

Phosphate concentrations in plasma or serum are increased by prolonged storage at room temperature or 37°C. Hemolyzed specimens are unacceptable, erythrocytes contain high concentrations of organic phosphate esters. Inorganic phosphate increases by 4 to 5 mg/dL (1.29 to 1.61 mmol/L) per 24 hours in hemolyzed specimens at 4°C, and more rapidly at 37°C.

Phosphate is stable in separated serum for several days at 4°C and for months when frozen, provided evaporation and lyophilization are prevented.

Interferences

Positive or negative interference has been noted with hemolyzed, icteric, and lipemic specimens. Mannitol, fluoride, and monoclonal immunoglobulins are reported to interfere.

Reference Intervals

Phosphate is often referred to as “phosphorus,” but this is inaccurate and misleading; only phosphate, not elemental phosphorus, circulates in blood.

In adults, the reference interval for serum phosphate is 2.5 to 4.5 mg/dL (0.81 to 1.45 mmol/L). In children, it is 4.0 to 7.0 mg/dL (1.29 to 2.26 mmol/L). Serum phosphate concentrations are about 50% higher in infants than in adults and decline throughout childhood. Detailed pediatric reference intervals were established in the CALIPER study (see Appendix).

Urinary phosphate excretion varies with age, muscle mass, renal function, PTH and time of day. Urinary excretion of phosphate is essentially equivalent to dietary intake. On a nonrestricted diet, the reference interval for urinary phosphate is 0.4 to 1.3 g/24 h (12.9 to 42.0 mmol/24 h).

Urine should be collected in 6 mol/L HCl, to avoid precipitation of phosphate complexes. Simultaneous measurement of phosphate and creatinine in serum and urine with fasting morning spot or 1- to 2-hour timed collections permits calculation of the renal phosphate threshold ($TmPO_4/GFR$). The clearance of phosphate divided by creatinine clearance can be plotted on a nomogram, and the $TmPO_4/GFR$ determined.

POINTS TO REMEMBER

Phosphate

- Phosphate can be stored in bone combined with calcium as hydroxyapatite.
- Abnormalities of phosphate metabolism can lead to significant bone disorders including rickets.
- Phosphate metabolism is under the regulation of PTH, vitamin D metabolites, and FGF23.
- Phosphate in serum is subject to significant fluctuation throughout the day influenced by nutritional intake.
- CKD results in significant increases in serum phosphate.

MAGNESIUM

Magnesium is the fourth most abundant cation in the body and the second most prevalent intracellular cation. The total body magnesium content is 25 g (~1 mol), of which 55% resides in the skeleton. One-third of skeletal magnesium is exchangeable and is thought to serve as a reservoir for maintaining the extracellular magnesium. Forty-five percent of magnesium is intracellular.

Biochemistry and Physiology

The concentration of magnesium in cells varies from 2.4 to 7.3 mg/dL (1 to 3 mmol/L). The higher the metabolic activity of a cell, the greater is its magnesium content. Within cells, most of the magnesium is bound to proteins and negatively charged molecules; 80% to 90% of cytosolic magnesium is bound to ATP, and MgATP is the substrate for numerous enzymes. Of the total cellular magnesium 0.5% to 5.0% is free. The transport of magnesium across the cellular membrane is regulated by a magnesium transport system.

Extracellular magnesium accounts for 1% of the total body magnesium content. Of the magnesium in plasma 55% is free, 30% is associated with proteins (primarily albumin), and 15% is complexed with phosphate, citrate, and other anions (Table 39.2).

Magnesium is a cofactor for 300+ enzymes. Magnesium is important in oxidative phosphorylation, glycolysis, cell replication, nucleotide metabolism, and protein biosynthesis. A decrease in plasma magnesium lowers the threshold of axonal stimulation and increases nerve conduction velocity. Magnesium influences neurotransmitter release at neuromuscular junctions. Reducing plasma magnesium results in increased neuromuscular excitability.

The Institute of Medicine recommends a daily magnesium intake of 310 to 420 mg. The small bowel absorbs 20% to 80% of dietary magnesium; absorption is proportional to the amount in the diet.

The kidneys play a major role in regulating magnesium balance. There is 70% to 80% of magnesium that is ultrafilterable with 5% to 15% being reabsorbed passively in the proximal

TABLE 39.2 Physicochemical States of Calcium, Phosphate, and Magnesium in Human Plasma

State	APPROXIMATE PERCENT OF TOTAL		
	Calcium	Phosphate	Magnesium
Free (ionized)	50	55	55
Protein-bound	40	10	30
Complexed	10	35	15
Total, mg/dL	8.6–10.3	2.5–4.5	1.7–2.4
Total mmol/L	2.15–2.57	0.81–1.45	0.70–0.99

Modified from Marshall RW. Plasma fractions. In: Nordin BEC, ed. *Calcium, Phosphate and Magnesium Metabolism*. London: Churchill Livingstone; 1976:162–85.

tubules. In the thick ascending limb of the loop of Henle 65% to 75% is absorbed paracellularly.

Clinical Significance

Hypomagnesemia/Magnesium Deficiency

Hypomagnesemia is common in hospital patients. Ten percent of patients admitted to hospital and 65% of patients in the intensive care unit (ICU) may be hypomagnesemic. Moderate or severe magnesium deficiency is usually due to loss of magnesium from the gastrointestinal tract (GI) or kidneys.

Vomiting, diarrhea, and nasogastric suction lower, and may deplete, body magnesium. Excessive urinary losses of magnesium from the kidneys are important causes of magnesium deficiency; other causes include alcohol, diabetes mellitus, and aminoglycoside antibiotics.

Magnesium deficiency is usually secondary to another disease or a therapeutic agent. Features of the primary disease may complicate or mask magnesium deficiency. Neuromuscular hyperexcitability with tetany and seizures may be present. Cardiac arrhythmia is a more serious outcome of deficiency.

Extracellular magnesium accounts for 1% of total body magnesium, but plasma magnesium correlates poorly with total body magnesium. Determination of serum magnesium is the most widely used test to assess magnesium status. Intracellular magnesium depletion and magnesium deficiency may exist despite a normal plasma magnesium. Hypocalcemia, hypokalemia, neuromuscular hyperirritability, and cardiac arrhythmias should be an alert to the possible presence of magnesium deficiency.

Acute symptomatic magnesium deficiency is treated with parenteral magnesium; mild depletion is treated with oral magnesium.

Hypermagnesemia

Magnesium intoxication is rarely encountered, a mild to moderate increase in magnesium concentration is observed in 12% of hospital patients. Symptomatic **hypermagnesemia** is almost always caused by excessive intake, resulting from administration of antacids, enemas, and parenteral fluids containing magnesium. Many patients have concomitant renal failure, limiting the kidneys ability to excrete magnesium.

Depression of the neuromuscular system is the most common manifestation of magnesium intoxication. Very high concentrations may result in cardiac arrest. Calcium acutely antagonizes the toxic effects of magnesium and can promote kidney excretion; patients with severe magnesium intoxication may require intravenous calcium. Peritoneal dialysis or hemodialysis against a low-magnesium dialysis bath effectively lowers magnesium.

Measurement of Total Magnesium

Photometric Methods

Several metallochromic indicators or dyes change color on selectively binding magnesium. Calmagite [1-(1-hydroxy-4-methyl-2-phenylazo)-2-naphthol-4-sulfonic acid], a metallochromic indicator, forms a colored complex with magnesium

in alkaline solution, measured at 530 to 550 nm. EGTA is added to reduce calcium interference. Potassium cyanide prevents the formation of heavy metal complexes, and polyvinylpyrrolidone and surfactants reduce interference from protein and lipemia. Methylthymol blue forms a blue complex with magnesium, measured around 600 nm. A formazan dye [1,5-bis(3,5-dichloro-2-hydroxyphenyl)-3-formazan carbonitrile] forms a complex with magnesium at alkaline pH, measured at 630 nm by thin-film reflectance photometry. *N,N'*-[1,2-ethanediybis(oxy-2,1-phenylene)]bis(*N*-carboxymethyl) glycine chelates calcium. This thin-film reflectance method shows relatively little interference from icteric, lipemic, and hemolyzed specimens. Magon, or xylidyl blue [1-azo-2-hydroxy-3-(2,4-dimethylcarboxanilido)-naphthalene-1'-(2-hydroxybenzene)], binds magnesium in alkaline solution, causing a spectral shift and forming a red complex, measured around 600 nm. Protein interferences are reduced by dimethyl sulfoxide.

Atomic Absorption Spectrometry

As with calcium, AAS methods provide greater accuracy and precision for magnesium measurements than do photometric methods.

Enzymatic Methods

Enzymatic methods have been developed with hexokinase using Mg^{2+} -ATP as a substrate. The rate of the enzyme-catalyzed reaction is dependent on magnesium concentration. When hexokinase is used with glucose 6-phosphate dehydrogenase, the rate of the dehydrogenase reaction is monitored by measuring the formation of NADPH at 340 nm.

Measurement of Free (Ionized) Magnesium

Free magnesium measurements in whole blood, plasma, or serum use ISEs with neutral carrier ionophores. Current ionophores or electrodes have insufficient selectivity for magnesium over calcium. It is necessary to determine both ions simultaneously and to correct for Ca^{2+} . pH should be measured simultaneously, as protein binding of magnesium in plasma is pH dependent.

Discordance between total and free magnesium measurements has been reported in selected populations—cardiovascular disorders, diabetes mellitus, alcoholism, migraine headaches, asthma, renal transplant, head trauma, and pregnant women. Interferences in measurements of total magnesium, such as thiocyanate in smokers, may explain some discrepancies.

Specimen Requirements for Total and Free Magnesium

Serum and heparinized plasma are preferred specimens for measuring free and total magnesium. Zinc heparin, lithium-zinc heparin, and some newer heparins, developed for free calcium determination, should be avoided because they increase free magnesium. Anticoagulants, such as citrate, oxalate, and EDTA, are not acceptable because they form complexes with magnesium. Storage of serum for days at 4°C

and for months frozen does not affect the measured concentrations of total magnesium.

Serum or plasma must be separated as soon as possible to prevent an increase in magnesium due to cell leakage. Hemolyzed specimens are unacceptable. Interference by icterus or lipemia depends on the method and can be decreased by bichromatic analysis or blanking with EDTA.

Factors altering free calcium also alter free magnesium concentration. Specimens should be handled anaerobically to prevent loss of carbon dioxide and analyzed without delay to prevent changes in pH. Certain silicones or other tube additives as well as thiocyanate (smokers and diet) interfere with free magnesium.

Magnesium is primarily an intracellular ion, so depletion is not necessarily reflected in decreased plasma concentrations.

Urine specimens should be collected in acid to prevent precipitation of magnesium complexes. If acid must be added after collection, the entire specimen must be acidified, warmed, and mixed thoroughly before analysis.

Reference Intervals for Total and Free (Ionized) Magnesium

Adult reference intervals for total serum magnesium are 1.7 to 2.4 mg/dL (0.66 to 1.07 mmol/L). The reference interval is a matter of debate, as low concentrations within the interval are associated with cardiovascular risk. Conversion factors for the units used to express magnesium concentration are given below.

$$\text{mmol/L} = \text{mEq/L} \times 0.5 = \text{mg/dL} \times 0.41$$

$$\text{mEq/L} = \text{mmol/L} \times 2 = \text{mg/dL} \times 0.82$$

$$\text{mg/dL} = \text{mEq/L} \times 1.22 = \text{mmol/L} \times 2.43$$

Reference intervals for total magnesium in infants, children, and adolescents have been published; they do not differ significantly from those of adults. Pediatric reference intervals have been established as part of the CALIPER study (see Appendix).

HORMONES REGULATING BONE AND MINERAL METABOLISM

PTH and 1,25(OH)₂D are the primary hormones regulating bone and mineral metabolism. FGF23 is involved in phosphate homeostasis. Calcitonin has pharmacologic actions, but no obvious physiologic role. PTHrP is the principal mediator of **humoral hypercalcemia of malignancy (HHM)**, but it also has physiologic functions in fetuses, and in pregnancy and lactation. Sclerostin inhibits the Wnt signaling pathway that plays a major role in osteoblast development and function, and results in decreased bone formation and turnover.

Parathyroid Hormone

Parathyroid hormone (PTH) is synthesized and secreted by the parathyroid glands, usually two superior and two inferior,

located bilaterally on or near the thyroid gland capsule. The chief cells are responsible for synthesizing, storing, and secreting PTH.

Biochemistry and Physiology

The concentration of PTH in blood is determined by the rates of synthesis and secretion by the parathyroids and its metabolism and clearance by the liver and kidneys. The primary regulators of PTH secretion are free calcium, 1,25(OH)₂D, and phosphate. PTH acts directly on bone and the kidneys, and indirectly on intestine via 1,25(OH)₂D, to increase plasma free calcium and ultimately decrease plasma phosphate.

Synthesis and secretion. Parathyroid cells have relatively few secretory granules for PTH storage. PTH must be synthesized as needed for secretion. Control of PTH synthesis by calcium and phosphate occurs largely at the post-transcriptional level.

PTH metabolism in the parathyroids results in the pre-sequence and the 6 amino acid long N-terminal 'pro-sequence' being enzymatically cleaved before packaging in the Golgi apparatus. Intact PTH (84 amino acids) is secreted, stored, or degraded intracellularly. Intracellular degradation is increased when plasma calcium is high and secretion of PTH is low. When PTH secretion is high (low plasma calcium), intracellular degradation is low. Together with intact PTH, several C-terminal fragments are secreted.

The classic biological activity of PTH resides in the N-terminal third of the molecule. Synthetic PTH(1–34) is at least as potent as intact PTH(1–84) in interacting with the PTH/PTHrP receptor (PTH1R, type 1 PTH receptor) and stimulating calcemic, phosphaturic, and other biological responses in kidneys and bone.

The C-terminal metabolites of PTH, have effects that antagonize those of PTH (1–84), having their own receptors in kidneys and bone, that are distinct from those mediated by PTH1R.

The concentration of free calcium in blood or extracellular fluid is the primary acute physiologic regulator of PTH synthesis, metabolism, and secretion. An inverse sigmoid relationship exists between PTH secretion and free extracellular calcium. Maximal secretion and suppression are attained with hypocalcemia and hypercalcemia. The midpoint of this relationship (or set point) is the calcium concentration at which PTH secretion is half maximal.

1,25(OH)₂D, phosphate, and magnesium influence the synthesis and secretion of PTH. 1,25(OH)₂D interacts with vitamin D receptors in the parathyroid glands to decrease PTH secretion. Hyperphosphatemia and hypophosphatemia increase and decrease PTH synthesis and secretion, respectively, and the hyperphosphatemia of CKD leads to parathyroid hyperplasia and hyperparathyroidism. Chronic severe hypomagnesemia, such as in alcoholism, has been associated with impaired PTH secretion, acute hypomagnesemia may stimulate secretion. Chronic hypomagnesemia can cause resistance to the effects of PTH.

PTH demonstrates a circadian rhythm throughout 24 hours. Variation in phosphate is important in controlling the circadian secretion of PTH.

Biological actions. PTH influences calcium and phosphate homeostasis directly through its actions on bone and kidneys and indirectly through actions on the intestine through $1,25(\text{OH})_2\text{D}$ (see Fig. 39.3). PTH exerts its actions by interacting with type 1 PTH receptors located in the plasma membranes of target cells.

In the kidneys PTH induces 25-hydroxyvitamin D-1 α -hydroxylase, increasing $1,25(\text{OH})_2\text{D}$, which, in turn, stimulates intestinal absorption of both calcium and phosphate; it increases calcium reabsorption in the distal convoluted tubules; it decreases reabsorption of phosphate by the proximal tubules, and inhibits Na^+H^+ antiporter activity, which favors mild hyperchloremic metabolic acidosis in hyperparathyroidism.

The effects of PTH on bone are complex, as evidenced by its stimulation of bone resorption or bone formation, depending on the concentration of PTH, the duration of exposure and the PTH signaling profile. Chronic exposure to high concentrations of PTH leads to increased bone resorption that is an effect important for the maintenance of calcium homeostasis. Daily increase and decrease of PTH (seen following Teriparatide injection) results in an anabolic effect on bone that may be mediated by inhibition of sclerostin expression in osteocytes. PTH increases osteoblasts and enhances their differentiation from stromal cells.

Integration of the direct effects of PTH on bone and kidneys, and of the indirect effects on intestine through $1,25(\text{OH})_2\text{D}$, results in alterations in calcium and phosphate concentrations in blood and urine. Urinary calcium excretion is increased because the larger filtered load of calcium, derived from bone resorption and intestinal calcium absorption, overrides the increased tubular reabsorption of calcium.

Heterogeneity of circulating parathyroid hormone. PTH circulates as the biologically active hormone and as a series of N-terminally truncated fragments containing the mid-region and C-terminal amino acids. The heterogeneity is due to the secretion of both intact hormone and C-terminal fragments by the parathyroids, peripheral metabolism of intact hormone by liver and kidneys to C-terminal fragments, and renal clearance of intact hormone and C-terminal fragments. Biologically active intact PTH (amino acids 1–84) is rapidly cleared from plasma in normal subjects (half-life <5 minutes) by the liver (60% to 70%) and the kidneys (20% to 30%).

Circulating PTH measured by most immunoassays is composed of both “inactive” fragments and intact hormone. Fragments consisting of the middle and carboxyl regions of the molecule (e.g., amino acids 34–84, 36–84) are devoid of the N-terminal region and classic PTH activity and were considered inactive degradation products.

Clinical Significance

Determination of PTH is useful in the differential diagnosis of both hypercalcemia and hypocalcemia, for assessing parathyroid function in renal failure, and for evaluating parathyroid function in bone and mineral disorders.

Measurement of Parathyroid Hormone

PTH assays have yielded different estimations due to the presence of a series of immunologic determinants along the molecule and the physiologic heterogeneity of circulating PTH-related antigens. Noncompetitive (sandwich) immunoassays are commonly used for the measurement of intact PTH (see Chapter 15 for immunoassay discussion).

PTH assays developed to measure the intact molecule of PTH(1–84) only, were called *intact assays*. These assays incorporated the use of a noncompetitive immunometric assay (IMMA) format using two antibodies: (1) a solid-phase capture antibody against the C-terminus, and (2) a labeled detection antibody against the N-terminus, or vice versa. It has become clear that they can overestimate the severity of PTH-related bone disease because they detect several molecular species of PTH. Blood contains N-terminally truncated PTH fragments that are long enough to react in the intact PTH assays but do not bind the PTH receptor. The term *intact* as applied to these immunometric PTH assays is a misnomer because C terminal PTH fragments are detected along with PTH(1–84).

In the newest PTH assays, the epitope of the N-terminally binding antibody consists of the first four to six amino acids of the PTH molecule. Such assays have been variously termed *true intact* PTH assays, *whole* PTH assays, or *cyclase-activating* PTH assays. Despite theoretical improvement, in clinical practice they have not shown advantages over earlier IMMAs. A few methods have solved the problem, using capture antibodies against the N-terminal sequence (26–32) and signal antibodies against the middle or C-terminal sequence (55–64). With the latter arrangement, a higher quantity of signal antibody is needed because of the high concentration of inactive fragments relative to intact hormone, especially in CKD.

Affinity-purified polyclonal antibodies have been widely used, particularly for the signal antibody, because of the difficulty of producing high-affinity monoclonal PTH antibodies. Capture antibodies are noncovalently bound or are covalently attached to one of a variety of solid phases. Signal antibodies most often have been radiolabeled (IRMAs) with ^{125}I , or labeled with a chemiluminescent compound (ICMAs), such as acridinium ester or isoluminol, or an enzyme, ELISA or EIA, such as alkaline phosphatase (ALP). Other assay formats used on automated immunoassay analyzers include electrochemiluminescence detection (see Chapter 15).

N-terminal-truncated parathyroid hormone and intact parathyroid hormone methods. The N-terminal-truncated fragment(s) [non-(1–84)PTH and PTH(7–84)], containing all but a few of the N-terminal amino acids, account, on average, for 20% to 50% of intact PTH concentrations measured by early intact PTH assays in healthy subjects and CKD. The relative concentration of N-terminal-truncated PTH increases with hypercalcemia and decreases with hypocalcemia. N-terminal-truncated PTH originates from both secretion by the parathyroids and peripheral metabolism of intact hormone.

The newest intact PTH assay utilizes antibodies against PTH(1–4) and requires the presence of the most N-terminal amino acid, evidenced by its failure to recognize PTH(2–34) (Fig. 39.5).

Fig. 39.5 Relationship between parathyroid hormone (PTH) assays, PTH assay epitopes, and PTH molecular forms detected in circulation. The *upper panel* depicts the structure of human PTH and epitopes detected by various PTH assays. Early PTH assays detect full-length PTH(1–84) in addition to PTH fragments. These assays include RIAs that use antisera specific for the amino-terminal (N-RIA), middle (MID-RIA), or carboxy-terminal (C-RIA) region of PTH. “Intact PTH” assays detect full-length PTH(1–84) and non-(1–84)PTH fragments. PTH assays (Bio) detect the full-length PTH(1–84). The *lower panel* depicts the PTH molecular forms present in the circulation. (Modified from Henrich, L. M., Rogol, A. D., D’Amour, P., Levine, M. A., Hanks, J. B., & Bruns, D. E. [2006]. Persistent hypercalcemia after parathyroidectomy in an adolescent and effect of treatment with cinacalcet HCl. *Clin Chem*, 52, 2286–2293.)

The inability of some intact PTH methods to accurately measure biologically active intact hormone may explain why such intact PTH assays are not a reliable indicator of bone turnover in dialysis patients and fail to distinguish patients with low-, normal-, and high-turnover bone disease.

The newest intact PTH assays (whole PTH) are not totally specific for intact PTH, the presence of an amino-terminal form of PTH represents approximately 20% of the intact PTH measured with some new intact PTH methods. The clinical implications of this form have not yet been established.

Several studies highlight the lack of comparability of current PTH assays especially in patients with CKD or those receiving hemodialysis. This has raised concerns regarding the standardization of PTH assays; therefore recognized production and implementation of a commutable international standard material is required.

Mass spectrometry has been used to characterize PTH fragments and to measure intact PTH. The assay showed no detectable cross-reactivity with PTH fragments, including PTH(7–84). Using this method PTH(7–84) was not detected in the serum of CKD patients although other large C-terminal fragments were present.

Specimen requirements. EDTA plasma is often preferred, some assays require serum and results vary with sample type. Plasma should be analyzed within 72 hours if stored at 4°C. Lower concentrations of PTH are observed in serum incubated at room temperature for longer than a few hours, or after one to several days at 4°C. There is no consensus on the effects of storing samples in a freezer (–20°C or –80°C) before

analysis. PTH can stick to some plastic tubes and result in decreased values obtained with storage.

Reference Intervals

Reference intervals for PTH vary with the method used and can be affected by vitamin D status of the population studied.

Typical reference intervals are:

Intact PTH: 10 to 65 pg/mL or 1.1 to 6.8 pmol/L

PTH(1–84): 6 to 40 pg/mL or 0.6 to 42 pmol/L

Interpretation of PTH concentrations must take account of the patient’s circulating calcium at the time of sampling.

Lower intervals have been established by excluding individuals with vitamin D insufficiency.

Intact PTH increases with age; is low or normal during pregnancy; is lower in fetuses and umbilical cord blood; and increases during the first few days of life. Concentrations in children and adolescents are similar to adults.

Interpretation of Parathyroid Hormone Results

PTH is the most important test for the differential diagnosis of hypercalcemia. Intact PTH is increased in most patients with PHPT (Fig. 39.6) and is below normal or close to the lower limit of the reference interval in most patients with nonparathyroid hypercalcemia. In stable hypercalcemia, increased or inappropriately detectable PTH in patients with hypercalcemia and malignancy suggests coexisting PHPT and malignancy, ectopic PTH production by tumors is extremely rare. Measurements of

Fig. 39.6 Parathyroid hormone (PTH) in healthy individuals and patients with primary hyperparathyroidism, hypercalcemia-associated malignancy, and hypoparathyroidism. PTH was measured with immunoassay for its mid-region (A) and for intact PTH (B). (Modified from Endres, D. B., Villanueva, R., Sharp, C. F., Jr., & Singer, F. R. [1989]. Measurement of parathyroid hormone. *Endocrinol Metab Clin North Am*, 18, 611–629.)

urinary calcium excretion are necessary to confirm hypocalciuria in cases of suspected FBHH.

The short half-life of PTH (≤ 5 minutes) allows intraoperative determination of intact PTH to assess the completeness of parathyroidectomy and facilitates minimally invasive parathyroidectomy. Preoperative or intraoperative PTH may be useful for localizing hyperfunctioning parathyroid tissue by sampling multiple veins from the cervical and mediastinal regions. Postoperative PTH concentrations after thyroidectomy may be predictive of development of hypocalcemia due to a large influx of calcium into bone (hungry bone syndrome).

Subnormal or low-normal PTH is observed in most patients with hypoparathyroidism (see Fig. 39.6). The apparently detectable concentrations in patients with hypoparathyroidism or nonparathyroid hypercalcemia may be a result of imprecision of methods at low concentrations, a nonspecific serum (ligand-free matrix) effect, and/or measurement of N-terminal-truncated PTH. In 2°HPT, PTH is increased before total or free calcium becomes abnormally low—a consequence of homeostatic mechanisms for the maintenance of serum calcium.

In patients with end-stage renal disease (ESRD), the measurement of PTH is helpful in assessing parathyroid function, in estimating bone turnover, and in improving management.

Parathyroid status is usually determined by measuring PTH on predialysis specimens because factors, including changes in plasma calcium and the type of dialysis membrane, affect PTH secretion and clearance.

The whole PTH(1–84) assay theoretically should more accurately assess parathyroid status and bone turnover and thus better guide therapy in patients with ESRD compared with the intact PTH assay.

POINTS TO REMEMBER

Parathyroid Hormone

- Several assays exist for the measurement of PTH. Cross reactivity with PTH metabolites and standardization remains a current problem resulting in significant variation in values obtained particularly in CKD.
- Measurement of intact PTH is pivotal in the differential diagnosis of calcium disorders.
- Surgical removal of the parathyroid glands is the commonest cause of hypoparathyroidism.
- Hypomagnesemia can result in failure of the chief cells to release PTH resulting in hypoparathyroidism. In such cases, patients will not normalize their circulating calcium until there is adequate magnesium replacement.
- PTH by daily injection is a treatment for osteoporosis.

Vitamin D and Its Metabolites

Vitamin D₃ is produced endogenously through exposure of skin to sunlight (cholecalciferol) and is absorbed from foods containing or supplemented with vitamin D₃ or D₂ (ergocalciferol). The vitamin is metabolized to its biologically active form, 1,25(OH)₂ D₃/D₂, promoted by hormones that regulate calcium and phosphate metabolism. Deficiency of vitamin D results in impaired formation of bone, producing rickets in children and osteomalacia in adults.

Biochemistry and Physiology

Vitamin D and its metabolites may be categorized as cholecalciferols or ergocalciferols (Fig. 39.7). Cholecalciferol (vitamin D₃) is the parent compound and is produced in skin from 7-dehydrocholesterol on exposure to UV B from sunlight. Latitude, season, aging, sunscreen use, and skin pigmentation influence the production of vitamin D₃ by skin. Vitamin D₂ is manufactured by irradiation of ergosterol produced by yeasts. Total vitamin D refers to vitamin D or metabolites written without a subscript.

Fig. 39.7 Metabolism of vitamin D. Vitamin D₂ and vitamin D₃ are enzymatically hydroxylated to 25-hydroxyvitamin D in the liver and to 1,25-dihydroxyvitamin D by the kidneys.

A total of 90% of vitamin D is produced by synthesis in the skin. In North America, a significant fraction of vitamin D is acquired by ingestion of fortified foods (cereals, bread, and milk) or supplements. The recommended daily allowance is 400 IU (10 µg). In some European countries, the recommendation for people older than 60 years is 800 IU (20 µg). There is debate about the doses of vitamin D that are considered optimal for bone health and that can improve vitamin D status sufficiently to result in increases in bone mineral density (BMD) and reduce risk of fracture. Prospective randomized trials of high-dose vitamin D supplementation have increased BMD and muscle function in women, but in some cases a detrimental effect has been observed resulting in increased falls and fractures. Increasing the dose of vitamin D supplementation results in a greater proportional production of 24,25(OH)₂D and this may block the action of 1,25(OH)₂D.

Metabolism, Regulation, and Transport

Vitamin D₂ and vitamin D₃ are metabolized to 25(OH)D₃ in the liver by vitamin D 25-hydroxylase, (see Fig. 39.7). The concentration and half-life of 25(OH)D in plasma are listed in Table 39.3.

25(OH)D₃ are metabolized to 1,25-dihydroxyvitamin D₂ or D₃, the biologically active hormone, by 25(OH)D 1α-hydroxylase, in the kidneys and placenta (see Fig. 39.7). Circulating 1,25(OH)₂D is tightly regulated, by PTH, phosphate, calcium, FGF23 and 1,25(OH)₂D. PTH and hypophosphatemia increase 25(OH)D-1α-hydroxylase activity; hypocalcemia stimulates PTH secretion. Hypercalcemia, hyperphosphatemia, FGF23, and 1,25(OH)₂D reduce 25(OH)D 1α-hydroxylase. 1,25(OH)₂D also induces 25(OH)D 24-hydroxylase, producing 24,25(OH)₂D. Normal concentrations and the half-life of 24,25(OH)₂D are listed in Table 39.2.

Vitamin D, 25(OH)D, and 1,25(OH)₂D are bound to vitamin D binding protein (DBP), a specific, high-affinity transport protein also known as *group-specific component of serum* or *Gc-globulin*. DBP is constitutively synthesized by the liver and circulates in excess (400 mg/L), with <5% of the vitamin D binding sites occupied. Only 0.03% of 25(OH)D and 0.4% of 1,25(OH)₂D are free in plasma (see Table 39.2). DBP concentrations are increased in pregnancy and estrogen therapy, and are decreased in nephrotic syndrome.

Biological Actions of 1,25-Dihydroxyvitamin D

1,25(OH)₂D maintains calcium and phosphate concentrations in blood through its actions on intestine, bone, kidney, and the parathyroids. In the small intestine, 1,25(OH)₂D stimulates calcium absorption, primarily in the duodenum, and phosphate absorption by the jejunum and ileum. Three processes absorb calcium from the diet: (1) calcium entry into the brush border cytoplasm, (2) diffusion of calcium within the cell, and (3) exit of calcium from the cell across its basolateral membrane.

At high concentrations, 1,25(OH)₂D increases bone resorption by inducing monocytic stem cells to differentiate into osteoclasts and by stimulating osteoblasts

to produce cytokine production influencing osteoclast activity. By stimulating osteoblasts, 1,25(OH)₂D increases ALP and **osteocalcin (OC)**. 1,25(OH)₂D acts directly on the parathyroids to inhibit the synthesis and secretion of PTH.

Clinical Significance

Determination of 25(OH)D may be useful in the differential diagnosis of hypocalcemia, hypercalcemia, or hypercalciuria and for evaluating vitamin D status in health and in bone and mineral disorders. Measurements of 25(OH)D, 1,25(OH)₂D and 24,25(OH)₂D have clinical value. The (UK) National Kidney Foundation guidelines have emphasized that vitamin D nutrition is assessed by measurements of 25(OH)D, not 1,25(OH)₂D.

Vitamin D nutritional status is best determined by measurement of 25(OH)D, because 25(OH)D is the main circulating form of vitamin D (Table 39.3), it has a long half-life and is less affected by day-to-day variation, exposure to sunlight, or food intake. Groups at higher risk for developing nutritional vitamin D deficiency include breast-fed infants, strict vegetarians who abstain from eggs and milk, strict vegans, individuals with darker skin pigmentation, and the elderly.

Concentrations of 25(OH)D may be decreased by reduced availability of vitamin D, inadequate conversion of vitamin D to 25(OH)D, accelerated metabolism of 25(OH)D, and urinary loss of DBP and 25(OH)D. Reduced availability of vitamin D may occur with inadequate exposure to sunlight, dietary deficiency, malabsorption syndromes, and following gastric or small bowel resection. Severe hepatocellular disease has been associated with inadequate conversion of vitamin D to 25(OH)D. Drugs such as phenytoin and phenobarbital induce drug-metabolizing enzymes that accelerate the metabolism of vitamin D and its metabolites. Plasma 25(OH)D concentrations may be reduced in patients with nephrotic syndrome because of the urinary loss of DBP and 25(OH)D.

A significant proportion of adults in Europe and North America have poor vitamin D status. It has been difficult to harmonize reference intervals for 25(OH)D, this may be related to differences of opinion regarding the definition of subclinical vitamin D insufficiency.

TABLE 39.3 Vitamin D and Its Metabolites in Plasma

Compound	Concentration	Free (%)	Half-Life
Vitamin D	<0.2–20 ng/mL <0.5–52 nmol/L	—	1–2 days
25-Hydroxyvitamin D	10–65 ng/mL	0.03	2–3 weeks
1,25-Dihydroxyvitamin D	25–162 nmol/L		
	15–60 pg/mL 36–144 pmol/L	0.4	4–6 h
24,25-Dihydroxyvitamin D	0.8–2.8 ng/mL 2.0–7.2 nmol/L	Not established	NA

In hypercalcemia, 25(OH)D measurement has limited value. It can confirm intoxication after ingestion of large amounts of vitamin D or 25(OH)D. The measurement of 1,25(OH)₂D is diagnostic in vitamin D-dependent rickets types 1 and 2, and is helpful in disease states associated with the overproduction of 1,25(OH)₂D such as granuloma-forming disorders, fungal infection, Hodgkin disease, and other lymphomas. 1,25(OH)₂D gives confirmatory information in the evaluation of hypercalcemia, hypercalciuria, hypocalcemia, and bone and mineral disorders. 1,25(OH)₂D concentrations are increased in vitamin D-dependent rickets type 2, in 1,25(OH)₂D intoxication, and in PHPT. Reduced 1,25(OH)₂D can be observed in renal failure, hypercalcemia of malignancy, hyperphosphatemia, hypoparathyroidism, pseudohypoparathyroidism, type 1 vitamin D-dependent rickets, hypomagnesemia, nephrotic syndrome, and severe hepatocellular disease.

24,25(OH)₂D measurements are increasingly valuable. The absence of 24,25(OH)₂D can result in childhood hypercalcemia and stone formation. Some reports of hypercalcemia in pregnancy have described low 24,25(OH)₂D contributing to the pathology. Higher 25(OH)D concentrations have a strong positive correlation with 24,25(OH)₂D, and increasing vitamin D supplementation results in proportionally greater increases in 24,25(OH)₂D than 1,25(OH)₂D.

Measurement of Vitamin D Metabolites

Specific and sensitive assays exist for measuring vitamin D, 25(OH)D, 1,25(OH)₂D, and 24,25(OH)₂D. All assays should measure D₂ and D₃ metabolites equally (equimolar reactivity), because both D₂ and D₃ are metabolized to produce biologically active 1,25(OH)₂D. Separate measurement of the D₂ and D₃ does not necessarily distinguish between dietary and endogenous sources of vitamin D, as food can be supplemented with D₃ or D₂.

The hydrophobic natures and small circulating concentrations of vitamin D metabolites, together with the possibility of matrix effects, have presented challenges for the development of assays that would be both specific and suitable for high-throughput clinical analysis. Two or three of the following steps are needed in any assay for 25(OH)D, 1,25(OH)₂D or 24,25(OH)₂D: deproteinization or extraction, purification, and quantification. The first step frees the metabolites from DBP. Purification steps, most often using column chromatography, separate the forms of vitamin D, lipids, and interfering substances. The method of quantification depends on the metabolite being measured.

Extraction and deproteinization. Protein precipitation using zinc sulfate is currently a common step in sample preparation. The most widely used methods use acetonitrile to deproteinize the specimen and to denature DBP, freeing vitamin D metabolites. One assay uses immunoextraction for 1,25(OH)₂D, and this process has been incorporated into an automated method.

Column chromatography. Differences in their polarities, related to their numbers of hydroxyl groups, have been used to separate vitamin D and its metabolites. 1,25(OH)₂D and

24,25(OH)₂D are more polar than 25(OH)D, which is more polar than vitamin D.

Measurement of 25-hydroxyvitamin D. Acceptance of serum 25(OH)D as an indicator of an individual's vitamin D status has resulted in the development of several assays. The metabolite is measured by competitive protein binding assay (CPBA), competitive or noncompetitive immunoassay (radioimmunoassay [RIA], enteroinsular axis enzyme assay [EIA], immunochemiluminometric assay [ICMA]), UV absorption after separation by high-performance liquid chromatography (HPLC), or by mass spectrometry after separation by chromatography (see Chapter 13). The 25(OH) D₂ and D₃ metabolites can be quantified separately by liquid chromatography-mass spectrometry (LC-MS)/MS. It is important to report the sum of the two concentrations [25(OH)D₂ + 25(OH)D₃] because vitamin D status depends on the total concentration.

Determination by HPLC with UV absorption or mass spectrometry requires appropriate equipment (see Chapters 12 and 13), specialized training, and a larger sample.

Most laboratories that measure 25(OH)D have chosen competitive immunoassays. These assays are easy to perform; use widely available reagents on multi-channel analyzers; and require only a small volume of plasma.

Measurement of 1,25-dihydroxyvitamin D. 1,25(OH)₂D circulates at 1/1000 of the concentration of 25(OH)D and at lower concentrations than other dihydroxylated metabolites (see Table 39.3). Together with the extreme hydrophobicity and instability of the compound this greatly complicates its determination in serum. Widely used methods require extraction, chromatography, and quantification by radioreceptor assay or RIA.

Measurement of 24,25 dihydroxyvitamin D. No immunoassays have sufficient antibody specificity that enable measurement of 24,25(OH)₂D. The methods currently in use are LC-MS/MS assays.

Specimen requirements. Serum is preferred for measuring vitamin D metabolites, although plasma is acceptable for assays using extraction and chromatography. Once separated from the clot, serum is stable at both room temperature and 4°C; specimens should be frozen if the analysis is delayed. Vitamin D metabolites in serum or plasma are not sensitive to light and do not require special handling.

Reference Intervals

Reference intervals for vitamin D metabolites are method dependent. Concentrations of less than 20 to 30 ng/mL (<50 to 75 nmol/L) can be associated with increased PTH and reduced calcium absorption. The Institute of Medicine published a recommendation that the lower limit for vitamin D sufficiency be lowered from 30 to 20 ng/mL (75 to 50 nmol/L) and that concentrations greater than 50 ng/mL (>125 nmol/L) be considered as cause for concern. Vitamin D insufficiency [25(OH)D <20 ng/mL (50 nmol/L)] was common during the winter in adults (>30 years) Caucasian men (15%) and women (30%) living in the southern United States.

25(OH)D concentrations in African Americans are lower than in non-Hispanic whites, but the clinical significance of this is uncertain. Compared with non-Hispanic whites, African Americans have higher BMD, higher PTH and 1,25(OH)₂D; lower biochemical markers of bone remodeling; and lower rates of osteoporosis.

25(OH)D is increased by exposure to sunlight and shows seasonal variation, with the highest concentrations in summer or fall and the lowest in winter or spring. It is recommended that testing be done at the end of winter; if results are above the cutoff, the subject is likely to have adequate concentrations throughout the year. Concentrations are influenced by latitude, sunscreen use, and skin pigmentation.

Vitamin D metabolite concentrations vary with age and are increased in pregnancy. Concentrations of 1,25(OH)₂D are higher in children than in adults, and are highest during periods of greatest growth. Although 25(OH)D and 1,25(OH)₂D decrease with age, this decline may be a consequence of poor nutrition, reduced exposure to sunlight, and declining health. Concentrations of metabolites were unchanged with age in studies limited to healthy, active subjects.

24,25(OH)₂D concentrations are method dependent. Ethnic differences have been reported, with black Americans having lower concentrations than Caucasians. Increasing supplementation with vitamin D results in increasing 24,25(OH)₂D concentrations.

POINTS TO REMEMBER

Vitamin D

- Measurement of 25 hydroxyvitamin D (25OHD) is accepted as the best reflection of vitamin D status.
- Tandem mass spectrometric methods are considered the best way of measuring 25OHD.
- A high percentage of the world's population are vitamin D deficient.
- Prolonged deficiency of vitamin D results in rickets in children and osteomalacia in adults.
- Care is required with high-dose vitamin D treatment as it can result in significant morbidity, increasing falls, and fractures in elderly women.

Fibroblast Growth Factor 23

Biochemistry and Physiology

Fibroblast growth factor 23 (FGF23) promotes phosphate excretion in urine. FGF23 consists of 251 amino acids, is present in embryonic and adult tissues, and has high expression in osteoblasts and osteocytes.

Biological Actions and Clinical Significance

FGF23 is involved in the medium- to long-term regulation of circulating phosphate. It acts directly on the kidney to decrease renal phosphate reabsorption.

FGF23 is increased in plasma in CKD and a variety of other conditions including X-linked hypophosphatemia (XLH). FGF23 may be the best measurement at predicting deterioration in CKD. It is unknown whether FGF23

is directly responsible for the decreased concentrations of 1,25(OH)₂D seen in CKD; FGF23 is markedly increased in CKD. The mechanism regulating FGF23 production in CKD remains unclear.

Measurement of FGF23

A single step IMMA incorporates an antibody to the C-terminal peptide fragments of FGF23 (cFGF23) that also reacts with the intact molecule (iFGF23) is available. This assay provides a combined estimate of both cFGF23 and iFGF23. Multiple other immunoassays for the measurement of the intact molecule are available. These assays can give different results in the same populations and so care is required when interpreting the results obtained. Reference intervals are considerably different for each assay. Pre-analytical factors are of importance and the sample type differs between assays. Users are advised to follow instructions provided by manufacturers.

Reference Intervals

There is significant variability in the reference intervals quoted. In healthy adults, the reference ranges are:

iFGF23: 11.7 to 48.6 pg/mL (Kainos)

cFGF23: 21.6 to 91.0 RU/mL (Immutopics)

Interpretation

Very high FGF23 concentrations can be obtained in XLH and CKD. An FGF23 concentration in the upper quartile of the reference interval may be inappropriate for a prevailing low phosphate and may require further investigation.

Calcitonin

The release of **calcitonin** from the parafollicular or C cells of the thyroid gland is stimulated by circulating calcium. Calcitonin has been used pharmacologically as an inhibitor of bone resorption, but the physiologic role of endogenous calcitonin is uncertain. Calcitonin measurements have a role in the diagnosis and follow-up of medullary thyroid carcinoma (MTC), a malignant tumor of the C cells.

POINTS TO REMEMBER

FGF23

- Osteocytes are major producers of FGF23.
- Several metabolic bone diseases result from abnormalities of FGF23 secretion and metabolism.
- FGF23 acts at the kidneys to promote phosphate excretion. Klotho is required to allow specific changes in FGF receptors in the kidney permitting FGF23 selective activity.
- Metabolism of FGF23 results in the generation of inactive C-terminal fragments that are measure in some assays. FGF23 inhibits alpha hydroxylase in the kidney resulting in a decrease in the circulating concentration of 1,25-dihydroxyvitamin D.

Biochemistry and Physiology

Calcitonin is a 32 amino acid peptide, molecular mass 3418 Da, an N-terminal disulfide bond links the cysteine residues

1 and 7, and a C-terminal proline-amide. The hormone interacts with a specific G-protein-coupled receptor found on fully differentiated osteoclasts. The structures necessary for biological function are the C-terminal portion of the molecule.

Pharmacological doses of calcitonin decrease plasma calcium and phosphate primarily by inhibiting osteoclastic bone resorption. Higher concentrations of calcitonin are observed in young children, and during pregnancy and lactation. The hormone may protect the skeleton during periods of calcium stress.

Multiple forms of calcitonin can be observed both in healthy individuals and in patients with MTC or nonthyroidal malignancies. Much of the immunoreactive calcitonin in the circulation is larger than the monomeric hormone.

During the biosynthesis of calcitonin, the original product is a larger precursor form known as procalcitonin.

Clinical Significance

MTC occurs as a sporadic disease and as part of the multiple endocrine syndromes MEN2A, MEN2B, and familial MTC. These account for 5% to 10% of thyroid malignancies, with sporadic MTC accounting for about 80%. After thyroidectomy in MTC patients, calcitonin can serve as a tumor marker. The use of calcitonin measurements in oncology is discussed [Chapter 20](#). Calcitonin is also increased in various nonthyroidal cancers, and other nonmalignant conditions including acute and chronic renal failure, hypercalcemia, hypergastrinemia, pulmonary disease, and severe illness.

Measurement of Calcitonin

Calcitonin is measured by immunoassay, interpretation can be complicated both by the heterogeneity of the circulating antigen and by the varying characteristics of the assays. Some assays may give results that are erroneously low at high concentrations (hook effect).

Reference Intervals

Reference intervals for calcitonin are method dependent. They should be determined for healthy and athyroidal individuals, by gender, for basal and stimulated (calcium and pentagastrin provocation tests) conditions.

An upper limit for the reference interval for basal calcitonin concentration in adults is 10 pg/mL (2.9 pmol/L) the mean concentrations are lower in women, 5.8 pg/mL (1.7 pmol/L) and higher 8.8 pg/mL (2.6 pmol/L) in men. Age, growth, pregnancy, and lactation—in addition to gender—have been reported to influence circulating calcitonin. Reference intervals are not given by assay manufacturers for groups other than healthy adults.

Parathyroid Hormone–Related Protein

PTHrP was discovered as a molecule responsible for causing HHM. It later proved to be an autocrine/paracrine factor with a multitude of functions in several organ systems. Among these are its effects on chondrocyte biology and endochondral bone formation, as well as on calcium metabolism in the fetus, and during pregnancy and lactation.

Biochemistry and Physiology

PTHrP is derived from a gene on chromosome 12 that is distinct from the *PTH* gene on chromosome 11. The N-terminal shows close homology to PTH and its PTH-like activity is contained within the N-terminal. Like PTH, PTHrP causes hypercalcemia and hypophosphatemia, and increases urinary cyclic adenosine monophosphate.

PTHrP exerts endocrine effects on skeletal development and calcium homeostasis during fetal life and lactation. Breast milk contains high PTHrP as does amniotic fluid. PTHrP regulates transepithelial calcium transport; it is a potent smooth muscle relaxant, and it regulates growth, differentiation, and development. The role of PTHrP in many tissues is unknown.

Clinical Significance

HCM is the third most frequent cause of hypercalcemia in hospitalized patients caused by HHM and local osteolysis. HHM is present in approximately 75% to 80% of patients with HCM. HHM is common in patients with squamous (lung, head and neck, esophagus, cervix, vulva, and skin), renal, bladder, and ovarian carcinomas. Hypercalcemia due to skeletal metastases and local osteolysis are common in breast cancer, multiple myeloma, lymphoma, and hematologic malignancies.

PTHrP is rarely required for diagnosis because HHM nearly always occurs in advanced disease when the diagnosis is clear. The need for PTHrP determination is greater when it becomes important in prognosis, selection of therapy, or monitoring.

Measurement of Parathyroid Hormone-Related Protein

Several competitive RIAs measure N-terminal, mid-region, and C-terminal. The N-terminal assays have been used most widely.

Specimen requirements. PTHrP is unstable in serum and plasma at 4°C and at room temperature unless collected in the presence of protease inhibitors and kept on ice. EDTA plasma should be promptly separated and frozen as red cell enzymes degrade PTHrP.

Reference Intervals

PTHrP concentrations are dependent on the assay and collection, varying from undetectable up to 5 pmol/L.

Interpretation

PTHrP is increased in 50% to 90% of patients with HCM ([Fig. 39.8](#)). In addition to squamous cell carcinoma of the lung, head and neck, esophagus, cervix, and skin, increased concentrations have been found in a wide variety of other malignancies.

Sclerostin. Sclerostin is secreted by osteocytes and articular chondrocytes, and absence favors bone formation.

Biochemistry and physiology. Sclerostin expression by osteocytes is regulated by mechanical forces. Immobilization increases sclerostin positive osteocytes and circulating sclerostin.

Clinical significance. Sclerostin is increased in hypoparathyroidism, type 2 diabetes, cancer-induced bone disease

Fig. 39.8 Parathyroid hormone-related protein (PTHrP) in healthy individuals, patients with malignancies and other disorders. The *hatched area* indicates the reference interval. (Modified from Pandian, M. R., Morgan, C. H., Carlton, E., & Segre, G. V. [1992]. Modified immunoradiometric assay of parathyroid hormone-related protein: clinical application in the differential diagnosis of hypercalcemia. *Clin Chem*, 38, 282–288.)

and **Paget disease of bone** (PDB). Sclerostin is decreased in 1HPT and ankylosing spondylitis.

Measurement of sclerostin. Several assays are available. EDTA-plasma and serum are the recommended sample types. Significant differences exist between commercial assays.

Reference intervals. Using the Biomedica assay in normal adults, the mean concentrations are:

Serum 0.8 pmol/L; plasma (EDTA) 1.3 pmol/L, plasma (heparin) 1.2 pmol/L, plasma (citrate 1.4 pmol/L).

BIOCHEMICAL MARKERS OF BONE TURNOVER

Markers can measure both bone formation and degradation. Markers of bone formation include products of the osteoblast, the amino- or carboxy-terminal propeptides of type I collagen, **procollagen type I N-terminal propeptide (PINP)**, and **procollagen type I carboxy-terminal propeptide (PICP)**, **bone alkaline phosphatase (bone ALP)**, and OC. Markers of bone resorption are breakdown products of type I collagen and include the amino-terminal and carboxy-terminal crosslinked telopeptide parts of collagen (**N-telopeptide [NTX]**, C-telopeptide [**CTX**], and C-telopeptide of type I collagen [ICTP]) and the **pyridinium crosslinks** (pyridinoline [PYD] and **deoxypyridinoline [DPD]**). TRAP5b is an enzyme released from resorbing osteoclasts. Osteoprotegerin (OPG) and receptor activator for nuclear factor kappa B (RANK) ligand assays are available—osteoblast proteins that influence osteoclast formation, activation, and bone resorption.

Markers of Bone Formation

Bone formation markers can be divided into three families, each reflecting a specific phase in development of the osteoblast. During each remodeling cycle, osteoblasts pass through the phases of proliferation, matrix maturation, and mineralization (see Fig. 39.2). Markers can give discordant results if bone formation is affected by a disease that targets a particular developmental phase of the osteoblast.

Propeptides of Type I Procollagen (Procollagen Type I N-Terminal Propeptide and Procollagen Type I Carboxy-Terminal Propeptide)

Type I collagen accounts for 90% of the bone organic matrix and provides it with tensile strength. The type I collagen, a triple helix of two identical $\alpha 1(I)$ chains and an $\alpha 2(I)$ chain, is synthesized as a precursor type I procollagen that contains large additional domains at both ends of the rod-like collagen molecule (Fig. 39.9). Cleavage of the C-terminal propeptide (PICP) is necessary before collagen molecules can be assembled into collagen fibers, whereas the N-terminal propeptide (PINP) may remain longer. PINP is released before bone mineralization, but in soft tissues, type I collagen may still contain the N-terminal propeptide. The concentrations of procollagen propeptides reflect the rate of collagen synthesis.

Plasma PINP in health is present mainly as intact, trimeric form. In certain situations (ESRD with hemodialysis, bedridden geriatric patients), smaller forms of PINP are detected in plasma. PINP assays differ with respect to whether they measure the trimeric form (intact PINP) or both forms (total PINP).

Fig. 39.9 Representation of a type I procollagen molecule. The non-triple helical domains at both ends of the collagen molecule are the telopeptides. The N-terminal propeptide consists of an N-terminal globular domain, a triple-helical domain, and a C-terminal non-triple helical domain. (From Prockop, D. J., Kivirikko, K. I., Tuderman, L., & Guzman, N. A. [1979]. The biosynthesis of collagen and its disorders [second of two parts]. *N Engl J Med*, 301, 13–23, 77–85.)

Clearance of propeptides. Intact propeptides are degraded by the endothelial cells of the liver. Renal clearance also occurs for the smaller circulating propeptides.

Clinical significance. In principle, measurement of either propeptide should give the same information. This is the case when PICP and PINP concentrations are compared in situ. In children, circulating propeptides closely reflect the somatic growth rate, and the peak of PICP and PINP concentrations occurs earlier in girls than in boys. During puberty, the increase is larger in boys than in girls.

The measurement of response to treatment for osteoporosis therapies is a major use of bone formation markers. The concentration of PINP is increased more during active bone growth than is the concentration of PICP.

Specimen requirements. The preferred sample for measuring procollagen propeptides is serum. The antigens are very stable in serum or plasma. Storage of serum at room temperature for 1 week does not decrease concentrations.

Assays for procollagen type I carboxy-terminal propeptide and procollagen type I N-terminal propeptide. An RIA and EIA (CICP) are available for PICP. Assays for PINP can be divided into intact and total PINP. An RIA for intact PINP has been approved by the US Food and Drug Administration.

Reference intervals. Reference intervals for PICP are 38 to 202 µg/L in men and 50 to 170 µg/L in women. For intact PINP, the reference intervals in men are 20 to 78 µg/L, and in women 19 to 84 µg/L. The reference interval for total PINP in young healthy premenopausal women (30 to 39 years) is 16.3 to 72.2 µg/L. The reference interval for total PINP in men is 13.9 to 85.5 µg/L. Children have higher concentrations immediately after birth and later during growth spurts. In neonates (younger than 1 month of age), the reference interval of intact PINP is high at 770 to 3202 µg/L. Detailed pediatric reference intervals have been established as part of the CALIPER study (see Appendix).

Bone Alkaline Phosphatase

ALP are membrane-bound ectoenzymes that catalyze the hydrolysis of monophosphates from ester linkage under

alkaline conditions (pH 8 to 10). Four different gene codes are known for the tissue: nonspecific, intestinal, placental, and germ cell (placental-like) isoenzymes. These isoforms are N-glycosylated, and only the liver ALP does not contain O-linked glycans. Bone ALP can be separated by anion-exchange HPLC or isoelectric focusing into four isoforms differing in their sialic acid content.

During mineralization of bone, the main function of bone ALP is to hydrolyze inorganic pyrophosphate (PPi) to generate phosphate (Pi). The balance between Pi and PPi is thought to be critical for mineralization because PPi inhibits the formation of hydroxyapatite.

Bone ALP is produced by osteoblasts during the matrix maturation phase (see Fig. 39.2), when the newly formed collagenous matrix is prepared for the deposition of mineral. Because ALP is firmly bound to cell membranes, release to plasma can be delayed, and increase in plasma activity takes time.

Clinical significance. Total ALP or bone ALP provides the highest clinical sensitivity and specificity in the diagnosis and monitoring of PDB. Bone ALP is more sensitive than total ALP in mild (monostotic) disease. ALP is increased in PDB and reflects increased bone formation.

Bone ALP is increased in osteoporosis, osteomalacia and rickets, hyperparathyroidism, renal osteodystrophy, thyrotoxicosis, acromegaly, and bone metastases.

ALP and bone ALP are stable in serum *in vitro* and do not require special specimen handling. Bone ALP is more useful than OC in individuals with impaired renal function because it is not cleared by GF.

Measurement of bone alkaline phosphatase. Measurement of the enzymatic activities of total and bone ALP was described in Chapter 19. Although internal standards for ALP isoenzymes have been used to increase assay precision for bone ALP activity; they tend to be technically complicated, labor intensive, imprecise, insensitive, and inaccurate.

Immunoassays are currently used for bone ALP. None of the monoclonal antibodies used is completely specific

for bone ALP. Current immunoassays exhibit 7% to 17% cross-reactivity with liver ALP.

Reference intervals. Plasma concentrations of bone ALP are influenced by age and gender. Concentrations are higher in men and increase with age in men and women.

The reference interval of bone ALP (IRMA) is 5 to 20 $\mu\text{g/L}$. With the immunoabsorption assay, it is 15.0 to 41.3 U/L for men and 11.6 to 29.6 U/L for premenopausal women. For the automated chemiluminescent immunoenzymatic method, the 95th percentile limit is 14.3 $\mu\text{g/L}$ for men and 20.1 $\mu\text{g/L}$ for premenopausal women. Children have much higher concentrations, especially at puberty (see Appendix).

Osteocalcin

OC is the most abundant noncollagenous protein of human bone; it is a small protein of 49 amino acids and contains three glutamyl residues at amino acid positions 17, 21, and 24, which can be converted to γ -carboxyglutamyl residues by a post-translational, vitamin K-dependent enzymatic carboxylation. These unique carboxylated amino acids bind calcium ions and are found in proteins involved in blood coagulation and in calcium transport, deposition, and homeostasis. OC binds calcium and hydroxyapatite, suggesting a physiologic role in bone mineralization.

Osteocalcin may regulate insulin secretion and sensitivity. Leptin formed in adipose tissues regulates synthesis of osteocalcin in osteoblasts. Adipose cells produce osteocalcin.

Osteocalcin is present in the plasma in carboxylated and undercarboxylated forms; it is the undercarboxylated form of osteocalcin that acts as a hormone. The undercarboxylated fraction represents 16% to 21% of total OC.

Plasma OC is cleared by the kidneys and has a half-life of 5 minutes. OC concentrations are increased in CKD. OC exhibits a diurnal variation with a nocturnal peak, decreasing by as much as 50% to a morning nadir. Circulating OC is heterogeneous; in addition to the intact molecule, several fragments also exist. Intact OC has been estimated to account for 35% of total OC, N-terminal/mid-region for 30%, and other fragments for much less in the circulation.

Clinical significance. The concentration of OC changes rapidly in situations that affect bone turnover. Plasma OC is increased in metabolic bone disease with increased bone formation—hyperparathyroidism, renal osteodystrophy, thyrotoxicosis, post fractures, acromegaly, and bone metastases. OC is decreased in hypoparathyroidism, hypothyroidism, GH deficiency, during estrogen therapy, treatment with glucocorticoids, bisphosphonates, and calcitonin.

OC concentrations may be misleading in several situations. They increase in impaired renal function without a similar increase in bone formation, because OC is cleared by the kidneys. OC may be increased during bed rest without an increase in bone formation.

About 10% to 30% of OC synthesized by the osteoblast is released into the circulation. OC fragments are released from the bone matrix during bone resorption and may contribute to circulating OC. Serum osteocalcin may be considered a marker of bone turnover rather than just bone formation.

Measurement of osteocalcin. Many immunoassays have been developed for OC since the first reported in 1980. Those assays measuring both intact OC plus the N-terminal/mid-region (1–43) fragment, are of particular interest. These assays do not measure smaller fragments of OC that are produced during bone resorption. OC concentrations are more stable when measured with assays that recognize both intact hormone (1–49) and the N-terminal/mid-region (1–43).

Specificities with respect to carboxylated and undercarboxylated forms of OC are often not known.

Circulating OC in healthy subjects varies widely between methods and laboratories.

An immunoassay for the undercarboxylated form of OC has been developed. This assay uses recombinant human undercarboxylated OC for calibration and two monoclonal antibodies, one of these specifically recognizes the 14–30 sequence, in which the three glutamic acid residues are not carboxylated.

Specimen requirements. OC is rapidly degraded in blood samples at room temperature or 4°C. Serum OC concentrations are more stable when assessed with methods measuring both intact OC and the N-terminal/mid-region fragment (1–43); concentrations are unchanged after 3 hours at room temperature and after 24 hours at 4°C.

Reference intervals. OC concentrations are influenced by age, gender, and diurnal variation. Men have higher OC than women. OC concentrations are increased during menopause. In one OC ELISA, the reference interval was 9.6 to 40.8 $\mu\text{g/L}$ in men, 8.4 to 33.9 $\mu\text{g/L}$ in premenopausal women, and 12.8 to 55.0 $\mu\text{g/L}$ in postmenopausal women. Concentrations are higher in children—the highest of which are observed during periods of rapid growth.

Biochemical Markers of Bone Resorption

Most markers of bone resorption reflect degradation of type I collagen. These markers were initially measured in urine, but serum-based methods have been developed. An osteoclast-derived enzyme, serum TRAP5b, has been used to assess bone resorption.

Collagen Crosslinks

Extracellularly, type I collagen molecules are assembled into immature fibrils with limited tensile strength, which then are modified by formation of intramolecular and intermolecular covalent bonds or crosslinks. Intermolecular crosslinking sites are located in short non-triple-helical domains at each end of the type I collagen molecule, called *telopeptides*. The activities of two enzymes—intracellular lysyl hydroxylase 2b and extracellular lysyl oxidase—regulate which variant structures of crosslinks are formed. PYD and DPD are stable even to acid hydrolysis, whereas the pyrrole variants are quite unstable. Trivalent crosslinks are found in soft tissues and in collagen types other than type I (type II, III).

PYDs were the first mature crosslinks to be identified, but their quantity in bone is relatively low, one per three to five collagen molecules, compared with the quantity of their divalent precursors, 1 per collagen molecule. The pyrrole

crosslinks are concentrated at the N-terminal end of human bone collagen. Both telopeptides have a sequence including an aspartic acid residue, which can undergo racemization and α -isomerization. Immunoassays detect only one form of these structures.

Degradation of bone collagen. Cathepsin K is the main enzyme that degrades bone collagen. Its activity alone is sufficient to completely dissolve insoluble collagen of adult cortical bone. Osteoclasts produce other proteases, notably several matrix metalloproteinase (MMP) enzymes (MMP-9, MMP-10, MMP-12, MMP-14). Crosslinked telopeptides are released from type I collagen during bone resorption because crosslinks resist proteolysis of adjacent polypeptide chains. This may lead to the generation of a neoepitope, such as NTX, that can be detected by immunoassays.

For C-terminal telopeptides, two immunoassays, ICTP and CTX, reflect different enzymatic pathways of bone breakdown. Cathepsin K releases CTX antigen but destroys reactivity in the ICTP assay. ICTP antigen is stable after MMP-1, MMP-9, and MMP-13 digestion. The ICTP assay is also called the *CTX-MMP assay*.

NTX and CTX reflect normal osteoclast function. ICTP detects pathologic degradation of bone and soft connective tissue as seen in multiple myeloma, bone metastasis, and rheumatoid arthritis.

Comparison of urine and serum analyses. Urine was the sample of choice for measuring bone collagen degradation. Urinary hydroxyproline analysis was replaced by more sensitive and specific crosslinks (DPD, PYD) and telopeptide (CTX, NTX) assays. Urinary measurements need to be corrected for creatinine excretion to adjust for effects of urinary concentration or dilution. Including a second analyte, with its analytical variation, adds to the uncertainty of the result.

Serum and urine telopeptide assays have been compared in several studies; correlation coefficients varied from 0.6 to 0.9. Kidneys are involved in degradation of crosslinked peptides; as a result, 40% of total crosslinks in the urine are free. The mean fractional excretion of NTX (0.22) is lower than that of CTX (0.44), indicating renal degradation is greater for the former.

During antiresorptive treatment, urinary telopeptides may overestimate the decrease in bone resorption because the renal metabolism of these peptides can change. The response to antiresorptive therapy is generally greatest when measured with telopeptide assays, intermediate with total DPD, and lowest with free DPD. Serum or plasma assays have replaced urine assays in many countries.

Clinical significance of telopeptides and crosslinks. Increased urinary CTX, NTX, and DPD have been reported in osteoporosis, PDB, PHPT, and 2°HPT, hyperthyroidism, carcinoma metastases, and multiple myeloma.

Inhibition of bone resorption with pharmacologic agents (bisphosphonates, denosumab) leads to a decrease in serum/plasma or urinary CTX, NTX, and DPD; this is the most common use of these markers in clinical practice.

Measurement of telopeptides and pyridinium crosslinks. Several methods are available; the ones most often

used are serum and urine assays for NTX and CTX, serum assay for ICTP, and urine assays for DPD.

N-telopeptide. NTX in urine is measured with an ELISA. The NTX method has been adapted for the measurement of N-telopeptides in serum. The use of serum can significantly reduce within-subject day-to-day variation.

C-telopeptide CTX assay. EDTA plasma is the preferred sample. Serum can be used if rapidly separated prior to storing frozen at a minimum of -20°C . The most widely used methods recognize the α -isomer. In healthy human bone, 70% to 80% of C-telopeptides have α -isomerization, but in PDB, it accounts for only 50 to 60. α -Isomerization and racemization may vary between individuals. All CTX methods require the C-terminal amino acid to be a free arginine. Serum/plasma CTX is measured using two monoclonal antibodies.

C-telopeptide ICTP assay. An RIA for ICTP detects collagen degradation fragments in serum. The epitope measured is vulnerable to digestion by cathepsin K; this method is relatively insensitive to changes in bone resorption caused by normal bone turnover. The method is suitable for detecting the osteolytic processes taking place in multiple myeloma and metastatic bone disease, as well as the erosion process in rheumatoid arthritis.

Deoxypyridinoline and pyridinoline. DPD and PYD were originally measured by HPLC. Today, DPD is measured primarily by immunoassay using automated analyzers or manual ELISA. Unlike most HPLC methods, which can measure total DPD and PYD, the immunoassays for DPD or DPD/PYD measure primarily free, but not peptide-bound, forms.

Specimen requirements. Serum or plasma is best collected after overnight fasting. A second morning void urine, collected by 10:00 hours, is recommended. For treatment monitoring, specimens should be collected at the same time as the baseline specimen. Peak urinary excretion of PYDs occurs at 05:00 to 08:00 hours, reflecting the nocturnal peak in bone turnover. Urinary PYDs reach a nadir between 14:00 and 23:00 hours.

PYDs and telopeptides are relatively stable in urine. Exposure to UV light decreases DPD and PYD.

Reference intervals. Concentrations of collagen crosslinks are influenced by age and gender. Concentrations are markedly higher in children, with highest concentrations observed during early infancy and adolescence, which are periods of rapid bone growth. In adults, concentrations of collagen crosslinks are relatively constant between 30 and 45 years, increasing significantly after menopause. Age-related increases have been reported in men.

Tartrate-Resistant Acid Phosphatase 5b (TRACP5b)

Osteoclasts produce and secrete **tartrate-resistant acid phosphatase 5b (TRACP5b)** (see Fig. 39.2) during bone resorption. Osteoclast number can be increased in bone disorders and is decreased by antiresorptive treatment. Early methods failed to distinguish between two isoforms: TRACP5b produced by the osteoclasts, and TRACP5a produced by inflammatory macrophages and dendritic cells. Isoform 5b is a

dimer, 5a is a monomer. 10% of TRACP circulates in an enzymatically active form, the remaining 90% present as inactive fragments.

In a kinetic method, TRACP5b activity is estimated by subtracting tartrate-resistant fluoride-resistant acid phosphatase activity from total activity. Immunoassays are available for TRACP5b.

Specimen requirements. The preferred sample is serum. Diurnal variation is minor, indicating that the half-life of TRACP5b is longer than those of the other markers of bone resorption. TRACP5b is unstable on storage; it can be stored for up to 8 hours at room temperature and up to 3 days at 4°C. Long-term samples must be stored at -80°C. Six months' storage at -20°C reduces activity by 40%.

Clinical significance. In response to alendronate, TRACP5b decreased by a mean (SE) of 39% (4%), compared with 49% (4%) to 69% (5%) for urinary telopeptides (CTX and NTX), and 75% (8%) for serum/plasma CTX. Boys aged 13 to 17 years have higher concentrations than girls in the same age group.

Reference interval. An immunoassay for TRACP5b has upper limits of reference intervals of 4.2 U/L for women and 4.8 U/L for men.

Preanalytical and Analytical Variables of Bone Turnover Marker

Controllable sources of preanalytical variability include sampling time, sample preservation, and food intake. Most bone markers have a diurnal rhythm with a peak in the early morning hours (04:00 to 08:00 hours) and nadir in the afternoon/evening (13:00 to 23:00 hours). The amplitude of this variation is greatest for resorption markers, with nadir values averaging 70% of peak values. Specimens should be collected at a standardized time of day to minimize the impact of diurnal variability. For urinary markers, collection of the second morning void is recommended.

Urinary resorption markers are usually normalized by dividing by the urinary creatinine concentration. Variability (within- and between-method) in creatinine measurements, within-subject variability in urinary creatinine, and its dependence on muscle mass contribute to the variability of urinary markers.

Within-individual variability of urine markers is higher (15% to 60%) than that of plasma markers (5% to 10%). Bone ALP and TRACP5b do not demonstrate much diurnal variation because of their long half-lives.

Food intake affects CTX concentration. The diurnal variation of plasma CTX is $\pm 40\%$ around the 24 hours mean; fasting reduces circadian variation. Exercise can acutely increase the concentration of CTX. With other bone markers, the clinical impact of feeding versus fasting is small. The collection of samples in the fasting and resting state is standard practice.

METABOLIC BONE DISEASES

Metabolic bone disease results from a partial uncoupling or imbalance between bone resorption and formation. Decreased bone mass, or **osteopenia**, is more common than increases

in bone mass. The most prevalent metabolic bone diseases are osteoporosis, osteomalacia/rickets, and **renal osteodystrophy**. Osteoporosis is characterized by loss of bone mass, microarchitectural deterioration of bone tissue and increased risk of fracture. Rickets and osteomalacia are characterized by the defective mineralization of the bone matrix. Renal osteodystrophy is a complex condition that develops in response to abnormalities of the endocrine and excretory functions of the kidneys.

Osteoporosis

Osteoporosis results in over 1.5 million fractures each year. It is associated with increased risk for vertebral, hip, and distal forearm fractures. At age 50, women have a lifetime fracture risk (at any of these sites) of 40%. Men have a lifetime fracture risk one-third that of women. Trabecular bone turns over at five to seven times the rate of cortical bone and so fractures of bones that are predominantly trabecular (vertebrae and distal forearm) occur earlier in life. One third of women older than 65 years suffer vertebral crush fracture, which can occur acutely and result in disabling pain and discomfort. Long-term complications include immobility and loss of height, protuberant abdomen, hiatus hernia, chronic constipation, urinary incontinence, and loss of self-esteem. Up to 50% of vertebral fractures may be clinically silent when they occur, only to manifest later as an incidental finding on x-ray.

Fractures of cortical bone (proximal femur or hip) occur later in life. For women, the lifetime risk of hip fracture is 15% and for men 3%. The mortality rate accompanying hip fracture may be as high as 20% in the 6 months following fracture. Mortality is higher in men than women; it increases with age, and is higher for those with coexisting illness and poor pre-fracture functional status. Twenty-five percent of survivors are confined to long-term care in nursing homes.

Peak bone mass is attained by 30 years and decreases slowly after 40 years in both men and women. Bone mass attained during growth is an important determinant of osteoporosis. Exercise and adequate nutrition play important roles in attaining and maintaining skeletal mass. During early adult life, bone formation is coupled with bone resorption so that bone mass remains stable. Aging is a major risk factor for bone loss. After 40 years, bone resorption exceeds bone formation, so that 0.5% of the skeletal mass is lost per year. In women, the decrease in sex steroids at menopause accelerates bone loss to 2% to 3% per year. Osteoporosis is commonly encountered in postmenopausal women. Advanced age, female gender, sex steroid deficiency, a family history of osteoporosis, alcohol abuse, smoking, and chronic disease are all risk factors.

After decreased bone mass is documented by bone mass measurements, the diagnostic work-up is directed at determining the cause, which could be due to endocrine or inflammatory conditions, malabsorption, and drugs, among others.

Bone markers can assess bone turnover in patients with osteoporosis, the rate of bone turnover is considered an important determinant of bone fragility in postmenopausal women. Markers for both bone resorption and bone formation

can be useful in monitoring effects of antiresorptive therapy. The International Osteoporosis Foundation and International Federation of Clinical Chemistry and Laboratory Medicine recommend one formation marker (serum PINP) and one resorption marker (plasma CTX) be used as reference markers.

High calcium intake (1000 to 1500 mg/day), adequate vitamin D (400 to 800 IU/day), sufficient protein intake, and a regular exercise program are helpful in maintaining bone mass and preventing osteoporosis.

In secondary osteoporosis, treatment is directed at the underlying condition. Most therapies for postmenopausal osteoporosis are directed at decreasing osteoclast bone resorption.

Osteomalacia and Rickets

Osteomalacia in adults and **rickets** in children are caused by a mineralization defect that occurs during bone formation, resulting in an increase in osteoid. Osteomalacia or rickets is due to either vitamin D deficiency or phosphate depletion.

Despite supplementation in some countries, of milk, bread, and some cereals with vitamin D, vitamin D insufficiency is common in North America and Europe. Breastfed infants, the elderly, strict vegetarians, and individuals with darker skin pigmentation are at increased risk. Clinical osteomalacia is uncommon. Mild to moderate vitamin D deficiency may be associated with reduced muscle strength, impaired physical performance, and falls—all of which are factors that contribute to osteoporotic fracture. Vitamin D deficiency may develop in cases of malabsorption.

Vitamin D-dependent rickets type I is an inherited defect in 25(OH)D-1 α -hydroxylase that causes impaired formation of 1,25(OH)₂D. The disease is manifested in infancy and can be treated with 1,25(OH)₂D. Vitamin D-dependent rickets type II is an inherited disorder that is characterized by high plasma concentrations of 1,25(OH)₂D caused by resistance to 1,25(OH)₂D, secondary to defects in the 1,25(OH)₂D receptor.

Osteomalacia and rickets may occur as the result of phosphate depletion. In developing countries, dietary calcium deprivation may lead to rickets, without vitamin D or phosphate deficiency.

Clinical manifestations of rickets and osteomalacia are a consequence of the defect in mineralization. In adults, bone pain is the most common symptom, stress fractures and frank skeletal fractures occur.

Vitamin D deficiency is diagnosed by measuring serum 25(OH)D (Table 39.3). Other findings in rickets and osteomalacia include increased ALP due to increased osteoblast activity associated with producing unmineralized osteoid.

Treatment of rickets and osteomalacia is dictated by the cause. Nutritional rickets and osteomalacia are healed by treatment with physiologic doses of vitamin D, whereas higher doses may be required in malabsorption.

Disorders of Bone and Mineral in Chronic Kidney Disease (Renal Osteodystrophy)

CKD is associated with a multitude of disorders of bone and mineral metabolism. Renal bone diseases include both

high-turnover bone disease (**osteitis fibrosa** or 2°HPT) and low-turnover bone disease (osteomalacia and **adynamic bone disease [ABD]**). Quantitative histomorphometric analysis of bone biopsies, measurement of bone formation by double tetracycline labeling, and special stains are often necessary for correct diagnosis of patients with osteitis fibrosa, osteomalacia, ABD, and mixed bone disease of renal osteodystrophy.

Osteitis fibrosa (hyperparathyroid bone disease) is the most common high-turnover disease. This disorder is caused by high concentrations of serum PTH, which is a consequence of the hypocalcemia associated with hyperphosphatemia and 1,25(OH)₂D deficiency.

Low-turnover bone diseases include osteomalacia and adynamic (*aplastic*) bone disease. Osteomalacia and ABD are distinguished by the extent of unmineralized bone matrix. Osteomalacia in chronic renal failure may reflect vitamin D deficiency caused by decreased renal synthesis of 1,25(OH)₂D.

Bone pain is the most common complaint of patients with renal osteodystrophy. The weight-bearing bones are the sites of greatest discomfort, with leg, hip, and back pain being common.

The central role of PTH in guiding therapy requires that the PTH assay used can be relied on to measure only the active hormone. This is not true for any of the assays available, and kidney disease leads to accumulation of inactive PTH fragments above concentrations seen in healthy individuals. Treatment guidelines take this into account, but inconsistencies among assays can lead to situations in which opposite therapeutic decisions could be made for a single patient, depending on the assay used.

Biochemical findings in CKD include hyperphosphatemia and hypocalcemia (see Chapter 35). The measured concentration of immunoreactive PTH is increased, and 1,25(OH)₂D is decreased. Plasma ALP is increased in patients with hyperparathyroidism or osteomalacia. Because magnesium is cleared by the kidney, modest increases in plasma concentration (2 to 4 mg/dL [0.08 to 0.16 mmol/L]) are common.

Early management of CKD calls for dietary restriction of phosphate and administration of phosphate-binding agents. Calcium supplements are also used. Administration of 1,25(OH)₂D or other active forms of vitamin D enhances intestinal calcium absorption and may act directly on the parathyroid glands to reduce PTH secretion. Ultimately dialysis or renal transplantation may be necessary.

Paget Disease of Bone

PDB is a localized disease of bone characterized by osteoclastic bone resorption, followed by replacement of bone in a chaotic fashion. It is most common in Northern Europe, North America, Australia, and New Zealand in persons of Anglo-Saxon descent; prevalence may be up to 5% among people older than 40 years. It is uncommon in Asia, Africa, and Scandinavia. A family history of PDB is reported by 20% to 50% of patients. Environmental factors, especially a possible paramyxovirus infection (measles, canine distemper, respiratory syncytial), may play a role in causation.

PDB may affect one bone (monostotic) or several bones (polyostotic). Signs and symptoms depend on which skeletal site is affected; the skull, femur, pelvis, and vertebrae are common sites. The disease is often diagnosed from radiographs or laboratory tests (total ALP) performed for another reason. Advanced disease can produce deformities such as skull enlargement and anterior bowing of the weight-bearing bones (femur and tibia).

Increases in biochemical markers of bone resorption reflect the osteoclastic nature of the disease.

Therapy is directed at decreasing osteoclastic bone resorption. Patients may require surgery for skeletal deformity that limits mobility, or for arthritic changes, fractures, or nerve compression.

Osteogenesis Imperfecta

Osteogenesis imperfecta (OI), often termed “brittle bone disease,” is a heterogeneous group of inherited connective tissue disorders that share similar skeletal abnormalities resulting in low bone mass, minimal trauma fractures, and subsequent bone deformity. In its most severe form it can be lethal in fetal life and in neonates.

Biochemical and molecular studies have identified that milder forms of OI are caused by quantitative defects in type 1 collagen and that more severe types are caused by structural

defects in either of the two chains that form the heterotrimer. There is a spectrum of signs and symptoms including frontal bossing of the skull, bluish sclera, yellowish teeth, barrel chest/pectus excavatum, joint laxity, vertebral compression, and growth retardation. Recurrent fractures with minimal trauma may lead to suspicion of child abuse. When a diagnosis is in doubt, biochemical studies of collagen expressed by cultured cells, DNA sequencing of type 1 collagen, and genetic expression plus gene sequencing studies may be of value in confirming the diagnosis.

Involvement of Bone in Malignancies

Bone metastases are the most common skeletal complication of malignancy, occurring in up to 70% of patients with advanced breast or prostate cancer, and in 15% to 30% of patients with carcinoma of lung, colon, stomach, bladder, uterus, rectum, thyroid, or kidney. Metastases can have a markedly osteolytic or osteoblastic character, but often they are mixed. Patients with breast cancer have predominantly osteolytic lesions, but 5% to 20% of metastases have an osteoblastic nature. Metastases of prostate cancer are mainly osteoblastic. In most carcinoma metastases, both bone degradation and formation take place and both biochemical markers of bone formation and resorption are valuable in assessing the presence of bone metastasis.

REVIEW QUESTIONS

- Which of the following cells is the main producer of RANKL in bone?
 - Osteoclast
 - Osteoblast
 - Osteocyte
 - Bone lining cell
 - Chondrocyte
- Where is the major site of regulation of magnesium excretion in the kidney?
 - Glomerulus
 - Proximal convoluted tubule (PCT)
 - Cortical collecting duct (CCD)
 - Distal convoluted tubule (DCT)
 - Thick ascending limb of the Loop of Henle
- When is measurement of parathyroid hormone-related peptide of greatest clinical value?
 - In the differential diagnosis of hypocalcemia
 - In pregnancy
 - In patients with hypercalcemia thought to be caused by a tumor but with no obvious clear diagnosis of malignancy
 - In chronic kidney disease
 - In patients suspected to have primary hyperparathyroidism
- Biochemical markers of bone metabolism are of clinical value in—
 - Indicating a response to treatment of metabolic bone disease
 - Diagnosing osteoporosis
 - Diagnosing osteomalacia
 - Indicating a requirement for calcium supplementation
 - The guidelines for recommending parathyroidectomy
- Which of the following biochemical tests are of diagnostic value in Paget disease of bone?
 - Parathyroid hormone
 - Fibroblast growth factor 23
 - Alkaline phosphatase
 - 25 hydroxyvitamin D
 - Acid phosphatase
- What can cause a falsely high 25 hydroxyvitamin D measurement in many immunoassays?
 - Hypercalcemia
 - Li heparin contamination
 - Ingestion of magnesium sulfate
 - High concentration of the 3-epimer of 25OHD in the sample
 - High concentration of 24,25-dihydroxyvitamin D in the sample

Disorders of the Pituitary Gland

Neil S. Harris, William E. Winter, Ann McCormack, Roger L. Bertholf

OBJECTIVES

1. Describe the anterior pituitary hormones and their release/inhibiting factors.
2. Discuss the levels of control of the anterior pituitary hormones including the long and short feedback loops.
3. Be familiar with the critical role of pulsatility in the release of hypothalamic-releasing hormones.
4. Discuss the factors that contribute to variations in reference intervals for anterior pituitary hormones.
5. Describe the physiologic effects of hormones synthesized by the anterior pituitary gland.
6. Understand the complex interplay between growth hormone and insulin-like growth factor 1 (IGF-1).
7. List the main causes of hyperprolactinemia.
8. Be aware of macroprolactinemia as a common cause of an elevated plasma prolactin.
9. Describe the role of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) in gonadal steroid synthesis and ovulation.
10. State the effects of increased and decreased anterior pituitary hormone secretion and list the laboratory tests used to assess hypersecretion and hypopituitarism.
11. With respect to the posterior pituitary, understand the role of antidiuretic hormone (ADH) and its physiologic control.
12. Discuss the pathophysiology of diabetes insipidus and the syndrome of inappropriate antidiuretic hormone (SIADH).

KEY WORDS AND DEFINITIONS

Acid-labile subunit (ALS) IGF-1 and IGF-2 circulate together with insulin-like growth factor binding protein-3 (IGFBP-3) and the acid-labile subunit (ALS) to form a 150-kDa trimeric protein complex.

Acromegaly A chronic disease of adults caused by hypersecretion of pituitary growth hormone, characterized by enlargement of many parts of the skeleton and soft tissues as well as many organs.

Adrenocorticotrophic hormone (ACTH) A 39-amino acid peptide hormone secreted by the anterior pituitary that stimulates the adrenal cortex to secrete cortisol.

Antidiuretic hormone (ADH) A 9-amino acid peptide hormone synthesized in the hypothalamus but stored and released from the posterior pituitary lobe; also known as vasopressin.

Corticotropin-releasing hormone (CRH) A 41-amino acid neuropeptide released by the hypothalamus that stimulates the release of ACTH by the anterior pituitary.

Diabetes insipidus Failure of the kidney tubules to reabsorb sufficient water; caused by either a deficiency of ADH or defective receptor action.

Follicle-stimulating hormone (FSH) A glycoprotein hormone secreted by the anterior pituitary. In women FSH stimulates the growth and maturation of ovarian follicles (eggs), stimulates estrogen secretion, and

promotes endometrial changes. In males, FSH stimulates the Sertoli cells; in this way spermatogenesis is supported.

Gigantism Excessive growth caused by increased synthesis of GH before the epiphyses have fused.

Growth hormone (GH) A polypeptide of 191 amino acids produced by the anterior pituitary that affects carbohydrate, lipid, and protein metabolism. GH regulates the secretion of insulin-like growth factor I (IGF-1).

Insulin-like growth factors (IGFs) These are members of the insulin-related peptide family; they include insulin and relaxin. Proinsulin, IGF-1, IGF-2, and relaxin are all composed of two domains joined by a connecting domain. In children, IGF-1 secretion is a major determinant of normal linear growth.

Insulin-like growth factor binding proteins

(IGFBPs) IGFBPs have a very high affinity for IGFs and function as inhibitors of IGF action. IGFBPs have higher affinity for IGFs than do the IGF receptors.

Luteinizing hormone (LH) A glycoprotein gonadotropic hormone secreted by the anterior pituitary that acts with FSH to promote ovulation and progesterone production. In males, LH stimulates testosterone secretion.

Oxytocin A nonapeptide hormone synthesized in the hypothalamus and stored in the posterior lobe of the

pituitary. It induces smooth muscle contraction in the uterus and mammary glands.

Polydipsia Chronic excessive intake of water, as in diabetes mellitus or diabetes insipidus.

Polyuria The passage of a large volume of urine in a given period of time, a characteristic of diabetes mellitus and diabetes insipidus.

Pro-opiomelanocortin (POMC) This is the precursor 266-amino acid protein of ACTH as well as the melanocyte-stimulating hormones and beta-endorphin.

Prolactin (PRL) A lactogenic hormone synthesized by the anterior pituitary.

Syndrome of inappropriate antidiuretic hormone

(SIADH) A condition where inappropriately excessive ADH secretion produces dilutional hyponatremia with an elevated urine osmolality.

Thyroid-stimulating hormone (TSH) A glycoprotein hormone synthesized by the anterior pituitary that sustains, stimulates, and promotes the growth of the hormonal secretion of the thyroid gland; also called thyrotropin.

Thyrotropin-releasing hormone (TRH) A tripeptide produced in the hypothalamus that stimulates the release of TSH from the anterior pituitary.

Vasopressin See ADH or antidiuretic hormone.

BACKGROUND

The anterior and posterior lobes of the pituitary gland control processes vital for survival of the individual and the species.

CONTENT

This chapter focuses on disorders of the anterior and posterior pituitary that produce deficient or excess hormone activity. The hypophysis is composed of the adenohypophysis (the anterior lobe of the pituitary; $\approx 75\%$ of the mass of the pituitary) and the neurohypophysis (the posterior lobe of the pituitary, $\approx 25\%$ of the mass of the pituitary) (Fig. 40.1).

The biology of the adenohypophysis is distinctly different from that of the neurohypophysis; the adenohypophysis is controlled by the hypothalamus via releasing or inhibiting hormones, whereas

the cell bodies of the neurohypophysis are anatomically located in hypothalamic nuclei, with **oxytocin** or **antidiuretic hormone (ADH)** reaching the neurohypophysis through nerve axons.

The roles of the various hormones secreted by the pituitary are exceedingly diverse and include regulation of (1) the body's response to stress (**adrenocorticotropic hormone [ACTH]** and **growth hormone [GH]**), (2) the metabolic rate (**thyroid-stimulating hormone [TSH]**), (3) growth (TSH and GH), (4) reproduction (**luteinizing hormone [LH]** and **follicle-stimulating hormone [FSH]**), (5) nourishment for the newborn and infant (prolactin), (6) parturition and milk letdown during breast feeding (oxytocin), and (7) fluid balance and blood pressure regulation in states of stress (ADH and cortisol).

ANATOMY

The pituitary is located at the base of the brain and is protected by the bony sella turcica. Direct delivery of hypothalamic regulatory hormones to the adenohypophysis occurs through the hypothalamic-pituitary portal system. Anterior and superior to the pituitary is the optic chiasm. These relations are clinically important because pituitary neoplasms can invade or compress these structures.

Regulation of Function of the Adenohypophysis

The synthesis and release of the following anterior pituitary hormones are stimulated by hypothalamic-releasing hormones: ACTH, TSH, GH, LH, and FSH. **Prolactin** is the sole anterior pituitary hormone whose release is predominantly regulated through suppression. Corticotrophs secrete ACTH, thyrotrophs secrete TSH, somatotrophs secrete GH, gonadotrophs secrete both LH and FSH, and lactotrophs secrete prolactin. Except for LH and FSH, each hormone is normally produced by a unique cell type. The molecular composition of the anterior pituitary hormones is summarized in Table 40.1.

Multiple levels of control of the hypothalamic-pituitary-end organ-hormone axis are known (Fig. 40.2). Except for prolactin and LH at the midpoint of the menstrual cycle, negative feedback controls secretion of the adenohypophyseal hormones. The long feedback loop involves suppression

Fig. 40.1 The hypophysis (pituitary gland) is composed of the adenohypophysis (the anterior lobe of the pituitary) and the neurohypophysis (the posterior lobe of the pituitary; pars nervosa). The adenohypophysis has three parts: the pars distalis, where most of the hormone-producing cells are located; the pars tuberalis, which is part of the pituitary stalk; and the pars intermedia.

TABLE 40.1 Hypothalamic-Releasing or Hypothalamic-Inhibiting Hormones, Their Target Cells, and the Hormone That Is Regulated

Hypothalamic Hormone/ Abbreviation	Amino Acids	Anterior Pituitary Target Cell	Hormone Regulated	Amino Acids	MW (kDa)
Corticotropin-releasing hormone	41	Corticotroph	ACTH	39	4.5
Thyrotropin-releasing hormone	3	Thyrotroph	TSH ^a	α : 92 β : 118	28
Growth hormone–releasing hormone	44	Somatotroph	GH ^c	191	22
Somatotropin release–inhibiting hormone ^b (SRIH)	14	Somatotroph	GH ^c	191	22
Gonadotropin-releasing hormone	10	Gonadotroph	LH ^a	α : 92 β : 121	32
			FSH ^a	α : 92 β : 111	30
Prolactin release–inhibiting hormone	1	Lactotroph	Prolactin	199	22

^aAll α -glycoprotein chains are identical, including the α -chain of human chorionic gonadotropin.

^bAlso known as somatostatin.

^cNote: The 20 kDa form of GH is not shown in the table but is secreted together with the 22 kDa form of GH.

ACTH, Adrenocorticotrophic hormone; FSH, follicle-stimulating hormone; GH, growth hormone; LH, luteinizing hormone; MW, molecular weight; TSH, thyroid-stimulating hormone.

Fig. 40.2 Many anterior pituitary trophic hormones (e.g., adrenocorticotrophic hormone, thyroid-stimulating hormone, growth hormone, luteinizing hormone, follicle-stimulating hormone) are regulated by hypothalamic releasing hormones (HRHs). Releasing hormones secreted by the hypothalamus reach the pituitary via the hypothalamic-pituitary portal system (HPPT). Long feedback loops involve negative feedback of the target cell hormone at the pituitary gland and hypothalamus. The short feedback loop involves the anterior pituitary trophic hormone feeding back at the hypothalamus, whereas the ultrashort feedback loop involves the anterior pituitary hormone feeding back at the anterior pituitary. [+], Stimulation; [–], suppression; TH, trophic hormone.

of the hypothalamic-releasing hormones and the anterior pituitary trophic hormones by the hormonal product of the target tissue. The major site of negative feedback for cortisol (regulated by ACTH), insulin-like growth factor-I (IGF-I;

regulated by GH), and sex steroids and inhibins (regulated by LH and FSH) is the hypothalamus. In contrast, for thyroid hormone (regulated by TSH), the major site of negative feedback is the anterior pituitary. Retrograde flow from the pituitary to the hypothalamus via the portal system permits the existence of short negative feedback loops in which pituitary hormones suppress the secretion of hypothalamic-releasing hormones. Ultrashort feedback loops also exist in which pituitary hormones inhibit their own secretion.

AT A GLANCE

1. The pituitary is a master gland for many vital endocrine functions regulating growth (growth hormone [GH]), thyroid function (thyrotropin), reproduction (luteinizing hormone [LH], follicle-stimulating hormone [FSH], and prolactin), stress responses (ACTH), parturition (oxytocin), and water balance (**antidiuretic hormone [ADH]**).
2. The hypothalamus regulates pituitary hormone release or is the site of synthesis of the posterior pituitary hormones.

POINTS TO REMEMBER

1. Most anterior pituitary hormones are predominantly regulated by stimulatory hypothalamic hormones. The exception is prolactin, which is regulated by suppression.
2. The pulsatility of release of hypothalamic-releasing hormones can regulate the release of anterior pituitary hormones such as luteinizing hormone (LH) and follicle-stimulating hormone (FSH).
3. Reference intervals may depend on the time of the day at which a measurement is obtained, the sex of the subject, his or her age, and, for gonadotropin and sex steroid concentrations in women of reproductive age, the woman's menstrual cycle.

TABLE 40.2 Hypothalamic-Pituitary-End Organ Physiology

Hypothalamic Hormone	Anterior Pituitary Hormone	Target Organ/Tissue	Target Hormone
CRH	ACTH	Adrenal cortex: zona fasciculata and zona reticularis	Cortisol
TRH	TSH	Thyroid follicular cell	Thyroxine (T ₄) and 3,5,3'-triiodothyronine (T ₃)
GHRH and SRIH	GH	Liver and many tissues of the body	IGF-1, IGFBP-3, and ALS
GnRH	LH, FSH	Gonad	Sex steroids and inhibins
PRIH	Prolactin	Breast	Not applicable

ACTH, Adrenocorticotropic hormone; ALS, acid-labile subunit; CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; GnRH, gonadotropin-releasing hormone; IGFBP-3, IGF binding protein-3; IGF-1, insulin-like growth factor-1; LH, luteinizing hormone; MW, molecular weight; PRIH, prolactin release-inhibiting hormone; SRIH, somatotropin release-inhibiting hormone; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

HYPOTHALAMIC REGULATION

Hormones released by the hypothalamus that regulate the anterior pituitary hormones are listed in Table 40.2. The secretion of **corticotropin-releasing hormone (CRH)** is stimulated by systemic physiologic stress. Physiologically, stress, inflammation, and hypoglycemia stimulate ACTH release. The energy state and temperature of the organism influence the secretion of thyrotropin-releasing hormone (TRH). Acute inflammatory cytokines such as interleukin (IL)-1 β , IL-6, and tumor necrosis factor (TNF)- α stimulate ACTH release. Stimulators of GH-releasing hormone (GHRH) release include dopamine- and galanin-secreting neurons and brain stem neurons with catecholaminergic inputs. Physiologically, amino acids and hypoglycemia stimulate GH release. In turn, the secretion of IGF-1 in response to GH is influenced by nutrition, sex steroids, thyroid hormone, and the presence or absence of chronic disease. Malnutrition, sex hormone deficiency in adolescents and adults, hypothyroidism, and chronic disease all produce GH resistance to varying extents. The regulation of gonadotropin-releasing hormone (GnRH) is complicated by the fact that GnRH must differentially control the secretion of LH and FSH, which varies greatly during the menstrual cycle. GnRH pulsatility is essential to gonadotroph responsiveness. Tonic release of GnRH will downregulate GnRH receptors on gonadotrophs, which leads to hypogonadism. The rate of pulsatility may influence the relative secretion of LH and FSH.

Anterior Pituitary

In the anterior pituitary, (1) CRH receptors are expressed on corticotrophs, (2) thyrotropin-releasing hormone (TRH) receptors are expressed on thyrotrophs, (3) GHRH receptors are expressed on somatotrophs, (4) GnRH receptors are expressed on gonadotrophs, and (5) prolactin-release inhibiting hormone (PRIH) receptors are expressed on lactotrophs. In pathologically high concentrations, TRH stimulates the release of LH and prolactin. Corticotrophs are stimulated by high concentrations of proinflammatory cytokines, such as IL-1, IL-6, and TNF- α .

The hormonal products of each anterior pituitary target cell (if applicable) are listed in Table 40.1 together with a summary of each system. Deficiency of an individual pituitary hormone

is typically called hypopituitarism, whereas deficiency of all anterior pituitary hormones is termed panhypopituitarism.

Growth Hormone and Insulin-Like Growth Factors

Linear growth is the consequence of (1) genetic potential, (2) nutrition, (3) the presence or absence of disease, and (4) hormonal effects. Many hormones influence growth, but the most important are GH, thyroid hormone, and sex steroids. Excess glucocorticoids can impair growth in children. GH deficiency produces morbidity in adults, thus GH is essential for health throughout life.

Growth Hormone

Two circulating forms of GH are present: a 22-kDa form that represents 85% to 90% of circulating GH and a 20-kDa GH that results from alternative splicing of the GH mRNA transcript. Circulating GH also exists as aggregates and oligomers. “Big GH” is a dimer of GH monomers, and “big, big GH” is GH associated with its binding protein (GHBP). GHBP is the external domain of the GH receptor (GHR), which binds GH with high affinity and is produced by cleavage of the GHR (Fig. 40.3).

GH has both indirect and direct activity. The indirect activity of GH is mediated by IGF-1. To initiate its direct and indirect activity, GH binds to receptors (GHR) that appear to be expressed by all tissues.

Insulin-Like Growth Factors

Proinsulin, **insulin-like growth factor** (IGF)-1, IGF-2, and relaxin are all composed of two domains (A and B) joined by a connecting domain. Less than 1% of the total IGF-1 is free (the biologically active form).

Most of the circulating IGF-1 is produced by hepatocytes, but it is also produced locally throughout the body and thus acts as a paracrine and an autocrine hormone.

Similar to IGF-1, IGF-2 does not normally produce hypoglycemia. However, tumors that secrete a larger than normal form of IGF-2 and can cause hypoglycemia have been described (see Chapter 22).

Receptors for Insulin-Like Growth Factors

Two types of receptors for IGFs have been identified: type I and type II. Structurally, the type I IGF receptor is similar to

Fig. 40.3 The hypothalamus secretes growth hormone–releasing hormone (GHRH) and somatotropin release–inhibiting hormone (SRIH; somatostatin), which regulate growth hormone (GH) release. The receptor for GHRH (GHRHR) is illustrated because mutations in this receptor can cause some forms of inherited GH deficiency. GH circulates unbound and bound to its binding protein (GHBP). GHBP is the extracellular domain of the GHR, which is cleaved from the GHR and circulates in the plasma. GH releases IGF-1, IGF binding protein-3 (IGFBP-3), and the **acid-labile subunit (ALS)**. IGF-1 negatively feeds back at the anterior pituitary somatotrophs and at the hypothalamus. Because transection of the pituitary stalk leads to GH deficiency, the predominant hypothalamic control of GH is stimulatory via GHRH.

the insulin receptor. Because this receptor does not exclusively bind IGF-1, the terminology “IGF-1 receptor” is not recommended.

The type I IGF receptor binds IGF-1 with higher affinity than IGF-2, and affinity for insulin is lower than the affinity of the receptor for IGF-1 or IGF-2. The affinities of the insulin receptor are the opposite: insulin $\gg$ IGF-2 $>$ IGF-1. The type II IGF receptor is structurally dissimilar from the type I IGF receptor and the insulin receptor. The type II IGF receptor is monomeric and similar to the epidermal growth factor (EGF) receptor.

Regulation of Growth Hormone Secretion

GH ultimately stimulates the release of IGF-1, which negatively feeds back to regulate GH release via two hypothalamic hormones: somatotropin release–inhibiting hormone (SRIH) (or somatostatin) and GHRH (Fig. 40.3). Somatotrophs of the anterior pituitary gland have receptors for both hormones. Somatostatin inhibits GH release, whereas GHRH promotes the release of GH. In addition to its hypothalamic negative feedback effects, IGF-1 directly suppresses pituitary release of GH.

Physiologically, GH secretion is episodic and pulsatile. Consequently random measurements cannot exclude GH deficiency or confirm GH excess; between pulses, GH

BOX 40.1 Protocol for Glucose Suppression of Growth Hormone Test

Rationale

Normal subjects show suppression of serum growth hormone (GH) concentrations after oral administration of glucose. Subjects with acromegaly fail to exhibit appropriate GH suppression.

Procedure

The test should be performed after an overnight fast with the patient maintained at bed rest. After a baseline blood specimen is collected for GH and glucose measurement, a solution of 75 g of glucose is given orally (in children, 1.75 g/kg to a maximum dose of 75 g). Glucose and serum GH are measured again on specimens collected 30, 60, 90, and 120 min later.

Interpretation

Serum GH concentrations in normal individuals fall to less than 1 to 2 ng/mL (1 to 2 μ g/L) (i.e., below the lower limit of detection of the GH assay used). Subjects with acromegaly fail to show this suppression and sometimes show a paradoxical increase in GH concentration. Patients with liver disease, uremia, or heroin addiction may have false-positive results with this test (failure to suppress serum GH concentrations after oral glucose load).

concentrations can be quite low and do not distinguish GH insufficiency from normal GH production. During daytime hours, the plasma concentration of GH in healthy adults remains stable and relatively low (<2 ng/mL; <2 μ g/L), with several secretory spikes occurring approximately 3 hours after meals (particularly meals high in protein and arginine) and after exercise. In contrast, during the evening hours, adults and children show a marked rise in GH concentrations approximately 90 minutes after the onset of sleep, reaching a peak during the period of deepest sleep. GH is also increased by stress and hypoglycemia. Normal GH secretion requires thyroxine and age-appropriate concentrations of testosterone or estrogen.

GH is suppressed by increased blood glucose. One of the tests for GH excess measures GH after an oral glucose load (e.g., 75 g in adults and 1.75 g/kg in children); the normal response is a GH of less than 1 to 2 ng/mL (1–2 μ g/L), depending on the lower limit of detection of the GH immunoassay (Box 40.1). GH also declines with increases in free fatty acid concentrations and aging. In the presence of abnormally high concentrations of glucocorticoids, GH secretion is suppressed.

Physiologic Actions

GH *directly* raises blood glucose by stimulating gluconeogenesis and reducing insulin sensitivity. Also, GH causes adipose tissue lipolysis, and the resulting free fatty acids provide an alternative energy source. Therefore, when glucose and free fatty acid concentrations are raised with stress—in

partnership with epinephrine, glucagon, and cortisol—fuels for the fight-or-flight response are provided. GH directly stimulates the production of IGF-1, **insulin-like growth factor binding protein** (IGFBP)-3, and the ALS.

Indirect effects of GH are mediated through IGF-1 production, which (together with GH) is necessary for linear growth in childhood and promotes growth in soft tissue, cartilage, and bone. IGF-1 is mitogenic and antiapoptotic. GH (through IGF-1) and insulin induce growth in a similar manner because both have protein anabolic effects and stimulate the transport of amino acids into peripheral cells. Their respective effects on glucose homeostasis, however, oppose each other.

IGF-1 concentrations vary widely with age and gender. IGF-1 rises during childhood and puberty and then shows a gradual decline, reaching a steady state in the third decade of life.

GH is not the only determinant of IGF-1 concentration in the circulation. Therefore a decreased IGF-1 concentration is not necessarily synonymous with GH deficiency.

Clinical Significance

Clinically important states of GH excess or deficiency are uncommon and are often difficult to diagnose. GH measurements are best determined as part of dynamic testing: physiologic or pharmacologic provocative stimuli are used to diagnose GH deficiency, whereas GH suppression (or lack thereof) following glucose administration is useful in evaluating GH excess.

A single measurement of IGF-1, which has a much longer half-life than GH, reflects GH-IGF-1 production more accurately irrespective of the time of the day or meals.

Growth Hormone Excess

Growth hormone excess results in **acromegaly** in adults. Even less common is **gigantism**, which results from GH excess in childhood. The clinical features of acromegaly involve overgrowth of the skeleton and soft tissue, producing (1) acral (extremity) enlargement, (2) organomegaly (enlarged heart and/or liver), (3) facial coarsening, (4) intestinal polyposis, (5) premature cardiovascular disease, (6) increased sweating, (7) skin tags, (8) joint disease, (9) myopathy with weakness, (10) insulin resistance, and often (11) diabetes mellitus. Premature cardiovascular disease is the most common cause of death from acromegaly. Gigantism is characterized by extreme tall stature in addition to the clinical features of acromegaly, as pathologic GH excess occurs before epiphyseal fusion is complete.

Most cases of acromegaly (≈95%) result from anterior pituitary GH-secreting tumors (somatotropinomas). Somatotropinomas are usually large macroadenomas (>10 mm in diameter) by the time they come to clinical attention. Approximately 5% of GH-secreting tumors are familial and caused by disorders such as multiple endocrine neoplasia type 1 syndrome, familial acromegaly, Carney syndrome, McCune-Albright syndrome, and familial isolated pituitary adenoma. Approximately 5% of acromegaly cases result from GHRH-secreting hypothalamic tumors, and less than 1% result from extrapituitary somatotropinomas.

In severe or advanced cases of GH excess, the diagnosis may be established on the basis of physical appearance alone. In less severe or early cases, the physical changes may be subtle and gradual, so a high degree of clinical suspicion is needed. The reversibility of tissue changes depends largely on the duration of the disease. In addition to soft tissue changes, acromegaly may cause severe disability or death from cardiac, pulmonary, or neurologic sequelae. The most important requirement for the diagnosis of acromegaly is the demonstration of inappropriate and excessive GH secretion.

Essentially all patients with acromegaly have an abnormal GH response to oral glucose load (see **Box 40.1**). Patients with acromegaly typically show no change in their basal GH level or demonstrate a paradoxical increase in GH; in contrast, normal individuals show suppression of GH after a 75-g oral glucose load. Serum IGF-1 is also elevated in acromegaly.

Growth Hormone Deficiency and Growth Retardation

GH deficiency is not a common cause of short stature with a low growth velocity. Approximately 50% of children evaluated for growth retardation have no specific organic cause; approximately 15% have an endocrine disorder, of which approximately half have GH deficiency. Children with significantly reduced height and low growth velocities with no clear explanation should be screened for GH deficiency after other endocrine disorders have been excluded.

GH deficiency in children is characterized by (1) short stature, (2) low growth velocity, (3) immature facial appearance, (4) retarded bone age on radiologic examination, and (5) increased adiposity. In cases of congenital GH deficiency, size at birth is usually normal because in utero IGF-1 does not appear to be under GH control. GH replacement therapy forms an important part of the clinical care of GH-deficient children.

Adults with GH deficiency experience (1) reduced muscle mass, (2) increased central adiposity, (3) osteoporosis with decreased bone density, (4) an increase in fractures, (5) decreased quality of life, (6) dyslipidemia, and (7) an increased risk for cardiovascular disease. Whether GH therapy is required in GH-deficient adults is somewhat controversial.

GH insufficiency can be a consequence of (1) hypothalamic disease, (2) disruption of the portal system between hypothalamic nuclei and the anterior pituitary, (3) GHRHR loss-of-function mutations, or (4) somatotroph disease. GH deficiency can occur in isolation or together with other pituitary deficiencies. Patients with isolated GH deficiency should be followed clinically for the development of other pituitary hormone deficiencies because multiple pituitary hormone deficiencies can evolve over time. In most affected children, the cause of GH deficiency is unknown (idiopathic GH deficiency). Approximately one in four children with proven GH deficiency has an organic origin for his or her GH deficiency; half of these children will be diagnosed with a central nervous system (CNS) tumor. Biochemical stimulation testing is necessary to establish the diagnosis of GH deficiency, GH resistance, or multiple pituitary hormone deficiencies.

Investigation of growth hormone deficiency

Children. A staged approach for the evaluation of GH deficiency in children is advised. Initial screening can involve one of the following tests: (1) measurement of IGF-1 (with or without IGFBP-3) or (2) GH measurement after exercise or pharmacologic stimulation. If a GH screening test is abnormal (e.g., the GH and/or IGF-1 concentration is reduced), definitive testing should be pursued. All forms of GH testing should be performed after the subject has fasted overnight.

Exercise physiologically enhances GH release. A baseline GH measurement is not required. The child exercises vigorously for approximately 20 minutes and GH is then measured. GH is also measured 20 minutes later to capture delayed GH release. Screening for GH deficiency can also be performed by measuring GH 60 to 90 minutes following clonidine, glucagon, or L-dopa administration. (Note: L-dopa is not currently available in the United States.)

If IGF-1 is within its reference interval for age and sex in children, GH deficiency is excluded. If IGF-1 is low, definitive GH testing is required. Because IGF-1 concentrations can be depressed in states other than GH deficiency, a low IGF-1 concentration does not confirm GH deficiency. IGFBP-3 is less dependent on good nutrition to achieve normal concentrations, so it may be a better marker of GH deficiency than IGF-1.

GH responses to insulin-induced hypoglycemia (insulin tolerance test [ITT]) and GH responses to centrally acting pharmacologic or biologic agents are considered definitive tests. The stimuli are usually administered sequentially or, less commonly, on different days. The classic diagnosis of pediatric GH deficiency requires that GH responses to two different stimuli be deficient. Stimulated GH concentrations less than 7 to 10 ng/mL (7 to 10 µg/L) define GH deficiency in children. The cutoff defining GH deficiency is method-dependent and subject to interpretation by clinicians.

Of children with appropriate stature for age, approximately 80% will have a normal GH response to one stimulus and 95% will have normal GH responses to one or both of the two stimuli.

Adults. A history of childhood GH deficiency, CNS disease, trauma, or irradiation is an indication to test adults for GH deficiency, because not all adults with childhood GH deficiency remain GH-deficient as adults. In adults, a single deficient GH response to a stimulus is diagnostic of GH deficiency if the deficiency is congenital or genetic or if multiple pituitary hormone deficiencies are due to organic disease. In adults, GH deficiency is present when stimulated GH is generally less than 3 to 5 ng/mL (3 to 5 µg/L).

IGF-1 measurements in adults are often not diagnostically helpful. For reasons that are unclear, IGF-1 concentrations can be normal in GH-deficient adults. If the IGF-1 concentration is low and suspicion for GH deficiency is high, some experts would diagnose GH deficiency in the absence of GH testing in adults.

Growth Hormone Resistance

In children with short stature and low growth velocity, if (1) IGF-1 is below the reference interval for the child's bone age

and gender, (2) the random GH concentration is normal or elevated, and (3) non-GH-dependent causes of IGF-1 deficiency have been excluded, GH resistance should be considered. GH resistance is rare.

GH resistance can be congenital, resulting from loss-of-function GHR mutations or GHR signaling defects (STAT5b mutations) or from defects in the production of IGF-1 itself. Most cases of GHR deficiency display low or absent concentrations of GHBP. In acquired GH resistance, which is far more common, the IGF-1 is low (despite sufficient GH secretion) because of malnutrition, malabsorption, chronic disease, hypothyroidism, or sex hormone deficiency.

POINTS TO REMEMBER

1. Secretion of growth hormone (GH) by the pituitary gland is episodic and pulsatile, and transient elevations have been observed in normal healthy subjects.
2. A single basal or random concentration of GH provides limited diagnostic information.
3. The diagnosis of GH deficiency usually requires repeated stimulation tests, although some endocrinologists will diagnose GH deficiency based solely on the measurement of IGF-1.
4. GH excess is diagnosed by the failure of GH suppression after an oral glucose load and by elevated IGF-1 levels.

Prolactin

Prolactin is secreted by lactotrophs. Prolactin stimulates and sustains lactation in postpartum mammals after the mammary glands have been prepared by other hormones, including estrogens, progesterone, GH, corticosteroids, and insulin.

Biochemistry

The hypothalamic PRIH is dopamine. Occasionally and independent of the presence or absence of disease, IgG autoantibodies can bind to prolactin, forming macroprolactin, which is biologically inactive. Macroprolactin elevates the total prolactin concentration as the result of lower clearance. Failure to recognize macroprolactin can lead to the inappropriate diagnosis of hyperprolactinemia.

Physiology

Prolactin is necessary for lactation after delivery of the newborn. Prolactin is stimulated by breast-feeding, chest wall disease, and stress. Prolactin secretion by lactotrophs is controlled predominantly through suppression by PRIH.

It is unclear if prolactin has a physiologic function in men. Postpartum, a positive feedback loop occurs between suckling and milk production. Transmitted via nerve fibers from the nipple to the CNS, suckling reduces PRIH, which increases prolactin release. The positive feedback loop of suckling, prolactin secretion, and milk production is a "stimulus secretion" reflex. However, with continued breast-feeding, prolactin concentrations decline.

Hyperprolactinemia

Hyperprolactinemia is the most common hypothalamic-pituitary disorder encountered in clinical endocrinology. Prolactin may be elevated in women who have only subtle alterations in fertility, such as (1) anovulation with or without menstrual irregularity, (2) amenorrhea and galactorrhea, or (3) galactorrhea alone. In men, prolactin excess usually manifests as a result of low serum testosterone, with reduced libido and central weight gain. Hyperprolactinemia can also cause galactorrhea in men.

An irregular menstrual period may reveal a microadenoma (≤ 10 mm in diameter) in women. Elevated prolactin concentrations are observed in as many as 30% of women with polycystic ovarian syndrome and patients with clinically silent pituitary adenomas. If a borderline elevation of prolactin is found, it is advisable to repeat the measurement on at least two other occasions, taking care to obtain a morning specimen under conditions of minimal excitement or stress to the patient (i.e., no trauma and no breast stimulation). Ideally, the patient should not be on any medication that could stimulate prolactin release (see later in this section). The differential diagnosis of hyperprolactinemia is extensive (Table 40.3).

The higher the prolactin concentration, the greater the likelihood that hyperprolactinemia is the result of a prolactinoma. Idiopathic hyperprolactinemia is a diagnosis of exclusion. Early diagnosis of a prolactinoma is critical because therapy with oral dopamine agonists, such as bromocriptine, can reduce tumor size and control tumor progression. Surgical excision of a prolactinoma is usually considered if there is tumor growth or dopamine agonist therapy fails (the “dopamine-resistant prolactinoma”), if there is failure to quickly reverse associated visual loss, or if the patient is intolerant to dopamine agonists.

A diagnostic challenge in the investigation of hyperprolactinemia is the presence of a pituitary incidentaloma

(a radiologic image consistent with a mass that is not necessarily pathologic) in a patient with elevated prolactin that could potentially lead to inappropriate medical or surgical treatment. Unless a pituitary tumor can be demonstrated by magnetic resonance imaging (MRI), prolactin-secreting microadenoma (≤ 10 mm in diameter) is diagnosed by exclusion. Because half of all prolactin-secreting microadenomas are too small to be detected by imaging methods, differentiating between a small pituitary tumor, prolactin-cell hyperplasia, and idiopathic hyperprolactinemia may not be possible.

Medications that stimulate prolactin release (through PRIH suppression) are the most common cause of hyperprolactinemia in otherwise healthy individuals. When a significant elevation of prolactin is confirmed, a careful history should rule out the possibility that medications are the cause. A pregnancy test should be performed in women of reproductive age because pregnancy is a cause of hyperprolactinemia.

Prolactin Deficiency

Prolactin is of great clinical importance in the postpartum period because it is required for lactation. However, other than the necessity of breast-feeding, prolactin deficiency in humans may not have adverse consequences.

POINTS TO REMEMBER

1. Compared with the measurement of other anterior pituitary hormones, prolactin can be measured in the absence of stimulation or suppression.
2. There are many causes of hyperprolactinemia that should be considered in the evaluation of hyperprolactinemia.
3. The first line of treatment for prolactinomas is medical therapy through the administration of drugs with dopamine-like action.

TABLE 40.3 Differential Diagnosis of Hyperprolactinemia

PRIH (dopamine) deficiency	Hypothalamic disease Interruption in the hypothalamic-pituitary portal system
Drugs	Dopamine antagonists Cholinergic antagonists Serotonergic antagonists Antipsychotic medication
Hormones	Estrogen, pregnancy
Neurogenic	Nursing (nipple stimulation) Chest wall disease Spinal cord injury
Other diseases	Hypothyroidism (pathologically elevated TRH can release prolactin) Chronic renal disease Cirrhosis

PRIH, Prolactin release-inhibiting hormone; TRH, thyrotropin-releasing hormone.

Adrenocorticotrophic Hormone and Related Peptides

ACTH is secreted by the adenohypophysis as a derivative of pro-opiomelanocortin (POMC). ACTH acts on the adrenal cortex, stimulating its growth and the secretion of corticosteroids (specifically cortisol). ACTH production is increased during physiologic or psychologic stress.

Many variables affect the secretion of ACTH, which is both pulsatile and circadian in nature. Cortisol is the major negative feedback hormone for the inhibition of CRH and ACTH secretion. Regulation of ACTH—and a discussion of adrenal disorders including disorders of ACTH secretion—is found in Chapter 41.

Gonadotropins (Follicle-Stimulating Hormone, Luteinizing Hormone)

LH and FSH are synthesized by gonadotrophs. Their actions have already been described. LH and FSH control the functional activity of the gonads. In males and females, gonadotropin secretion is regulated via GnRH. For more details on FSH and LH action and regulation, refer to Chapter 43.

POINTS TO REMEMBER

1. Luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are secreted from pituitary gonadotrophs in response to pulsatile gonadotropin-releasing hormone (GnRH).
2. FSH stimulates growth of ovarian follicles and the secretion of estrogen (estradiol) in females and spermatogenesis in males.
3. LH in females assists in the formation of the corpus luteum and together with FSH promotes progesterone secretion; in males, LH stimulates Leydig cells to produce testosterone.

Thyroid-Stimulating Hormone

TSH, which is synthesized in thyrotrophs, promotes the growth of thyroid follicular cells and sustains and stimulates the hormonal secretion of thyroid gland hormones 3,5,3',5' tetraiodothyronine (thyroxine; T₄) and 3,5,3'-triiodothyronine (T₃).

TSH binds to TSH receptors (TSHRs) located on the surfaces of thyroid follicular cells. TSH (1) stimulates growth and vascularity of the thyroid gland, (2) stimulates the growth of thyroid follicular cells, (3) promotes thyroid hormone synthesis by increasing the uptake of iodine (via the sodium-iodide transporter), (4) promotes the organification (reduction) of

iodine, (5) promotes the coupling of tyrosines, and (6) promotes the proteolytic release of stored thyroid hormone from thyroglobulin. TSH release is stimulated by TRH and suppressed by thyroid hormone (principally circulating free T₄). TRH is a modified tripeptide produced by the hypothalamus. Details concerning the regulation and clinical significance of these hormones are discussed in detail in [Chapter 42](#).

Antidiuretic Hormone

Disorders of ADH involve excess hormone (**syndrome of inappropriate ADH [SIADH]**) or deficient ADH action (**diabetes insipidus [DI]**). DI can result from ADH deficiency, ADH resistance, or renal tubular disease; the latter two conditions are termed nephrogenic DI. Disorders of oxytocin secretion have not been described; therefore oxytocin is not discussed further in this chapter.

Biochemistry

ADH is a nonapeptide consisting of a cyclic hexapeptide and a three-amino-acid side chain. The ADH receptor in the renal collecting ducts is termed the arginine **vasopressin** receptor 2 (V₂ receptor). The action of ADH is to stimulate the movement of aquaporin-2 from the cytoplasm to the apical plasma membrane (Fig. 40.4). In this way ADH allows the

Fig. 40.4 Vasopressin type 2 receptors on collecting duct cells bind antidiuretic hormone (ADH). Through a G-protein system, adenosine triphosphate (ATP) is converted to cyclic adenosine 3',5'-monophosphate (cAMP) via adenylyl cyclase with protein kinase A activation. This leads to translocation of aquaporin-2 water channels from an intracellular pool to the apical plasma membrane, allowing free water uptake by cells of the collecting duct. Via the basolateral plasma membrane aquaporin-3 and aquaporin-4 water channels, free water then leaves these cells.

reabsorption of water from the collecting duct. As electrolyte is not also reabsorbed, the action of ADH can be described as increasing “free water” reabsorption.

Regulation of Antidiuretic Hormone Secretion

ADH secretion is controlled predominantly by plasma osmolality, which is sensed by osmoreceptors in the hypothalamus. Increased osmolality results in ADH release. Plasma osmolality above 280 mOsm/kg (mmol/kg) is thought to be the osmotic threshold for triggering ADH release.

In addition to the osmoreceptor mechanism of vasopressin release, physiologic regulation of ADH secretion involves a pressure–volume mechanism that is distinct from the osmotic sensor. High-pressure arterial baroreceptors of the aortic arch and carotid sinus and low-pressure volume receptors in the pulmonary venous system and atria also regulate ADH release. Therefore ADH is secreted in response to decreased circulating blood volume or decreased blood pressure.

The thirst center is regulated by many of the same factors that determine ADH release. This center has a higher set point than the osmoreceptors and responds to osmolalities above 290 mOsm/kg. Responses involving ADH, thirst, and renal reabsorption of sodium and water are coordinated in a complex scheme that maintains plasma osmolality in healthy individuals within a narrow interval (~285 to ~295 mOsm/kg [mmol/kg]).

Physiologic Activity

The actions of ADH are to conserve free water (via V2 receptors) and stimulate vasoconstriction (via V1a receptors). These effects combine to maintain proper osmolality of the extracellular space (the major action of ADH) and blood pressure through maintenance of circulating blood volume and prevention of dehydration and excessive loss of water.

ADH increases the permeability of renal collecting ducts to water, thereby increasing water reabsorption and concentrating the urine to a higher specific gravity.

Clinical Significance

Disorders of ADH activity have been divided into hypofunction (DI) and hyperfunction (SIADH) (Fig. 40.5).

Polyuric states and diabetes insipidus. Exclusive of diabetes mellitus, polyuric states are divided into two main categories: (1) deficient ADH action, producing DI (sometimes called “water diabetes”), and (2) excessive oral water intake (psychogenic **polydipsia**). Osmotic diuresis (e.g., secondary to hyperglycemia) may also produce **polyuria** and polydipsia.

In DI, polyuria results from excessive loss of water into the urine. Under normal circumstances, urine output is predominantly dependent on fluid intake. When urine output is greater than 2.5 L/d, investigation is usually indicated. In the absence of ADH, urine output may approach 1 L/h. Increased osmolality normally stimulates thirst. Therefore, if a patient with DI has an intact thirst mechanism and access to water, excessive urinary loss of water should be matched

Fig. 40.5 Antidiuretic hormone (ADH) concentration versus plasma osmolality is plotted. The shaded area [A] depicts the normal physiologic relationship between ADH and plasma osmolality. Area B illustrates cases of diabetes insipidus with ADH deficiency. Area C encompasses cases of ADH resistance. Area D includes cases of SIADH (syndrome of inappropriate ADH secretion).

by excessive intake of fluids. The major laboratory finding in DI is urine of low osmolality and serum sodium within the upper half of the reference interval, with a corresponding high-normal serum osmolality. If water is not available or the individual with DI is physically impaired or lacks a normal thirst mechanism, serum osmolality rises, serum sodium rises (producing hypernatremia), urine osmolality remains low, and polyuria continues. With dehydration, weight loss is acute (because of fluid loss) and blood pressure falls, inducing tachycardia.

Central DI can result from any destructive hypothalamic lesion or infundibular lesion (Table 40.4). DI resulting from such lesions can equally be termed hypothalamic, neurogenic, central, or cranial DI. When the thirst center is also abnormal, severe dehydration can occur.

In 30% of patients, central DI occurs without apparent cause. The remaining cases are associated with (1) neoplastic disease, (2) neurologic surgery, (3) head trauma, (4) ischemic or hypoxic disorders, (5) granulomatous disease, (6) infection, or (7) autoimmune disorders. DI can result from acquired or genetic tubular diseases that affect the responsiveness of renal tubules to ADH (nephrogenic DI). In the broadest sense, any form of tubular injury with impaired water reabsorption, including (1) polycystic kidney disease, (2) medullary cystic kidney, (3) chronic pyelonephritis, (4) acute tubular necrosis, (5) obstructive uropathy, (6) sickle cell nephropathy, and (7) renal amyloidosis can cause nephrogenic DI. A large number

TABLE 40.4 Causes of Central Diabetes Insipidus

Congenital	Midline malformations: septo-optic dysplasia, holoprosencephaly, single central incisor, cleft lip and/or palate Malformation of the pituitary (ectopia or hypogenesis) Diabetes insipidus–diabetes mellitus–optic atrophy syndrome (Wolfram syndrome) Familial diabetes insipidus (autosomal dominant and recessive forms)
Acquired	Tumors (craniopharyngioma, germinoma, pinealoma, optic glioma, pituitary adenoma, metastatic tumor, leukemia) Trauma (e.g., stalk section) Infarction (e.g., septic shock, Sheehan syndrome, hypoxic injury) Infiltrative disease (sarcoidosis, hypophysitis, histiocytosis) Cysts and aneurysms Drugs (opiates, alcohol, phenytoin, alpha-adrenergic agents, etc.) Infection Increased metabolism of ADH (vasopressinase in pregnancy)

ADH, Antidiuretic hormone.

of drugs can cause nephrogenic DI, including (1) lithium, (2) various antimicrobials, and (3) several antineoplastic drugs. In psychogenic polydipsia (primary polydipsia), excessive water intake eventually begins to impair the concentrating ability of the kidney.

Investigation of polyuria. Assuming that diabetes mellitus is excluded, the examination of polyuric states is undertaken with measurements of plasma and urine osmolality and, if the findings are equivocal, plasma ADH concentrations. A screening test for ADH sufficiency is the measurement of the urine specific gravity in the first morning-voided urine sample where the specific gravity should be 1.010 or greater. Failure to demonstrate an appropriate urine specific gravity and response in a subject with a history of polyuria and polydipsia should trigger assessment of a basic metabolic panel, urinalysis, serum osmolality, and urine osmolality.

Urine osmolality less than 300 mOsm/kg (mmol/kg) combined with serum osmolality more than 300 mOsm/kg (mmol/kg) (or with hypernatremia) is diagnostic for DI. If urine osmolality is above 600 mOsm/kg (mmol/kg), and serum osmolality is below 270 mOsm/kg (mmol/kg), DI is unlikely.

If the diagnosis of DI is unclear, a water deprivation test should be performed. Water deprivation testing should not be carried out if the subject is dehydrated at baseline or has renal insufficiency. The overnight water deprivation test is usually conducted in a hospital setting because of the immediate concerns of profound hypotension and possible mortality. The water deprivation test is usually begun on the

morning after an overnight fast unless the history describes large volumes of water ingested and urine produced, in which case the test should begin after breakfast. The subject remains fasting throughout the entire test. A heparin lock is inserted intravenously, so that serial blood samples are obtained easily. Baseline laboratory tests include (1) sodium, (2) potassium, (3) chloride, (4) serum carbon dioxide (CO_2), (5) urea (blood urea nitrogen [BUN]), (6) creatinine, (7) glucose, (8) calcium, and (9) serum osmolality. Potassium and calcium are measured to exclude hypokalemia and hypercalcemia as causes of nephrogenic DI (see later).

Measurements of serum or plasma sodium, chloride, CO_2 , and urine pH provide an assessment of the patient's renal tubular acid-base function. Renal function and hydration status are evaluated with creatinine and urea (BUN) measurements. A urine specimen is obtained for measurement of urine sodium, urine osmolality, and urine specific gravity. Body weight and vital signs at baseline are recorded. Thereafter, each hour, serum and urine tests are repeated with measurement of hourly urine output, body weight, and urine volume. If ADH measurements are requested, they can be performed at the beginning, middle, and completion of the test; however, ADH measurements are not required for making the diagnosis of DI. The test is continued for 8 to 10 hours unless the diagnosis of DI is confirmed before the full time period has elapsed.

During the water deprivation test, if urine osmolality exceeds 600 mOsm/kg (mmol/kg) on two samples 1 hour apart or a single urine sample exceeds 1000 mOsm/kg (mmol/kg), DI is ruled out and the test can be concluded. If urine osmolality is less than 600 mOsm/kg (mmol/kg), and serum osmolality is more than 300 mOsm/kg (mmol/kg), DI is diagnosed and the test can be concluded. If serum osmolality does not exceed 300 mOsm/kg (mmol/kg), the test should be continued. If mental status changes or hypotension occurs or weight loss exceeds 3%, the test should be terminated.

If DI is diagnosed during a water deprivation test, aqueous vasopressin is injected subcutaneously (1 U/ m^2 or, according to some sources, 5 U total), or des-amino-D-arginine vasopressin (desmopressin) is given intravenously or intramuscularly (2 μg). A decline in urine volume with doubling of urine osmolality over the next 1 to 2 hours identifies the DI as central in origin with the patient being ADH deficient. Failure to respond to exogenous ADH defines nephrogenic DI. Most patients with psychogenic polydipsia have normal urine osmolality after water deprivation, but some fail to produce concentrated urine unless the water deprivation is prolonged.

Syndrome of inappropriate antidiuretic hormone secretion. SIADH is a common cause of hyponatremia in hospitalized patients. The autonomous sustained production of ADH in the absence of recognized and appropriate stimuli (such as hyperosmolality) is termed SIADH. In this syndrome, plasma ADH concentrations are “inappropriately” elevated relative to decreased plasma osmolality and to normal or increased plasma volume.

TABLE 40.5 Causes of the Syndrome of Inappropriate Antidiuretic Hormone

CNS disease	Brain tumor Infection (e.g., meningitis, encephalitis, abscess) Prolonged seizure Psychiatric disease Stress (e.g., prolonged nausea)
Non-CNS tumor (e.g., leukemia)	
Pulmonary disease	Hypoxia (e.g., neonatal) Infection (e.g., pneumonia, emphysema)
Nonpulmonary infection (e.g., AIDS)	
Drugs	Drugs with CNS effects (anticonvulsants, antiparkinson drugs, antipsychotics, antipyretics, antidepressants) Angiotensin-converting enzyme inhibitors Antineoplastic drugs First-generation sulfonylureas

AIDS, Acquired immunodeficiency syndrome; *CNS*, central nervous system.

SIADH may be the result of one of several factors (Table 40.5), including (1) production of ADH by a malignancy (such as small cell carcinoma of the lung), (2) the presence of acute or chronic disease of the CNS, (3) pulmonary disorders, or (4) as a side effect of certain drug therapies.

In SIADH, primary excess of ADH coupled with unrestricted fluid intake promotes increased reabsorption of water by the kidney. The consequences are decreased urine volume and increased urine osmolality. The increase in intravascular volume causes hemodilution accompanied by dilutional hyponatremia and low plasma osmolality. It is important to recognize that although osmoregulation is tightly controlled, volume regulation always takes precedence over osmoregulation. Via suppression of the renin-angiotensin-aldosterone axis, volume expansion also decreases renal sodium reabsorption; thus the urine sodium concentration is typically 20 to 40 mEq/L (mmol/L) despite dilutional hyponatremia in the blood. This hypervolemia-induced urinary sodium excretion coupled with water loss explains why patients with SIADH are euvolemic and not edematous.

Clinical manifestations of hyponatremia are nonspecific and include nausea, weakness, and apathy in mild cases and CNS changes such as lethargy, coma, and seizures in more severe cases. No signs or symptoms are specific for SIADH. History, physical examination, and routine laboratory test results often suggest that hyponatremia is dilutional (decreased urea, hemoglobin, or albumin) or depletion (increased urea, hemoglobin, or albumin). Measurements of sodium and osmolality in blood and urine combined with clinical assessment of volume status

TABLE 40.6 Disorders of Overproduction and Underproduction of Pituitary Hormones

Pituitary Hormone	Consequences of Hormone Excess	Consequences of Hormone Deficiency
ACTH	Cushing disease	Cortisol deficiency
TSH	Central hyperthyroidism	Central hypothyroidism
GH	Children: gigantism Adults: acromegaly	Children: short stature Adults: adult GH deficiency
LH, FSH	Alpha-chain overproduction	Hypogonadism
Prolactin	Galactorrhea, hypogonadism	Inadequate lactation or lactation failure in mothers after delivery
ADH	SIADH	DI

ACTH, Adrenocorticotrophic hormone; *ADH*, antidiuretic hormone; *DI*, diabetes insipidus; *FSH*, follicle-stimulating hormone; *GH*, growth hormone; *LH*, luteinizing hormone; *SIADH*, syndrome of inappropriate ADH; *TSH*, thyroid-stimulating hormone.

usually permit the appropriate differential diagnosis of hyponatremic conditions.

Diagnostic Studies

Serum osmolality can be estimated from serum sodium, glucose, and urea (BUN) but is more reliably measured directly. Various formulas are available for estimating serum osmolality (see Chapter 24 for detail).

POINTS TO REMEMBER

1. Antidiuretic hormone (ADH) and oxytocin-synthesizing cells are located in the hypothalamus.
2. ADH deficiency or resistance causes diabetes insipidus (DI) with the excess loss of free water.
3. ADH excess causes the syndrome of inappropriate ADH (SIADH), which results in the excess retention of free water.

SUMMARY OF PITUITARY-RELATED DISORDERS

Disorders that result from the over- or underproduction of pituitary hormones are tremendously diverse (Table 40.6). Pituitary adenomas may be secretory or nonsecretory. Corticotropinomas secrete ACTH, somatotropinomas secrete GH, and prolactinomas secrete prolactin. Gonadotropinomas usually do not secrete intact LH and/or FSH but may secrete free α subunits. Pituitary adenomas, whether functional or not, can lead to deficiencies of other pituitary hormones through the compression and destruction of the adjacent pituitary cells. These topics are reviewed in depth in many chapters of this textbook.

REVIEW QUESTIONS

- Which one of the following anterior pituitary hormones is regulated through suppression via the secretion of a hypothalamic hormone?
 - ACTH
 - Prolactin
 - Growth hormone
 - LH, FSH
 - IGF-1
- Which one of the following hormones exerts a predominant negative feedback via the anterior pituitary? The other hormones predominantly feed back at the level of the hypothalamus.
 - IGF-1
 - Sex steroids
 - Inhibins
 - Cortisol
 - Thyroid hormone
- Which one of the following statements is correct?
 - IGF-1 and IGF-2 circulate bound to albumin.
 - IGF-1 and IGFBP-3 levels are independent of one another.
 - IGF-1 and IGF-2 circulate together bound to IGFBP-3 and the acid-labile subunit (ALS).
 - The acid-stable subunit binds to IGF-1.
 - IGF-1 and insulin form a complex.
- Which of the following statements is correct regarding growth hormone (GH)?
 - Physiologically, GH secretion is episodic and pulsatile.
 - GH concentrations reach a very low levels during the period of deepest sleep.
 - GH actions are mediated through cortisol.
 - GH secretion is stable throughout the day.
 - A single measurement of GH is sufficient for diagnostic purposes.
- Which one of the following statements is true?
 - GH lowers blood glucose and can cause hypoglycemia.
 - GH raises blood glucose by stimulating gluconeogenesis and reducing insulin sensitivity.
 - GH is suppressed by hypoglycemia.
 - GH inhibits lipolysis.
 - GH is the only determinant of IGF-1 concentrations.
- What is the most common cause of acromegaly?
 - IGF-1-secreting tumors
 - Macro GH
 - Anterior pituitary GH-secreting tumors (somatotropinomas)
 - Multiple endocrine neoplasia type 1 syndrome
 - Gonadotropin-secreting tumors
- Which one of the following statements is true regarding macroprolactin?
 - This is a complex between prolactin and an immunoglobulin.
 - This is a very high-molecular-weight form of prolactin due to alternative splicing.
 - Macroprolactin lowers the plasma prolactin concentration.
 - Macroprolactin heralds a dangerous pituitary tumor.
 - Macroprolactin cannot be detected in the laboratory.
- Which one of the following statements is true?
 - In men, FSH stimulates testosterone production by Leydig cells. LH directs Sertoli cells to nourish developing sperm during spermatogenesis.
 - LH and FSH are secreted by separate and distinct pituitary cells.
 - LH and FSH secretion is stimulated by steady high concentrations of GnRH.
 - LH and FSH are single-chain polypeptides.
 - LH and FSH are secreted episodically.
- Which one of the following statements is true?
 - Cortisol is directly regulated by CRH.
 - The major site of cortisol feedback is the anterior pituitary gland.
 - ACTH directly regulates CRH.
 - Increased ACTH increases cortisol secretion.
 - ACTH is a glycoprotein hormone made up of alpha and beta subunits.
- Which of the following suggests diabetes insipidus (DI)?
 - Urine osmolality >600 mOsm/kg (mmol/kg)
 - Serum osmolality <270 mOsm/kg (mmol/kg)
 - Urine osmolality <300 mOsm/kg (mmol/kg) plus serum osmolality >300 mOsm/kg
 - Edema and hypertension
 - Very high urine sodium

Adrenal Cortex

Roger L. Bertholf, Mark Cooper, William E. Winter

OBJECTIVES

1. Define the following:
 - Androgen
 - Angiotensin
 - Glucocorticoid
 - Incidentaloma
 - Mineralocorticoid
 - Renin
 - Steroid hormone
2. State how adrenocortical steroid hormones are synthesized from cholesterol.
3. Describe the anatomy and physiology of the adrenal cortex.
4. For each of the following hormones, state the function, regulation (including anterior pituitary or hypothalamic hormones involved, if any), site of synthesis, circulatory transport, metabolism, and urinary metabolite:
 - Aldosterone
 - Androstenedione
 - Cortisol
 - Dehydroepiandrosterone (DHEA)
5. Describe the following dynamic test of adrenal function, including the reasons for performing it, protocol followed, and interpretation of results:
 - Adrenocorticotrophic hormone (ACTH) (cosyntropin) stimulation
 - Corticotropin-releasing hormone (CRH) stimulation
 - Dexamethasone suppression
 - Insulin-induced hypoglycemia stimulation
 - Metyrapone stimulation
 - Mineralocorticoid stimulation/suppression
6. Discuss the following adrenocortical disorders including the hormone(s) involved, symptoms, primary/secondary/tertiary causes, and screening and suppression/stimulation tests used for assessment:
 - Addison disease
 - Conn syndrome
 - Cushing syndrome/Cushing disease
 - Congenital adrenal hyperplasia (CAH)
7. Summarize the circadian variation of cortisol and aldosterone; list the preanalytical variables that must be considered when assessing aldosterone.
8. Diagram the renin-angiotensin-aldosterone axis.
9. List and describe the laboratory analyses used to assess adrenocortical function, including methodology, specimen type, collection, and storage requirements for the following analytes:
 - Aldosterone
 - Angiotensin
 - Cortisol (serum and urine)
 - 17-Hydroxyprogesterone
 - Renin
 - Urinary free cortisol (UFC)
10. Assess and solve case studies related to disorders of the adrenal cortex and their laboratory assessment.

KEY WORDS AND DEFINITIONS

Addison disease Deficiency of adrenocortical hormones secondary to disease of the adrenal glands, characterized by hypotension and a bronze-like hyperpigmentation of the skin. Also called *primary hypoadrenalism* to distinguish it from secondary hypoadrenalism (deficiency of pituitary adrenocorticotrophic hormone).

Adrenal androgens A class of sex hormones that produce masculinization.

Adrenocorticotrophic hormone (ACTH) A 39-amino-acid anterior pituitary hormone that acts primarily on the adrenal cortex, stimulating its growth and the secretion of corticosteroids. Also called *corticotropin*.

Aldosterone The major mineralocorticoid steroid hormone secreted by the adrenal cortex.

Androstenedione An androgenic steroid produced by the testis, adrenal cortex, and ovary.

Angiotensin II A small (eight-amino-acid) polypeptide hormone; among its functions, it stimulates release of aldosterone and other hormones, constricts blood vessels, and controls arterial pressure.

Angiotensin-converting enzyme (ACE) Enzyme that catalyzes the removal of two amino acids from angiotensin I, thus converting it to the active hormone angiotensin II.

Angiotensin-converting enzyme inhibitors Pharmaceuticals that are competitive inhibitors of the angiotensin-converting enzyme. They are used in the treatment of hypertension.

Angiotensinogen A serum globulin formed by the liver that is cleaved by renin to produce angiotensin I.

Conn syndrome A condition of primary aldosteronism arising from oversecretion of aldosterone by an adrenocortical adenoma.

Congenital adrenal hyperplasia (CAH) A group of inherited disorders in which deficiencies of enzymes that catalyze the biosynthesis of cortisol result in compensatory hypersecretion of corticotropin and subsequent adrenal hyperplasia as well as excessive androgen production.

Cortisol The major adrenal glucocorticoid synthesized in the zone fasciculata (and, to a lesser extent, the zona reticularis) of the adrenal cortex.

Cushing syndrome A condition characterized by an increased concentration of adrenal glucocorticoid hormone in the bloodstream and its effects on the body.

Dehydroepiandrosterone (DHEA) A weak androgenic steroid secreted by the adrenal cortex. It is the major androgen precursor in females.

Glucocorticoids Any of the group of C21 steroids produced by the adrenal cortex that regulate carbohydrate, fat, and protein metabolism.

Hyperaldosteronism A condition in which the adrenal gland secretes and releases increased quantities of aldosterone.

Hypovolemia A condition characterized by an abnormal decrease in the volume of circulating blood in the body.

Mineralocorticoids Any of the group of 21-carbon corticosteroids (principally aldosterone) that contribute to the regulation of (1) water, (2) acid-base, and (3) electrolyte balance in the body.

Renin A hydrolase enzyme that catalyzes cleavage of the leucine-leucine bond in angiotensinogen to generate angiotensin I.

Steroidogenic acute regulatory protein (StAR) A transport protein that functions to regulate cholesterol transfer within the mitochondria.

Waterhouse-Friderichsen syndrome Adrenal gland failure caused by bleeding into the adrenal gland; it is a fulminating complication of bacterial infections, notably meningococcemia, characterized by a sudden onset and short course, cyanosis with petechial hemorrhages of the skin and mucous membranes, fever, and hypotension, which can lead to shock and coma.

Zona fasciculata The thick middle layer of the adrenal cortex that contains large lipid-laden cells. It is the major source of glucocorticoids and, to a lesser extent, adrenal androgens.

Zona glomerulosa The thin outer layer of the adrenal cortex. It is the source of mineralocorticoids.

Zona reticularis The inner layer of the adrenal cortex. Its cells resemble those of the zona fasciculata except that they contain less lipid. The zona reticularis is the major source of adrenal androgens and produces glucocorticoids to a lesser degree.

The adrenal cortex produces steroid hormones that regulate salt and water balance (mineralocorticoids); metabolism of fat, proteins, and carbohydrates (glucocorticoids); and sexual development (androgens). Secretion of adrenocortical hormones is influenced by multiple physiologic signals originating in the kidney, liver, lungs, pituitary, hypothalamus, and elsewhere. Disease can result from overproduction as well as deficiency of adrenocortical hormones. Moreover, excess or deficiency of these hormones can be primary (i.e., resulting from adrenal gland dysfunction) or secondary (i.e., resulting from dysregulation of stimulating hormones). Mineralocorticoid excess causes hypertension and hypokalemia (called **Conn syndrome**), whereas deficiency causes salt wasting, sometimes in the form of **Addison disease** (primary adrenal insufficiency). Glucocorticoid excess causes **Cushing syndrome**, characterized by hypertension, abdominal obesity, weakness, and abnormal fat distribution. Glucocorticoid deficiency, as in Addison disease, causes weakness, hypotension, and hyperpigmentation of the skin among other symptoms. Because regulation of adrenocortical hormones is multifactorial, laboratory investigation of adrenal disorders often

requires measuring the response to various stimulating factors, both chemical and physiologic. Analytic methods are available to measure most adrenocortical hormones.

ANATOMY

The adrenal (or suprarenal) glands are pyramid-shaped, 2 to 3 cm wide, 4 to 6 cm long, and about 1 cm thick. The adrenal cortex and the gonads share several metabolic pathways for synthesis of steroid hormones because both are derived from mesodermal anlagen. The postnatal adrenal cortex is composed of three layers: the glomerulosa (10% to 15% of the cortex), the fasciculata (up to 75% of the cortex), and the reticularis (5% to 10% of the cortex). At birth the adrenal gland is nearly equal in weight to that of an adult (8 to 12 g). The large size of the fetal adrenal gland (≈ 250 mg/100 g body weight) may explain its propensity to occasionally be traumatized during delivery. Between 3 and 18 months of age, the adrenal glands involute to approximately half their size at birth. Later in life, the adrenal glands are less susceptible to trauma and represent less than 50 mg/100 g of body weight.

TABLE 41.1 Anatomy and Products of the Adrenal Gland

Adrenal Layer	Major Product(s)	Action
Cortex		
Zona glomerulosa	Aldosterone	Mineralocorticoid
Zona fasciculata	Cortisol	Glucocorticoid
Zona reticularis	Dehydroepiandrosterone	Adrenal androgen
	Androstenedione	
Medulla	Epinephrine	Catecholamine

Adult adrenal glands weigh 4 to 6 g each. Table 41.1 lists the location and action of hormones produced by the adrenal gland. Hormones produced by the adrenal cortex include mineralocorticoids, glucocorticoids, and adrenal androgens.

Mineralocorticoids (Aldosterone)

Mineralocorticoids bind to the mineralocorticoid receptor (MR) in the distal convoluted tubule (DCT) and collecting duct of the nephron, the colon, and the salivary glands to promote sodium reabsorption and potassium and hydrogen ion excretion. The principal mineralocorticoid is **aldosterone**, but other compounds with mineralocorticoid activity include 11-deoxycorticosterone (DOC), 18-hydroxycorticosterone, corticosterone, and **cortisol**. Although aldosterone binds to the MR in the cytoplasm, with subsequent transit of the complex to the nucleus, some free MR is present in the nucleus. The MR binds cortisol and DOC with affinity equal to that of aldosterone. However, the MR is protected from cortisol and DOC by 11 beta-hydroxysteroid dehydrogenase-2 (HSD11B2), which converts cortisol to cortisone. Cortisone does not bind to the MR. The actions of mineralocorticoids include sodium retention (causing water to be retained), and potassium and hydrogen ion excretion.

Glucocorticoids (Cortisol)

Glucocorticoids bind to the glucocorticoid receptor (GR), which is expressed in a variety of tissues including lymphocytes, hepatocytes, and bone. Because of the wide distribution of the GR, glucocorticoid effects are diverse, including changes in intermediary metabolism and immunoregulation. Glucocorticoids raise blood glucose concentrations by enhancing the synthesis of gluconeogenic enzymes, increase liver glycogen content by activation of glycogen synthase, and inhibit glycogen phosphorylase, producing insulin resistance in both muscle and adipose tissue, further raising blood glucose concentrations. Protein catabolism causes thinning of the skin and loss of strength in connective tissues. Excess glucocorticoids may result in bone loss from collagen catabolism and loss of osteoid, leading to fractures and compressed vertebrae.

Glucocorticoids promote the redistribution of adipose tissue centrally to the trunk, neck, and face. Insulin resistance raises very low-density lipoprotein (VLDL) and triglyceride concentrations and lowers high-density lipoprotein concentrations. Insulin resistance decreases the activity of

hormone-sensitive lipase in adipose tissue, allowing triglyceride hydrolysis to free fatty acids. In the liver, those free fatty acids provide substrate for the synthesis of hepatic triglycerides and subsequent VLDL production and export. Glucocorticoids increase appetite, thereby increasing caloric intake and weight gain.

Glucocorticoids are powerful anti-inflammatory hormones. They suppress immune hypersensitivity by inhibiting the production of histamine by basophils and mast cells. Modest doses of glucocorticoids can improve mood, but at therapeutic doses they can cause psychosis.

Adrenal Androgens (Dehydroepiandrosterone and Androstenedione)

The **adrenal androgens dehydroepiandrosterone (DHEA)**, dehydroepiandrosterone sulfate (DHEA-S), and **androstenedione** are peripherally converted to testosterone, which binds to the androgen receptor. Between ages 7 and 8 years, urinary excretion of 17-ketosteroids (breakdown products of adrenal androgens) increases, signaling that puberty will begin within 3 to 5 years.

In males, adrenal androgens such as DHEA and androstenedione are mostly unimportant because testosterone, produced in the testes, is a much more potent androgen. In pubertal and adult women, however, the adrenal androgens produce axillary and pubic hair. DHEA is highly sulfated; circulating concentrations of DHEA-S exceed those of DHEA by at least 100-fold. DHEA-S decreases slightly in women following menopause.

PHYSIOLOGY AND REGULATION OF ADRENOCORTICAL HORMONES

Steroid hormones are not stored and therefore must be produced as needed. Steroids are lipophilic and pass through cell membranes to exit the hormone-producing cells, enter the circulation to be distributed throughout the body, and enter target cells by passing through the membrane into the cytoplasm, where they bind to receptors. Translocation of the cytosolic hormone-receptor complex into the nucleus results in hormonal activity. Evidence suggests that steroid hormones may affect more than DNA transcription alone. In the circulation, steroids exist as free and protein-bound species. (For a more detailed discussion of free vs. bound hormone, refer to the section titled Adrenocortical Hormones in the Circulation.)

Aldosterone

The production and secretion of aldosterone are regulated by the renin-angiotensin system (Fig. 41.1). The rate-limiting component in this system is **renin**, the release of which is regulated by the juxtaglomerular (“next to the glomerulus”) apparatus. The juxtaglomerular apparatus is composed of the juxtaglomerular cells of the afferent arteriole, which immediately leads to the glomerulus, lacis cells, and macula densa. Juxtaglomerular cells are modified smooth muscle cells that synthesize and secrete renin in response to decreased renal

Fig. 41.1 The juxtaglomerular (*JG*) apparatus monitors hydrostatic pressure in the glomerulus and the sodium concentration in the distal convoluted tubule (*DCT*). Renin is released in cases of decreased renal perfusion or decreased sodium concentration in the *DCT*. Renin cleaves angiotensinogen to angiotensin I. Angiotensin-converting enzyme (*ACE*), predominantly in the lung, converts angiotensin I to angiotensin II. Angiotensin II has powerful vasoconstrictive effects, promotes sodium reabsorption by the proximal convoluted tubule (*PCT*), and stimulates thirst, antidiuretic hormone (*ADH*) release, catecholamine release, and aldosterone synthesis and secretion. Aldosterone stimulates sodium and water reabsorption, increasing blood volume and blood pressure. Overall these effects enhance renal perfusion. Adrenocorticotrophic hormone (*ACTH*) and increased potassium have minor effects in stimulating aldosterone synthesis and secretion. *Epi*, Epinephrine; *NE*, norepinephrine.

perfusion. The macula densa monitors the sodium concentration in the *DCT*. If a decline in sodium concentration is detected, the macula densa signals the juxtaglomerular cells via the hormone prostacyclin to release renin.

Sodium delivery to the *DCT* is decreased in hyponatremia and when renal perfusion declines, both of which stimulate renin release. The catecholamines norepinephrine and dopamine also stimulate renin release. Upright posture and catecholamine release thereby stimulate renin release. Potassium also directly stimulates renin release. Overall, renin release is physiologically stimulated by **hypovolemia**, reduced cardiac output, systemic vasodilation, selectively reduced renal perfusion, hyponatremia, and stress (mediated by catecholamines).

Angiotensinogen is an approximately 60-kDa α_2 -globulin synthesized in the liver. Renin cleaves 10 N-terminal residues from angiotensinogen to form the decapeptide angiotensin I, a prohormone that has no innate activity. **Angiotensin-converting enzyme (ACE)**, expressed mostly in the lung, removes the two C-terminal residues from angiotensin I to generate the octapeptide **angiotensin II**. Further degradation of angiotensin II by aminopeptidase A yields the heptapeptide angiotensin III. The ratio of angiotensin II to angiotensin III is usually 4 to 1. An arginyl aminopeptidase generates angiotensin IV from angiotensin III. Angiotensin III and IV are active but overall have less potency than angiotensin II.

Angiotensin II preserves circulating blood volume and maintains blood pressure through several mechanisms: (1) stimulation of aldosterone synthase to produce aldosterone; (2) direct vasoconstriction; (3) increased release of epinephrine and norepinephrine, which also act as vasoconstrictors, from the adrenal medulla; (4) stimulation of sodium reabsorption in the proximal convoluted tubule (*PCT*); (5) stimulation of thirst; and (6) stimulated release of antidiuretic hormone (*ADH*). Aldosterone secretion occurs at approximately one-tenth the rate of cortisol secretion on a weight basis. The half-life of circulating aldosterone is less than 15 minutes.

Cortisol

Cortisol is regulated through a traditional hypothalamic-pituitary-end organ negative feedback system (Fig. 41.2). Corticotropin-releasing hormone (*CRH*) is released from the hypothalamus by stress, exercise, and hypoglycemia. Examples of physiological stress include pain, trauma, surgery, and hemorrhage. Examples of psychological stress include severe anxiety and major depression. Secreted *CRH* reaches the anterior pituitary gland via the hypothalamic pituitary portal system and stimulates the release of **adrenocorticotrophic hormone (ACTH)**, also called corticotropin). *ACTH* is also released in response to *ADH*, but to a lesser degree than *CRH*. The proinflammatory cytokines interleukin (*IL*)-1, *IL*-6, and tumor necrosis factor- α also stimulate *ACTH* release.

Fig. 41.2 Cortisol synthesis and release are controlled through a traditional hypothalamic–pituitary–end organ negative feedback loop. Corticotropin-releasing hormone (*CRH*) released from the hypothalamus is delivered to the anterior pituitary via the hypothalamic–pituitary portal system. CRH releases adrenocorticotrophic hormone (*ACTH*) from anterior pituitary corticotrophs. Increased concentrations of antidiuretic hormone (*ADH*) and proinflammatory cytokines (e.g., interleukin [*IL*]-1, *IL*-6, and tumor necrosis factor- α) also stimulate ACTH release. ACTH stimulates the synthesis and release of cortisol from the adrenal cortex. Cortisol feeds back negatively at the pituitary, but the major site of negative feedback is the hypothalamus.

Hyperpigmentation of the skin occurs with ACTH excess, and this appears to be a direct consequence of the melanocyte stimulating hormone (MSH)-like activity of ACTH. Certain amino acid sequences in MSH are contained within ACTH. Pro-opiomelanocortin (POMC) is the precursor polypeptide of ACTH, the MSHs, and beta-endorphin.

Corticotropin circulates systemically and binds to ACTH receptors on cells in the adrenal cortex, resulting in cortisol synthesis and release. Cortisol inhibits hypothalamic and pituitary release of CRH and ACTH, respectively. Other negative feedback loops include ACTH suppression of hypothalamic CRH and an ultrashort feedback loop whereby ACTH suppresses its own release. There is diurnal variation in the secretion of cortisol; highest concentrations occur approximately 2 hours before awakening and lowest concentrations shortly after falling asleep.

Adrenal Androgens

Regulation of adrenal androgen synthesis and secretion is not well understood. The existence of a pituitary adrenal androgen-stimulating hormone or an adrenocortical androgen-stimulating hormone remains doubtful despite many years of research seeking its existence. The best-characterized regulator of androstenedione and DHEA secretion is ACTH. Diurnal rhythm in adrenal androgen concentrations parallels cortisol variations. Nevertheless, ACTH regulation of adrenal androgens does not explain the increase in adrenal androgen synthesis that occurs in both boys and girls during puberty;

ACTH does not increase prior to puberty. Evidence indicates that changes in the expression and activity of factors that regulate enzymes involved in androgen synthesis are responsible for prepubertal and pubertal increases in adrenal androgens.

The synthetic pathways for aldosterone, cortisol, and adrenal androgens are illustrated in Fig. 41.3.

ADRENOCORTICAL HORMONES IN THE CIRCULATION

Steroid hormones are 90% to 98% bound to specific carrier proteins or albumin. Steroids that are sulfated or glucuronidated circulate unbound in the plasma. Aldosterone is carried primarily by albumin because cortisol, corticosterone, and 17-hydroxyprogesterone occupy most of the binding sites on corticosteroid-binding globulin (CBG; transcortin). In the blood, 80% to 90% of cortisol is bound to CBG, 7% is loosely bound to albumin, and 2% to 3% is unbound (free). Total cortisol concentration normally exceeds the aldosterone concentration by about 1000-fold, which explains why little aldosterone is carried on CBG. Because more cortisol than aldosterone is bound to CBG, the half-life of cortisol is longer (60 to 80 minutes) than the half-life of aldosterone (20 to 30 minutes). When total cortisol rises in Cushing syndrome, the increased fraction of free cortisol is excreted in the urine, increasing the urinary free cortisol (UFC) concentration. At normal concentrations in the blood, only 0.25% to 0.5% of total cortisol is excreted in the urine.

Transcortin (CBG) concentrations rise in response to increasing estrogen. In pregnancy, CBG concentration may rise two- to threefold. CBG concentrations are also increased in some patients with chronic active hepatitis. CBG concentrations are reduced in nephrosis (as a result of CBG loss in the urine), cirrhosis (because of decreased production), and hyperthyroidism (due to increased metabolism) as well as with glucocorticoid treatment (probably as a result of catabolism). Even with changes in total cortisol due to variations in CBG, the concentration of free (active) cortisol remains stable if the hypothalamic–pituitary–adrenal axis is functioning normally.

DHEA and its sulfated form, DHEA-S, and estradiol are mostly bound to albumin. In contrast, testosterone and dihydrotestosterone (DHT) are carried by sex hormone-binding globulin (SHBG). Estrogens and thyroid hormone increase SHBG production, whereas insulin, growth hormone, glucocorticoids, androgens, and progestins inhibit SHBG synthesis. SHBG concentrations are higher in children than in adults.

DISORDERS OF THE ADRENAL CORTEX

Thomas Addison first reported hypofunction of the adrenal cortex in 1855. During the past 65 years, many diseases associated with abnormal adrenal function have been described.

Diseases of the adrenal cortex result from either hypofunction or hyperfunction.

Fig. 41.3 The zona glomerulosa is the site of aldosterone synthesis. CYP11B2 is predominantly controlled by angiotensin II, regulating aldosterone synthesis and secretion. In the fasciculata and reticularis layers, cortisol and the adrenal androgens DHEA and androstenedione are produced. CYP11A, 3 beta-HSD, CYP17, CYP21, and CYP11B1 activities are controlled by ACTH.

Adrenal Insufficiency (Addison Disease)

Adrenal insufficiency causing combined mineralocorticoid and glucocorticoid deficiency is a rare disorder with a prevalence of only 4 to 11 cases per 100,000. Untreated adrenal insufficiency can be fatal. Cortisol deficiency is classified as primary, secondary, or tertiary. Primary adrenal insufficiency, also known as Addison disease, results from progressive destruction or dysfunction of the adrenal glands by a systemic disorder, an inborn error of metabolism (endogenous causes), or an exogenous cause such as infection. Worldwide, infectious disease is the most common cause of primary adrenal insufficiency. Human immunodeficiency virus (HIV) infection increases the risk of adrenalitis. Autoimmune adrenalitis accounts for more than 70% of cases reported in the Western world, with adrenal autoantibodies measurable in more than 75% of cases.

The most common inborn steroidogenic defects involve synthesis of cortisol with or without concurrent aldosterone deficiency, producing **congenital adrenal hyperplasia (CAH)**. Because such disorders commonly lead to adrenal androgen overproduction, they are discussed in a later section concerning hyperfunction of the adrenal cortex.

Because the entire adrenal cortex is affected in primary adrenal insufficiency, all classes of adrenal steroids are deficient. The onset of clinical manifestations is usually gradual, and the degree and severity of symptoms depend on the extent of adrenal failure. Complete glucocorticoid deficiency can manifest in a variety of ways, including fatigue, weakness, weight loss, gastrointestinal disturbance, and fasting hypoglycemia. Mineralocorticoid deficiency leads to dehydration, with hypotension, acidosis, hyponatremia, and hyperkalemia. Excessive pituitary release of ACTH unchecked by the negative feedback system may cause hyperpigmentation of the skin and mucous membranes. Basal plasma ACTH concentrations greater than 150 pg/mL (33 pmol/L), along with serum cortisol concentrations less than 5 µg/dL (138 nmol/L), are diagnostic of adrenal insufficiency.

The **ACTH stimulation test**, sometimes referred to as the *cosyntropin test*, assesses the functional capacity of the adrenal glands to synthesize cortisol. Cosyntropin (other names are Cortrosyn and Synacthen) is the N-terminal 24-amino acid sequence of ACTH, which includes the biologically active domain. Cosyntropin is a potent stimulator of cortisol secretion and has a very brief half-life and minimal antigenicity. The protocols for the 1-hour (also known as the “short Synacthen test”) and multiple-day ACTH stimulation test (or “long or prolonged Synacthen test”) are shown in **Boxes 41.1 and 41.2**, respectively.

A subnormal cortisol response in the cosyntropin stimulation test supports the diagnosis of primary adrenal insufficiency. A normal cortisol response to cosyntropin stimulation establishes that the adrenal cortex is capable of releasing cortisol and excludes primary adrenal failure.

Mineralocorticoid and glucocorticoid deficiency may occur in cases of primary adrenal insufficiency. In contrast, when ACTH deficiency (secondary or tertiary) is the cause of adrenal insufficiency, mineralocorticoid secretion is typically normal. In secondary and tertiary adrenal insufficiency, inadequate cortisol production may be due to destructive processes in the hypothalamus and/or pituitary that result

BOX 41.1 Protocol for the 1-Hour (Rapid) Cosyntropin Stimulation Test

Rationale

Administration of adrenocorticotrophic hormone (ACTH) to normal subjects causes a rapid rise in the serum cortisol concentration. Patients with adrenal destruction (e.g., Addison disease) show no change or an inadequate change in serum cortisol concentration after ACTH stimulation. Patients with atrophy of the adrenal cortex caused by exogenous glucocorticoid treatment or dysfunction of the pituitary gland or hypothalamus may show a slight rise in serum cortisol concentration but not one of normal magnitude.

Procedure

A morning (baseline) blood specimen is collected for determination of serum cortisol concentration; then 250 µg of cosyntropin is administered intramuscularly or intravenously. Blood specimens for serum cortisol determination are collected 30 and 60 min after injection.

Interpretation

A peak serum cortisol concentration of 18 to 20 µg/dL (500–550 nmol/L) or greater is a normal response. The expected change (delta) in cortisol concentration is 7 to 10 µg/dL (193–276 nmol/L). The peak cortisol value is more important than the incremental change. The incremental change may not be seen in patients who are tested at times of stress, when their adrenal output of cortisol is already maximally stimulated by endogenous ACTH. Also, it should be noted that clinical thresholds depend on the specific quantitative method used and may vary based on the reference material with which the analytical method is standardized.

in a decreased ability to secrete CRH (tertiary) or ACTH (secondary). However, the most common cause of tertiary insufficiency is long-term pharmacologic administration of glucocorticoids that suppress CRH, leading to a decrease in both ACTH release and cortisol secretion. Mineralocorticoid deficiency, hyperkalemia, and ACTH excess are not seen in secondary or tertiary adrenal insufficiency.

ACTH and cortisol concentrations are often not useful for establishing the diagnosis of secondary adrenal insufficiency. Episodic secretion and circadian variation result in ACTH and cortisol concentrations that overlap between normal subjects and individuals with secondary or tertiary adrenal insufficiency. Elevated basal plasma ACTH in a patient with an abnormal response to acute ACTH stimulation suggests primary adrenal failure, whereas low ACTH and normal or subnormal response to the short Synacthen test suggest a hypothalamic or pituitary disorder. Apart from the prolonged ACTH stimulation test (see **Box 41.2**), several dynamic tests can be used to distinguish primary from secondary and/or tertiary (central) causes of adrenal insufficiency.

In the **CRH test**, administration of ovine CRH stimulates ACTH secretion in normal subjects within 60 to 180 minutes. Individuals with tertiary disease produce elevations in ACTH following CRH administration, whereas individuals with secondary disease demonstrate only minimal changes in ACTH concentration.

BOX 41.2 Protocol for the Multiple-Day Adrenocorticotrophic Hormone Stimulation Test

Rationale

Multiple-day adrenocorticotrophic hormone (ACTH) stimulation testing for assessment of adrenal cortex function is required occasionally to evaluate the responsiveness of adrenal cortisol. A common situation is adrenal insufficiency treated with glucocorticosteroids before the cause has been established. Prolonged ACTH stimulation is used to distinguish primary from secondary and/or tertiary (central) causes of adrenal insufficiency.

Procedure

A total of 250 µg of cosyntropin is injected daily for 3 days. This is followed by an 8-h infusion of 250 µg of cosyntropin. Urinary free cortisol and serum cortisol are measured daily.

Interpretation

Serum cortisol values of 18 to 20 µg/dL (500–550 nmol/L) or greater exclude primary adrenal insufficiency. Glucocorticoid withdrawal would be required before secondary or tertiary adrenal insufficiency could be assessed. Little or no increase in cortisol secretion, even over successive days, is seen in primary adrenal failure. A progressive (staircase) rise in cortisol is seen over 2 to 3 days in adrenal insufficiency caused by pituitary or hypothalamic disease or corticosteroid suppression. Little or no response is seen in congenital adrenal hyperplasia caused by 21- and 17-hydroxylase deficiencies. Two- and 5-day variations of this test have been used in clinical practice. Also, it should be noted that clinical thresholds depend on the specific quantitative method used and may vary based on the reference material with which the analytic method is standardized.

In the **insulin-induced hypoglycemia stimulation test**, insulin is administered to stimulate CRH release by hypoglycemia; then plasma ACTH or cortisol concentrations are measured. This test involves a risk of hypoglycemia (obtundation, seizure, coma, and death) and should be performed only in highly monitored settings. The test should not be performed in patients with a seizure disorder or coronary artery disease. Venous access must be maintained for immediate administration of intravenous glucose if hypoglycemic complications occur.

The **metyrapone stimulation test** is an alternative although less commonly used indirect test of the function of the hypothalamic-pituitary-adrenal axis. It involves the administration of metyrapone, an inhibitor of the 11-beta-hydroxylase enzyme that converts 11-deoxycortisol to cortisol. Several protocols have been designed for metyrapone stimulation testing; a simple and relatively safe protocol for outpatient testing is described in [Box 41.3](#).

The evolution of Addison disease passes through sequential stages: (1) normal to low aldosterone and elevated renin concentrations, (2) a deficient cortisol response to ACTH injection, (3) increased basal ACTH concentrations, and (4) deficient basal cortisol and aldosterone secretion. Autoantibodies against the adrenocortical cytoplasmic antigens or steroidogenic enzymes precede the clinical appearance of Addison disease; however, their predictive power

BOX 41.3 Protocol for the Overnight Single-Dose Metyrapone Stimulation Test

Rationale

Metyrapone inhibits 11-beta-hydroxylase (CYP11B1), the enzyme that catalyzes the step immediately preceding cortisol synthesis. As the blood concentration of cortisol falls, the negative feedback effect is diminished, causing the release of adrenocorticotrophic hormone (ACTH) from the pituitary gland. The stimulatory effect of ACTH on the adrenal cortex leads to a rise in 11-deoxycortisol, the compound immediately preceding cortisol in the biosynthetic pathway.

Procedure

Metyrapone (30 mg/kg body weight) is given orally at midnight with milk or a snack (to delay absorption). At 08:00 h the following morning, blood is collected for measurement of 11-deoxycortisol, cortisol, and ACTH concentrations.

Interpretation

In normal subjects, 11-deoxycortisol increases from less than 1 µg/dL (29 nmol/L) to greater than 7 µg/dL (200 nmol/L) after metyrapone stimulation, and ACTH values exceed 150 pg/mL (33 pmol/L). No response or an impaired response may be observed in pituitary or hypothalamic disease combined with inadequate enzyme blockade (plasma cortisol >3 µg/dL [>83 nmol/L]) or with Cushing syndrome caused by adrenal tumors or nonendocrine ACTH-secreting tumors. Exaggerated responses may be seen in pituitary Cushing syndrome.

Note: This test is not recommended in cases of suspected Addison disease for fear that suppression of cortisol production might precipitate an Addisonian crisis. However, patients with Addison disease have an inadequate rise in 11-deoxycortisol in response to metyrapone.

is more evident in children than in adults. High-titer autoantibodies are also more predictive of progression to clinical disease. Approaches to the diagnosis of Addison disease are provided in the boxes titled “At a Glance: Investigation of Clinically Suspected Addison Disease” and “At a Glance: Investigation of Suspected ACTH Deficiency.”

Hypoaldosteronism

Deficient aldosterone production occurs in conditions other than Addison disease ([Table 41.2](#)). Isolated aldosterone deficiency accompanied by normal cortisol production is seen in patients with (1) inadequate production of renin by the kidney, which leads to secondary aldosterone deficiency (hyporeninemic hypoaldosteronism); (2) inherited enzyme defects in aldosterone biosynthesis; and (3) acquired forms of primary aldosterone deficiency (heparin therapy and after surgery). The resulting metabolic changes are hyperkalemia and hyponatremia, often with mild hyperchloremic metabolic acidosis. Mild or moderate volume depletion, often with postural or unprovoked hypotension, may also occur. Hyporeninemic hypoaldosteronism can be established by demonstrating failure of both plasma renin and aldosterone to increase in response to furosemide stimulation or upright posture.

AT A GLANCE

Investigation of Clinically Suspected Addison Disease

In cases of clinically suspected Addison disease—at the time of an addisonian crisis with compatible hyponatremia, hyperkalemia, and acidosis—cortisol concentrations less than 5 µg/dL (<138 nmol/L) are diagnostic. Otherwise further testing guided by the cortisol concentration is required (either the “stress” cortisol concentration or the average of two cortisol levels at 08:00 h). Further testing can include the 1-hour cosyntropin stimulation test or an insulin tolerance test (ITT). If the stress or average morning cortisol is 18 to 20 µg/dL (500–550 nmol/L) or greater, and the index of suspicion for Addison disease is low, no further testing is required. However, if the index of suspicion for Addison disease is high despite a stress or average 08:00-hour cortisol of 18 to 20 µg/dL (500–550 nmol/L) or greater, further testing should be considered.

As depicted, results of the 1-hour cosyntropin stimulation test or the ITT determine whether cortisol deficiency is excluded or, alternatively, a multiple-day cosyntropin stimulation test is indicated. Failure to demonstrate increased cortisol production in response to multiple-day cosyntropin stimulation supports the diagnosis of Addison disease (primary adrenal insufficiency). Not shown but still important: an elevated adrenocorticotrophic hormone (ACTH) in the setting of proven cortisol deficiency also supports the diagnosis of Addison disease. If cortisol rises in response to prolonged cosyntropin stimulation, ACTH deficiency is evident (e.g., central ACTH deficiency). Note that cortisol assay results will exhibit bias based on calibration materials and other assay characteristics, so decision thresholds may vary and should be established by the laboratory.

Patients with primary adrenal insufficiency almost always suffer from aldosterone deficiency in addition to cortisol deficiency. Tests to confirm aldosterone deficiency in such patients are not usually necessary because hyperkalemia and hypotension support the diagnosis of primary adrenal insufficiency in patients with cortisol deficiency, elevated ACTH, and hyperpigmentation.

Glucocorticoid Excess (Cushing Syndrome)

Endogenous Cushing syndrome is the result of autonomous excessive production of cortisol, leading to the classic symptoms that are characteristic of this disorder. Exogenous Cushing syndrome is caused by excessive glucocorticoid therapy. The common clinical picture includes truncal obesity, moon face, a “buffalo” hump on the upper back below the neck,

supraclavicular fat pads, purple striae, myopathy, hypertension, hirsutism, hypokalemic alkalosis, carbohydrate intolerance, disturbed reproductive function, and neuropsychiatric symptoms.

Endogenous disorders that cause hypersecretion of cortisol and Cushing syndrome may be classified as ACTH-dependent or ACTH-independent (Fig. 41.4).

ACTH-independent Cushing syndrome is caused by an adrenal adenoma or, less commonly by adrenal hyperplasia, leading to cortisol excess and suppressed pituitary secretion of ACTH. In bilateral micronodular hyperplasia (also called *primary nodular hyperplasia* or *adrenocortical dysplasia*), nodules 0.1 to 0.3 cm in diameter are observed that may be pigmented. The clinical outcome is similar to that of adrenal adenoma. Affected patients can display a spotty skin pigmentation pattern. In bilateral macronodular hyperplasia (also

AT A GLANCE

Investigation of Suspected Adrenocorticotrophic Hormone Deficiency

When adrenocorticotrophic hormone (ACTH) deficiency is suspected (e.g., central glucocorticoid deficiency), unless the 08:00-hour cortisol is 18 to 20 $\mu\text{g/dL}$ (500–550 nmol/L) or greater and the index of suspicion for ACTH deficiency is low, the 1-hour cosyntropin stimulation test, an insulin tolerance test, or an overnight metyrapone test is performed. (Note: Metyrapone is not currently available in the United States.) Normal responses to such tests rule out cortisol deficiency.

deficiency. An abnormal response to such testing triggers testing via the multiple-day cosyntropin stimulation test. If cortisol rises in response to prolonged cosyntropin stimulation, ACTH deficiency is evident. Failure to respond to prolonged cosyntropin stimulation indicates primary adrenal failure, and concurrent mineralocorticoid deficiency should be investigated. Note that cortisol assay results will exhibit bias based on calibration materials and other assay characteristics, so decision thresholds may vary and should be established by the laboratory.

called *massive macronodular hyperplasia* or *macronodular adrenal dysplasia*), large nodules ranging from 0.2 to more than 4 cm in diameter are evident.

Cushing disease is the pituitary-dependent form of Cushing syndrome. In Cushing disease, hypersecretion of ACTH by a pituitary microadenoma is the primary defect that leads to bilateral adrenal hyperplasia and cortisol overproduction. In ectopic ACTH syndrome, nonendocrine tumors develop the ability to secrete ACTH or modified ACTH, resulting in bilateral adrenal hyperplasia, unregulated cortisol secretion, and suppression of pituitary ACTH release. Rarely, ectopic secretion of CRH occurs. In ectopic ACTH syndrome, the clinical presentation is usually dominated by the presence of cancer, and the patient may not display classic clinical findings of Cushing syndrome, such as centripetal obesity.

Screening Tests for Cushing Syndrome

Cushing syndrome is an uncommon disorder, but many of the usual signs and symptoms of this syndrome are seen in

patients with normal adrenal function. The initial diagnosis of Cushing syndrome, particularly in mild or early disease, rests on laboratory evidence of excessive and autonomous cortisol production. Three simple screening tests are available for detecting Cushing syndrome—namely, 24-hour UFC, the 1-mg overnight dexamethasone suppression test, and salivary cortisol (see the following section titled Analytical Methods). The 2008 Endocrine Society guidelines recommend that two of the aforementioned three screening tests should be abnormal before proceeding to more definitive evaluation.

Under normal circumstances, less than 2% of secreted cortisol appears in urine as free cortisol. A **24-hour UFC** excretion of less than 50 $\mu\text{g/d}$ (1380 nmol/d) excludes the diagnosis of Cushing syndrome. Diagnostic accuracy is greater than 90%.

The **overnight low-dose dexamethasone suppression test** is a reliable and convenient screening test for Cushing syndrome. Elevated cortisol normally inhibits ACTH

TABLE 41.2 Causes of Primary Adrenal Insufficiency or Failure of Aldosterone Production**Endogenous Causes**

Autoimmune disease	Sporadic Autoimmune polyglandular syndrome type 1 (Addison disease, candidiasis, hypoparathyroidism, and primary gonadal failure) Autoimmune polyglandular syndrome type 2 (Addison disease, primary hypothyroidism, primary hypogonadism, diabetes, and pernicious anemia)
Inborn errors	Congenital adrenal hyperplasia Congenital adrenal hypoplasia (<i>DAX-1</i> mutation) Demyelinating disorders: adrenoleukodystrophies Childhood X-linked recessive adrenoleukodystrophy (ALD; Brown-Schilder disease) Neonatal autosomal recessive ALD X-linked recessive adrenomyeloneuropathy (sudanophilic leukodystrophy) Familial (isolated) glucocorticoid deficiency (degeneration of fasciculata-reticularis layers) Wolman disease (lysosomal acid lipase deficiency) Steroidogenic factor-1 mutations Mitochondrial forms of Addison disease (Kearns-Sayre syndrome) Smith-Lemli-Opitz syndrome (sterol delta-7-reductase mutations) Adrenocorticotrophic hormone resistance syndromes
Vascular disorders	Intra-adrenal hemorrhage (Waterhouse-Friderichsen syndrome): infection (caused by <i>Neisseria meningitidis</i> , <i>Pseudomonas aeruginosa</i> , <i>Haemophilus influenzae</i> , <i>Streptococcus pyogenes</i> , <i>Streptococcus pneumoniae</i>) or anticoagulants
Glandular infiltration	Neoplastic Leukemia, lymphoma, carcinoma of the lung, carcinoma of the breast Nonneoplastic Amyloid Hemochromatosis

Exogenous Causes

Infection	Granulomatous disease Tuberculosis, sarcoidosis, histoplasmosis, cryptococcosis, blastomycosis (North and South American), sporotrichosis, and coccidiomycosis Other infections Cytomegalovirus, human immunodeficiency virus
Drugs	Blockers of steroid synthesis: mitotane, aminoglutethimide, trilostane, ketoconazole, metyrapone Glucocorticoid receptor blockers: RU-486

Abdominal Irradiation

Bilateral adrenalectomy	Intra-adrenal thrombosis: renal vein thrombosis in neonates, heparin-induced thrombocytopenia, the antiphospholipid syndrome

Fig. 41.4 Endogenous Cushing syndrome can be classified as Cushing disease (*left*), ectopic adrenocorticotrophic hormone (ACTH) syndrome (*center*), or adrenal Cushing syndrome (*right*). ACTH is elevated in cases of Cushing disease and ectopic ACTH syndrome. ACTH is suppressed in cases of adrenal Cushing syndrome. CRH, Corticotropin-releasing hormone.

release from the pituitary gland, resulting in decreased production of cortisol and other ACTH-dependent steroids by the adrenal cortex. The integrity of this feedback mechanism is tested by administering a potent glucocorticoid such as dexamethasone and assessing ACTH secretion by measuring serum or urine cortisol concentrations. Dexamethasone does not significantly cross-react with cortisol immunoassays, so the secreted endogenous glucocorticoid, cortisol, can be distinguished from the exogenous glucocorticoid, dexamethasone. Several dexamethasone suppression tests are available for clinical use. Their protocols and interpretation are explained in [Boxes 41.4 through 41.6](#).

Differential Diagnosis of Cushing Syndrome

Hypercortisolism supports the diagnosis of endogenous Cushing syndrome. **Plasma ACTH** concentrations are low in patients with an adrenal tumor (<10 pg/mL; <2.2 pmol/L) and are normal or moderately elevated in patients with Cushing disease (generally >50 pg/mL; >11 pmol/L). Plasma ACTH is often markedly elevated in patients with nonendocrine ACTH-secreting tumors (ectopic ACTH syndrome) because the tumor source of the ACTH does not respond to negative feedback from cortisol. On the other hand, the ACTH-secreting pituitary adenoma of Cushing disease has an elevated set point for negative feedback; if the cortisol (or other glucocorticoid) concentration is elevated high enough, some measure of negative feedback will occur (e.g., 60% of patients with Cushing disease achieve ACTH and UFC suppression when treated with high-dose dexamethasone). Plasma ACTH concentrations greater than 300 pg/mL (66 pmol/L) usually suggest a nonendocrine ACTH-secreting tumor (ectopic ACTH syndrome).

BOX 41.4 Protocol for the Overnight Low-Dose Dexamethasone Suppression Test

Rationale

In low doses, dexamethasone, a synthetic glucocorticoid and cortisol analog, suppresses adrenocorticotrophic hormone (ACTH) and cortisol production in normal subjects but not in patients with Cushing syndrome.

Procedure

One milligram of dexamethasone is given orally between 22:00 and 24:00 h. Blood is collected for measurement of serum cortisol at 08:00 h the next morning.

Interpretation

In normal subjects, the serum cortisol concentration is suppressed to 2 µg/dL (55 nmol/L) or less after administration of 1 mg of dexamethasone. A postdexamethasone cortisol cutoff below 5 µg/dL (138 nmol/L) at 08:00 h is more sensitive for the detection of Cushing syndrome but less specific. Most patients with Cushing syndrome do not show adequate suppression, and cortisol concentrations at 08:00 h are usually 10 µg/dL (276 nmol/L) or greater. Serum cortisol above 2 µg/dL (55 nmol/L) may be seen in cases of stress, obesity, infection, acute or chronic illness, alcohol abuse, severe depression, oral contraceptive use, pregnancy, estrogen therapy, failure to take dexamethasone, or treatment with phenytoin or phenobarbital (which can enhance dexamethasone metabolism).

In a **CRH stimulation test**, plasma cortisol usually increases by 20% and plasma ACTH increases by 50% following CRH (1.0 µg/kg) administration. In cases of Cushing syndrome or ectopic ACTH secretion, glucocorticoid excess inhibits ACTH release in response to

BOX 41.5 Protocol for the Classic Low-Dose/High-Dose Dexamethasone Suppression Test**Rationale**

Normal subjects show a decline in urinary free cortisol (UFC) concentrations in response to low-dose dexamethasone. However, cortisol in patients with excess cortisol production, regardless of the cause, is not suppressed by low-dose dexamethasone. Patients with Cushing syndrome caused by an adrenocorticotrophic hormone (ACTH)-producing pituitary adenoma (e.g., Cushing disease from a corticotropinoma) may show suppression of cortisol with high-dose dexamethasone. Patients with Cushing syndrome from other causes—adrenocortical adenoma, carcinoma, or ectopic production of ACTH or corticotropin-releasing hormone (CRH)—usually do not demonstrate cortisol suppression with high-dose dexamethasone treatment.

Procedure

Twenty-four-hour urine samples are collected daily for 6 consecutive days. Free cortisol and creatinine are measured in each 24-h urine sample. UFC is regarded as a more specific measure of cortisol secretion than 17-hydroxycorticosteroids. The first 2 days provide baseline measurements of the excretion of cortisol. Dexamethasone 0.5 mg ("low-dose dexamethasone") is given orally every 6 h starting at 08:00 h on day 3 (for a total of eight doses: days 3 and 4). Dexamethasone 2.0 mg ("high-dose dexamethasone") is then given orally every 6

h starting at 08:00 h on day 5 (for a total of eight doses: days 5 and 6).

Interpretation

On the first 2 days, urinary excretion of cortisol (i.e., the baseline measurements) should be elevated in cases of Cushing syndrome. In cases of true endogenous Cushing syndrome, baseline UFC is usually at least two to three times higher than the upper limit of the reference interval. In normal individuals, baseline UFC excretion should be within the reference interval. Should a normal individual be stressed psychologically or physiologically and the baseline UFC is elevated, UFC on days 3 and 4 should be suppressed to less than 50% of the baseline level—that is, UFC suppression was achieved. All subjects with true endogenous hypercortisolism should not suppress on day 3 or 4. If suppression of UFC excretion occurs on days 5 and 6 (or on day 6), Cushing disease is diagnosed. However, not all cases of Cushing disease suppress on high-dose dexamethasone. Therefore failure to suppress on high-dose dexamethasone leaves three diagnostic possibilities: Cushing disease, adrenal adenoma (or, less commonly, adrenal carcinoma), and ectopic ACTH or CRH syndrome. Patients taking phenytoin or phenobarbital (or both) may metabolize dexamethasone more rapidly than normal subjects and may not show appropriate suppression.

BOX 41.6 Protocol for the High-Dose Overnight Dexamethasone Suppression Test**Rationale**

The rationale for this test is similar to the rationale for the multiple high-dose dexamethasone suppression test.

Procedure

Four milligrams of dexamethasone are given orally at 23:00 and 24:00 h. Blood is collected for measurement of plasma cortisol at 07:00 or 08:00 h the next morning, or 8 to 9 h after dexamethasone is given.

Interpretation

Most patients with Cushing disease show at least 50% suppression of the baseline cortisol concentration. If suppression is not greater than 50%, the test should be repeated with 8 to 24 mg of dexamethasone.

exogenous CRH. In about 90% of patients with Cushing disease, however, the CRH stimulation test produces a normal or exaggerated ACTH or cortisol response or both.

To differentiate pituitary-dependent Cushing disease from ectopic ACTH syndrome, a variation of the CRH stimulation test can be performed that measures ACTH in blood collected from the two inferior petrosal sinuses (IPSs). Blood specimens are collected from both right and left IPSs and from a peripheral vein (e.g., the inferior vena cava) at -30, 0, +2, +5, +10, and +30 minutes after intravenous administration of ovine CRH (1 µg/kg body weight) over 20 to 60 seconds. The ratio of the IPS concentration to the peripheral venous concentration of plasma ACTH is used to predict the location of excess ACTH secretion. An

IPS-to-peripheral vein ratio greater than 2.0 is consistent with a pituitary lesion (Cushing disease), whereas a ratio less than 1.4 to 1.7 supports the diagnosis of an ectopic ACTH syndrome.

In patients with Cushing syndrome, plasma DHEA-S is usually normal or moderately elevated (plasma DHEA-S ~500 µg/dL; 13.5 µmol/L). Patients with an adrenal adenoma usually have low (age-adjusted) plasma DHEA-S levels. Plasma DHEA-S in patients with nonendocrine ACTH-secreting tumors is normal to elevated. In patients with CAH, adrenal androgens are usually suppressed after administration of 0.75 mg/d of dexamethasone for 2 to 3 weeks, but suppression does not occur in patients with adrenal tumors and nonendocrine ACTH-secreting tumors.

AT A GLANCE

Investigation of the Causes of Hypercortisolism

When hypercortisolism is established, low-dose/high-dose dexamethasone suppression testing (see [Box 41.5](#) for protocol) can clarify the cause. Suppression of urinary free cortisol (UFC) on low-dose dexamethasone excludes cortisol excess. Suppression on high-dose dexamethasone establishes the diagnosis of Cush-

ing disease, but not all patients with Cushing disease are suppressed on high-dose dexamethasone. Lack of cortisol suppression on high-dose dexamethasone triggers the measurement of ACTH. Elevated ACTH (>50 pg/mL or >10 pmol/L) favors a central or ectopic source, whereas a suppressed ACTH (<10 pg/mL or <2.2 pmol/L) favors an adrenal lesion.

AT A GLANCE

Differentiation of Endogenous Cushing Syndromes

A suppressed ACTH (<10 pg/mL or <2.2 pmol/L) establishes the diagnosis of adrenal Cushing syndrome (i.e., a cortisol-secreting adrenal cortical tumor). If ACTH is elevated

(>50 pg/mL or >10 pmol/L), the pituitary is examined via inferior petrosal sinus sampling (and magnetic resonance imaging) to resolve Cushing disease versus ectopic ACTH syndrome.

Conditions That Mimic Cushing Syndrome

Alcohol abuse can induce a “pseudo-Cushing syndrome” that mimics the clinical and biochemical features of the disease. The abnormalities are reversible when alcohol consumption stops. HIV infection, anorexia nervosa, and depression are associated with elevated serum cortisol concentrations, and patients with these disorders may have abnormal low-dose, overnight dexamethasone suppression tests (morning cortisol ≥ 5 $\mu\text{g/dL}$; ≥ 138 nmol/L). Cortisol measurements at 24:00 hours may help to exclude Cushing syndrome in these circumstances. However, the clinical features of Cushing syndrome patients with HIV and anorexia nervosa are not typical. Measurement of UFC and plasma cortisol with the dexamethasone suppression test improves the predictive value in the diagnosis of both Cushing syndrome and depression. In patients with depression, it is best to repeat testing after the depression has been treated.

Obese patients may also display clinical features that mimic Cushing syndrome. Truncal obesity, striae, and enhanced excretion of 17-hydroxycorticosteroids (17-OHCS) are features of Cushing syndrome that occur in normal obese subjects. However, UFC is normal in obese individuals and can effectively differentiate normal subjects from those with true Cushing syndrome. Likewise, 48 hours of low-dose dexamethasone (0.5 mg orally every 6 hours) should suppress UFC excretion by more than 50% in obese patients.

Congenital Adrenal Hyperplasia

CAH is the most common cause of adrenocortical insufficiency in newborns. However, CAH is discussed under adrenal hormone overproduction syndromes because CAH commonly leads to overproduction of adrenal androgens. CAH presents a mixed picture of cortisol deficiency (hypo-function) and adrenal androgen overproduction (hyper-function). Rarely, adrenal hemorrhage from trauma or sepsis causes adrenal failure in newborns, but CAH is the most common cause of adrenal failure in this age group.

CAH results from loss-of-function mutations in adrenocortical enzymes responsible for cortisol synthesis. With insufficient cortisol production, ACTH concentrations increase and stimulate fetal adrenal hyperplasia in utero. About 95% of CAH cases result from 21-alpha-hydroxylase deficiency, and 11-beta-hydroxylase deficiency accounts for most of the remaining cases. Other causes of CAH are very rare. The incidence of 21-alpha-hydroxylase CAH in western societies varies from 1 in 5000 to 15,000 live births. The incidence of 11-beta hydroxylase deficiency is approximately 1 in 100,000. Diagnosis of both conditions depends on finding elevated concentrations of 17-alpha-hydroxyprogesterone (17-OHP) in plasma or serum. Newborn screening for 21-alpha-hydroxylase and 11-beta-hydroxylase deficiency is standard practice in the United States and many other countries.

The metabolic block in cortisol biosynthesis leads to an accumulation of precursors, which are shunted into production of adrenal androgens. Measurements of the precursor steroids in blood help identify the specific enzyme defect and

to monitor the response to cortisol replacement therapy. A partial block may cause marked or subtle clinical manifestations, whereas a complete enzyme block can be fatal without treatment. The closer the enzyme block to the final cortisol product, the less life-threatening the symptoms.

Because 21-alpha-hydroxylase and 11-beta-hydroxylase CAH produce elevations of adrenal androgens (DHEA and androstenedione) in utero, virilization of the external genitalia of a female fetus occurs, producing sexual ambiguity (ambiguous genitalia). Only rarely does CAH lead to inadequate male sexual development.

Cortisol deficiency in affected individuals leads to malaise, failure to thrive, hypoglycemia, and vascular instability. In approximately half of infants afflicted with 21-alpha-hydroxylase deficiency, insufficient aldosterone production can cause hyponatremia, hyperkalemia, acidosis, dehydration, and hypotension. In its most severe form, the “salt losing” 21-alpha-hydroxylase deficiency presents clinically at 10 to 14 days of age with addisonian crisis and a high mortality if left untreated. The non-salt-losing form of this disease is customarily referred to as *simple virilizing* 21-alpha-hydroxylase deficiency.

In males, adrenal androgen overproduction in 21-alpha-hydroxylase deficiency produces precocious pseudopuberty and some degree of hyperpigmentation of the male external genitalia during infancy or childhood; in the neonatal period they present with salt-losing crisis. Untreated, postnatal males will experience early-onset puberty with advanced secondary sex characteristics, and despite an early acceleration in their growth rate and tall stature, they may ultimately suffer from short stature because of premature closure of their epiphyses. The more profound the defect in cortisol biosynthesis, the greater the degree of precocious pseudopuberty in males.

Because the conversion of DOC to corticosterone in the **zona glomerulosa** is predominantly catalyzed by CYP11B2, mineralocorticoid levels are not affected in 11-beta-hydroxylase (CYP11B1) deficiency. Also, elevated ACTH may have some effect in stimulating DOC production, and DOC may be elevated in 11-beta-hydroxylase deficiency. Whereas females with 11-beta-hydroxylase deficiency have ambiguous genitalia and males undergo precocious pseudopuberty, salt loss does not occur. Thus electrolyte disturbances and acidosis do not occur, nor does addisonian crisis in the newborn period or later.

Once a child is diagnosed with CAH, fetal DNA testing in subsequent pregnancies allows prenatal diagnosis of CAH, which can prompt maternal treatment with high-dose dexamethasone to suppress excess fetal adrenal androgen production. This treatment prevents ambiguous genitalia in females and the androgenic effects of excess fetal adrenal androgens on the fetal brain.

A late-onset or attenuated (nonclassical) form of 21-alpha-hydroxylase deficiency can occur in female adolescents, presenting as hirsutism or virilization associated with menstrual irregularities, oligomenorrhea, amenorrhea, and a polycystic ovary-like syndrome. Late-onset 21-alpha-hydroxylase deficiency CAH is much milder than the classical prenatal virilizing form of 21-alpha-hydroxylase deficiency.

Early-morning 17-OHP or random androstenedione measurements are used to assess the response to glucocorticoid replacement in CAH patients. With adequate glucocorticoid replacement, 17-OHP or androstenedione should not exceed the upper limit of the reference interval for age and sex.

17-Alpha-hydroxylase deficiency is a rare cause of CAH. *CYP17* mutations influence sex steroid production of both androgens and estrogens in males in utero and in females at the time of puberty. Absence of 17-alpha-hydroxylase activity impedes cortisol biosynthesis and, as a result, ACTH concentrations increase. Elevated ACTH stimulates mineralocorticoid overproduction in the zona glomerulosa. Salt and water retention suppress aldosterone release. Salt-wasting is not present in 17-alpha-hydroxylase deficiency; in fact, excessive salt and water retention from excessive mineralocorticoid activity frequently produces hypertension in childhood. When sex steroids are not produced, genetic males will appear as sexually ambiguous or phenotypic females with delayed puberty. The uterus, fallopian tubes, and upper third of the vagina are absent because of anti-Müllerian hormone secretion by the Sertoli cells of the testes. Virilization of the external genitalia is reduced or absent in males in utero because of the block in testosterone biosynthesis. In genetic females, genitalia are not ambiguous; however, puberty and menses will not occur spontaneously because estrogens will not be produced.

The least common but most severe form of CAH is not an enzyme deficiency but a disorder involving **steroidogenic acute regulatory protein (StAR)**. StAR mediates the transport of cholesterol across the mitochondrial membrane. A deficiency of StAR is potentially lethal and causes congenital lipoid adrenal hyperplasia when the adrenal glands are saturated with cholesterol and cholesterol esters that are not further metabolized. In this disorder, deficiencies of all steroid hormones are present. Failure of androgen production in males results in ambiguous genitalia.

Functioning Adrenocortical Tumors

Plasma DHEA-S, DHEA, androstenedione, and testosterone concentrations are elevated in patients with virilizing adrenal adenomas and Cushing syndrome. The plasma concentrations of DHEA may also be elevated in women with virilizing ovarian tumors. Aldosterone-producing adenomas, referred to as *Conn syndrome*, are typically small microadenomas found in the zona glomerulosa that hypersecrete aldosterone, producing a syndrome characterized by low renin hypertension.

Adrenal carcinomas are rare, with an incidence of only 1 per million; they are usually larger than 4 cm and may cause only virilization, without the typical features of Cushing syndrome. Adrenal carcinomas are more common in women than in men by a 2.5:1 ratio. Most adrenal carcinomas are functional, producing glucocorticoids alone or glucocorticoids and androgens. Plasma DHEA-S, DHEA, and androstenedione concentrations are markedly elevated in patients with functional adrenal carcinomas. Peripheral conversion of adrenal androgens to testosterone results in hirsutism and

virilization. DHEA-S concentrations can exceed 1000 µg/dL (27 µmol/L) in patients with adrenal carcinoma and usually are diagnostic for this malignancy. High-dose glucocorticoids do not suppress elevated androgen production.

Feminizing adrenocortical carcinomas are rare. These tumors result in elevated plasma DHEA-S, DHEA, androstenedione, estrone, and estradiol concentrations. Gynecomastia and sexual dysfunction occur in males; precocious pseudopuberty occurs in females. Dexamethasone does not suppress cortisol production in these cases.

Nonfunctioning Adrenocortical Tumors

Approximately 2% of the population have an adrenal tumor; most of these tumors are nonfunctioning and benign and are called *incidentalomas* (or *incidentomas*). The tumors are usually found when computed tomography (CT) or magnetic resonance imaging (MRI) scans of the abdomen are performed; these easily detect tumors 1 cm in diameter or 5 g in weight. No virilizing tumor smaller than 1 cm in diameter has been reported. Carcinomas usually weigh more than 30 g.

Mineralocorticoid Excess (Hyperaldosteronism)

Primary **hyperaldosteronism**, also known as *Conn syndrome*, is a syndrome caused by aldosterone excess. In primary hyperaldosteronism, excessive aldosterone production originates within the adrenal gland, whereas in secondary hyperaldosteronism, a stimulus outside the adrenal gland activates the renin-angiotensin system. (Note: The term *aldosteronism* is often used synonymously with *hyperaldosteronism*.) The interaction of renin, angiotensin, and aldosterone is important in the regulation of extracellular fluid volume and blood pressure, the balance of sodium and potassium ions, and acid-base balance.

Primary Hyperaldosteronism

Primary hyperaldosteronism is characterized by elevated plasma aldosterone and suppressed renin release, along with hypertension and hypokalemic alkalosis. Historically it was believed that no more than 1% of hypertensive patients had primary hyperaldosteronism. However, results from a 2007 study identified primary hyperaldosteronism in 10% or more of cases otherwise defined as “essential” hypertension.

Overproduction of aldosterone may be due to autonomous and inappropriate secretion of aldosterone by (1) an adenoma of one adrenal gland (aldosterone-producing adrenal adenoma [APA], or Conn syndrome), (2) hyperplasia of aldosterone-producing cells in both glands (bilateral idiopathic adrenal hyperplasia [IAH]), (3) an aldosterone-producing adrenal carcinoma, or (4) a rare familial condition known as *glucocorticoid-suppressible hyperaldosteronism* (familial hyperaldosteronism type 1). There are other rarer familial causes of hyperaldosteronism.

Clinical features of primary hyperaldosteronism are generally related to the consequences of aldosterone overproduction. Increased retention of sodium, expansion of extracellular fluid volume, and increased tubular secretion of potassium and hydrogen ions are the cardinal manifestations.

Hypokalemic alkalosis results from excessive renal excretion of potassium and hydrogen ions. Sodium retention causes a modest expansion of extracellular fluid volume along with an increase in arterial blood pressure.

Elevated aldosterone and low renin activity are key diagnostic features in primary hyperaldosteronism. Other factors influence the secretion of renin and aldosterone, however, and these factors must be considered before further laboratory evaluation. Drugs such as ACE inhibitors, beta blockers, and spironolactone alter renin release, and patients should be withdrawn from these medications for several weeks before the plasma aldosterone-to-renin ratio is determined. When patients with suspected primary hyperaldosteronism are evaluated, it is helpful to compare ambulatory plasma renin activity (PRA) to the patient's urinary sodium excretion or stimulate renin production with a potent diuretic such as furosemide.

Unusual conditions that suggest aldosterone excess but do not involve disorders of renin, angiotensin II, or aldosterone include apparent mineralocorticoid excess (AME), type 1 pseudohyperaldosteronism (Liddle syndrome), type 2 pseudohyperaldosteronism, and cortisol resistance.

Secondary events that disrupt normal renin release are much more common than primary abnormalities of renin secretion (Table 41.3). For example, a decrease in effective plasma volume or mean arterial pressure from sudden blood loss leads to release of renin from the juxtaglomerular cells of the kidneys; more angiotensin I and angiotensin II are formed, and production of aldosterone by the adrenal glands is increased. Angiotensin II promotes sodium reabsorption in the PCT, increases thirst, and increases release of ADH and catecholamines. Overall, angiotensin II promotes retention of sodium and water, an increase in extracellular volume, hydrogen ion wasting, and a decrease in the serum potassium due to enhanced renal potassium excretion. Secondary hyperaldosteronism is common in patients with congestive heart failure, nephrotic syndrome, cirrhosis of the liver, other hypoproteinemic states, or conditions that chronically deplete plasma volume.

Non-Mineralocorticoid-Deficient Causes of Urinary Sodium Loss

Bartter syndrome is a consequence of sodium loss from dysfunction of the ascending, thick loop of Henle or the DCT. Sodium loss evokes a compensatory hyperaldosteronism with increased renin and aldosterone, producing hypokalemia and alkalosis. Bartter syndrome in adults may be asymptomatic, but in infants it can manifest as failure to thrive, salt craving, polyuria, and polydipsia. A variety of genetic mutations cause urinary sodium loss leading to secondary hyperaldosteronism with hypokalemia and alkalosis.

In pseudohypoaldosteronism (PHA; aldosterone resistance), clinical symptoms of hypoaldosteronism are concurrent with elevated concentrations of aldosterone. PHA may be classified as renal type 1, multiple target organ defects type 1, early childhood hyperkalemia type 1, Spitzer-Weinstein syndrome (adolescent hyperkalemic syndrome), subtype 3

TABLE 41.3 Causes of Functional Hypermineralocorticoidism

Hyperaldosteronism	Primary (hyporeninemic) • Aldosterone-producing adenoma • Aldosterone-producing carcinoma • Idiopathic adrenal hyperplasia • Unilateral adrenocortical hyperplasia • Glucocorticoid remediable hypertension Secondary (hyperreninemic) • Renin-secreting tumors • Renovascular hypertension • Compensatory (nephrosis, cirrhosis, CHF) • Bartter syndrome • Gitelman syndrome
Deoxycorticosterone (DOC) excess	DOC-secreting adrenal adenoma 11 Beta-hydroxylase (CYP11B1) deficiency 17-Hydroxylase (CYP17) deficiency
Glucocorticoid excess	Cushing syndrome Cortisol resistance
Increased mineralocorticoid action without circulating mineralocorticoid excess	Apparent mineralocorticoid excess (HSD11B2 deficiency) Acquired HSD11B2 inhibition (glycyrrhizic acid induced) • Liddle syndrome (type 1 pseudohyperaldosteronism) • MR gain-of-function mutation (type 2 pseudohyperaldosteronism)

CHF, Congestive heart failure; MR, mineralocorticoid receptor.

RTA (renal tubular acidosis, IV type 2 PHA), and Gordon syndrome (mineralocorticoid-resistant hyperkalemia, chloride shunt syndrome type 2 PHA).

LABORATORY EVALUATION OF ADRENOCORTICAL FUNCTION

Laboratory evaluation of adrenal cortical function centers on the measurement of cortisol, the primary corticosteroid; aldosterone, the primary mineralocorticoid; and the sex hormones, of which the adrenal cortex is a secondary source. Underproduction or overproduction of cortisol and aldosterone produces characteristic clinical syndromes, and genetic defects in steroid hormone biosynthesis produce abnormalities in sex hormone concentrations associated with clinical symptoms as well. Therefore measurement of steroid hormones produced in the adrenal cortex is essential to the clinical diagnosis of a variety of endocrine disorders.

Steroid hormones such as those produced in the adrenal cortex share considerable structural similarity based on their terpenoid sterane core, which is modified by functional groups at various locations on the tetracyclic backbone. In general, steroids are lipophilic compounds, but they require additional modification—esterification to fatty acids—to facilitate their transport across cellular membranes. Transport in the bloodstream typically involves carrier

proteins (e.g., transcortin, SHBG). These properties influence the choice of analytical methods for measuring steroid hormone concentrations; most procedures begin with enzymatic or chemical hydrolysis of steroid esters and displacement of the steroid from carrier proteins through addition of a protein-binding agent such as 8-anilino-1-naphthalene-sulfonic acid (ANS) or salicylate. Photometric and fluorometric measurements of steroids lack specificity unless extraction and purification procedures are used. Immunoassays are practical for the measurement of steroid hormones and are widely available on a variety of automated chemistry platforms, but cross-reactivity with structurally similar hormones often results in bias between various immunochemical methods. Endogenous interferences also occur—for example, near the time of birth, when placental steroid concentrations are very high. Steroids can be extracted into organic solvents and analyzed by chromatographic methods coupled with mass spectrometric detection, which provides sensitive and specific quantitative results for these compounds. In contrast to peptide hormones, most of which exhibit considerable heterogeneity as the result of posttranslational modifications, steroid hormones constitute a relatively homogenous group of compounds that are calibrated against gravimetrically validated synthetic standards.

Choice of Specimen

Steroid hormones have been measured in urine, blood, saliva, and hair. The choice of specimen depends on the application. For clinical assessment of adrenal function, blood (plasma) measurements are convenient, but conditions that cause the binding protein concentration to increase can produce clinically irrelevant elevations in the total cortisol concentration. Urinary concentrations are helpful in determining time-integrated hormone production and provide useful estimates of free hormone concentrations in blood if an appropriately timed urine specimen collection is available. Measurement of steroid hormones in saliva has been proposed as an alternative to urinary hormone assays to estimate free hormone concentrations in blood, the principal advantage being ease of collection. Hair analysis, while not widely used, may be useful for assessing adrenal hormone production over an extended time.

Urine

Urinary concentrations of a hormone or its metabolites provide an approximation of the amount secreted over the time the urine is collected, typically 24 hours. Thus urinary hormone or metabolite measurements are useful when the hormone has a very short biological half-life and/or its secretion is pulsatile. Timed urine collections suffer variability associated with factors such as completeness of collection and impaired renal function. Urinary metabolites may reflect only a fraction of the active steroid hormones; these metabolites, in turn, may be affected by metabolic disease as well as diet and medications. Despite these limitations, UFC and measurement of urinary free estradiol, estrone, and testosterone are most useful for estimating the rates at which these

steroids are produced and are not affected by variations in the concentrations of proteins that bind hormones, such as CBG and albumin.

Blood

Circulating concentrations of steroids in the blood provide the most direct measure of endocrine activity mediated by these hormones. Immunoassays and chromatographic methods have been developed for measuring most of the clinically relevant steroids in blood; mass spectrometric methods for steroid profiling have recently been reviewed. Provocative testing (stimulation and suppression tests, discussed earlier) may require blood samples because of the rapid changes that occur in hormone activity after stimulus or suppression. Many steroid hormones are released in a pulsatile or rhythmic fashion, so their concentrations in isolated blood specimens should take these variables into account.

Saliva

Most steroids of clinical interest have been measured in saliva, and for some steroids—such as cortisol, estriol, testosterone, and progesterone—salivary concentrations appear to correlate with the free hormone concentration in plasma. For other steroids (e.g., 17α -hydroxyprogesterone, estradiol, aldosterone), the clinical usefulness of salivary measurements has not been established. Measurement of steroids in saliva is attractive because specimens are simple to collect; this consideration is particularly important in pediatric patients.

Hair

Hair grows at an average rate of 1 cm per month; therefore it can reveal historical blood concentrations of substances that are deposited in the forming hair matrix. Several reports describe methods for measuring steroid hormones in hair. These methods have shown potential as diagnostic tools but will require additional validation studies before they can be applied generally.

Basal Peptide and Steroid Hormone Concentrations

Concentrations of adrenal mineralocorticoids and elements of the renin-angiotensin system are routinely measured in body fluids by various immunoassay and mass spectrometric methods. In healthy subjects, consuming a low-sodium diet, maintaining an upright posture, and using diuretics all increase plasma aldosterone concentrations, whereas consuming a high-sodium diet and lying in the supine position decrease aldosterone secretion. Standardized procedures for obtaining blood and urine specimens are required for proper interpretation of test results. It is useful to interpret aldosterone concentrations together with urinary sodium excretion because salt intake can profoundly influence the aldosterone concentration. Normally the aldosterone concentration is inversely proportional to the urinary sodium concentration.

Because it has enzymatic activity, renin can be measured either by its activity or its mass, and both methods are available; a MALDI-TOF method for measuring renin was recently

described. PRA is measured by its stimulation of angiotensin I release, which is measured using immunoassay techniques.

Renin release is controlled by many physiologic factors. Consuming a low-sodium diet, maintaining an upright posture, and using diuretic medications all serve to increase renin release (causing a rise in aldosterone) and should be controlled or eliminated before testing of the renin-angiotensin-aldosterone axis is begun. Because plasma renin varies with sodium balance, it is helpful to interpret ambulatory renin measurements together with urinary sodium excretion. An inverse relationship exists (similar to aldosterone), allowing the identification of low-, normal-, and high-plasma renin groups from a nomogram.

Even when time of sampling, posture, drug intake, and diet are controlled, it is often difficult to identify disorders of mineralocorticoid secretion on the basis of basal hormone concentrations alone. A variety of dynamic tests have been developed to assess hypersecretion or hyposecretion of aldosterone and renin.

The diagnosis of adrenal insufficiency in critically ill patients is controversial. On one hand, if the diagnosis of cortisol and/or aldosterone deficiency is missed and replacement therapy is not initiated, the patient can die of an Addisonian crisis, as might occur in **Waterhouse-Friderichsen syndrome** (bilateral adrenal hemorrhage). However, inappropriate administration of cortisol in a septic patient can produce immunosuppression that may be fatal. Some investigators believe that free cortisol measurements are diagnostically helpful because CBG concentrations frequently decline from liver disease or acute malnutrition, which could lead to the misdiagnosis of cortisol deficiency. In equivocal cases of adrenal insufficiency, some authors caution that a single low cortisol concentration should not be used to make the diagnosis of cortisol deficiency. Just as free testosterone can be estimated from total testosterone and SHBG concentrations, a free cortisol index has been described as the simple ratio of total cortisol to CBG.

Free Versus Bound Steroids

Many hormones bound to carrier proteins circulate in the blood. Hormone-binding proteins serve two functions: they solubilize lipophilic compounds such as steroid hormones to facilitate their transport in the primarily aqueous circulatory environment and buffer the concentration of free active hormone in tissue. For hormones that are highly protein-bound, the concentration of the binding protein is the principal determinant of the total concentration of hormone. Therefore total hormone concentrations vary significantly, whereas the free, active hormone concentration remains within physiologically appropriate limits. Measurement of free (unbound) hormone concentrations provides the best indicator of hormone activity, but analytic methods that isolate free hormone concentrations without disrupting the free/bound equilibrium are difficult to design. Antibodies that recognize steroid hormones may have binding affinities that compete with binding proteins and detect significant portions of the bound fraction. Preanalytical methods to separate bound and free

fractions often disrupt the physiologic equilibrium between bound and free hormone. Urinary and salivary steroid hormone measurements have been widely used to estimate free hormone concentrations.

Analytical Methods

Sensitive immunoassays for measuring steroid hormones have been available for decades and include most, if not all, of the common labels (radioisotope, enzyme, fluorescent, chemiluminescent) and immunoassay designs (heterogeneous, homogeneous, competitive, noncompetitive). However, analytical methods involving liquid chromatography coupled with tandem mass spectrometry are becoming more common.

Measurement of Cortisol

Approximately 90% of circulating cortisol is bound to plasma proteins, primarily to CBG. Cortisol also binds weakly to albumin. The concentration of CBG in the plasma rises in hyperestrogenic states, including pregnancy and oral contraceptive use; therefore total cortisol in serum is increased in these conditions, although free cortisol remains normal. Analytic methods involving extraction or protein precipitation estimate the free and protein-bound cortisol in the circulation, but immunoassays for direct measurement of cortisol have mostly replaced extraction/chromatographic methods for routine cortisol determinations.

Chromatographic methods. Gas chromatography (GC), thin-layer chromatography (TLC), and high-performance liquid chromatography (HPLC) have been used to measure cortisol. GC and HPLC coupled to mass spectrophotometric detectors (GC/MS, LC/MS, and LC/MS-MS) provide the most specific methods for measuring corticosteroids. Cortisol methods based on capillary electrophoresis are also available. All of these methods demonstrate high specificity for cortisol but have relatively low throughput and require sample preparation steps before analysis. For example, most HPLC methods require preanalytical extraction of cortisol with solid-phase extraction columns or liquid-liquid extraction prior to separation and detection by reversed- or normal-phase HPLC and a fluorescence or ultraviolet absorption detector. A reference method for serum cortisol using isotope dilution GC/MS has been proposed.

Liquid chromatography–tandem mass spectrometry (LC/MS-MS) methods are becoming increasingly common. Liquid chromatography has the advantage of not requiring volatile derivatives, so specimen preparation can be vastly simplified. LC/MS-MS methods have been developed to measure cortisol, cortisone, and other corticosteroids. LC/MS-MS appears poised to become the method of choice for corticosteroid profiling owing to its greater analytical specificity.

Immunoassay. In routine laboratory practice, automated immunoassays are the most common methods used for measuring cortisol in serum and urine, and they are widely available on various automated immunoassay platforms. Most cortisol immunoassays in routine use are heterogeneous competitive-binding assays that do not require extraction of

steroids prior to analysis. Cortisol is displaced from CBG and other endogenous binding proteins by protein-binding agents such as ANS or salicylate, low pH, or heat treatment. The efficiency of cortisol displacement from proteins by agents such as ANS may be influenced by the concentration of binding proteins in the specimen. For example, the amount of ANS that is adequate for plasma obtained from healthy men and nonpregnant women may be insufficient to displace cortisol from CBG in pregnancy when CBG concentrations are elevated.

Most contemporary automated cortisol immunoassays use nonisotopic labels. Enzyme labels used in these immunoassays include horseradish peroxidase, alkaline phosphatase, or β -galactosidase, and enzyme activity has been measured using photometric, fluorescent, or chemiluminescent substrates. Nonenzymatic approaches typically involve fluorescent and chemiluminescent labels, and these are the most common methods currently in use. Both heterogeneous and homogeneous designs have been developed. Most current heterogeneous immunoassays for cortisol involve chemiluminescent labels and magnetic separation. Homogeneous immunoassays for cortisol include the enzyme-multiplied immunoassay technique and the cloned enzyme donor immunoassay. These assays do not require separation of bound and free fractions. Most immunoassay methods for cortisol are available on fully automated immunochemistry platforms.

Specimen collection and storage. Cortisol can be measured in serum, heparinized plasma, or ethylenediaminetetraacetic acid (EDTA) plasma, although some methods recommend against using EDTA plasma because of assay interference. In serum or plasma specimens, cortisol is stable for 7 days at room temperature or refrigerated and is stable for 3 months frozen at -20°C .

Comments. Blood cortisol concentrations parallel ACTH concentrations, with episodic and diurnal minima and maxima observed throughout the day. Serum cortisol concentrations are highest in the early morning hours and vary between 7 and 25 $\mu\text{g/dL}$ (193 and 690 nmol/L) between 04:00 and 12:00 hours. Late afternoon concentrations are about half the morning concentrations and are frequently less than 5 $\mu\text{g/dL}$ (138 nmol/L) between 22:00 and 02:00 hours. A midnight cortisol less than 5 $\mu\text{g/dL}$ (138 nmol/L) is considered normal. Serum cortisol combined with plasma ACTH improves the diagnostic accuracy of basal values, although ACTH concentrations display even greater variation throughout the day than cortisol concentrations.

Increased cortisol is associated with stress, glucocorticoid therapy, pregnancy, depression, hypoglycemia, and hyperthyroidism. No significant difference in cortisol concentrations has been observed between men and women, and reference intervals for cortisol are not age-dependent. The half-life of cortisol in the circulation is approximately 60 minutes, so concentrations of this hormone in blood can change rapidly. In newborns, a transient rise in cortisol occurs immediately after delivery, but after 12 to 48 hours, cortisol declines to concentrations below umbilical cord blood concentrations; it then increases to a stable reference interval by about 1 week of

age. Renal failure does not directly affect serum cortisol, but metabolites that are not cleared in the urine have the potential to cross-react with immunoassays, causing overestimation of blood cortisol concentrations. Extraction of cortisol into an organic solvent may eliminate interference from hydrophilic metabolites.

Measurement of Free Cortisol

Free or unbound cortisol is the biologically active form of the circulating hormone; its concentration is buffered by the large reservoir bound to its transport proteins: CBG and albumin. Various methods have been developed to measure the free fraction of cortisol in serum, including ultrafiltration, equilibrium dialysis, and gel filtration, but these assays are technically demanding and expensive, and they are not in general use. Algorithms have been suggested for estimating the free cortisol concentration on the basis of CBG and albumin concentrations. Measurement of urinary cortisol provides an estimate of the free hormone concentration and has been considered the gold standard screening test for Cushing disease, although salivary cortisol has been recommended as the first-line screening test. Approximately 2% of total cortisol is excreted into the urine, and urinary cortisol may be used as a screening test for cortisol hypersecretion.

Measurement of salivary cortisol (or oral fluid) is a practical and convenient way to assess the free hormone concentration. Salivary cortisol reflects the concentration of free cortisol in blood because CBG and albumin, the primary cortisol-binding proteins, do not appear in saliva. Most immunoassay kits for total serum cortisol can be used for the measurement of cortisol in saliva; extraction is not required because saliva contains virtually no cortisol-binding proteins or other cortisol metabolites. The glycoproteins in saliva can be precipitated by freezing and thawing, followed by centrifugation, producing a clear fluid that is free of protein interference. At this point, the challenge in measuring salivary cortisol involves achieving an adequate lower limit of detection because the concentration of cortisol in saliva is less than in serum or plasma. Typical salivary cortisol concentrations in healthy individuals are 0.14 to 1.0 $\mu\text{g/dL}$ (4 to 28 nmol/L) at 07:00 hours and 0.07 to 0.22 $\mu\text{g/L}$ (2 to 6 nmol/L) at 22:00 hours.

Measurement of Aldosterone

Measurement of aldosterone is technically challenging because the concentration of this hormone in blood is very low, nearly one-thousandth that of the cortisol concentration. Immunoassays for measuring aldosterone in blood and urine are available.

The cross-reactivity of aldosterone antibodies with other adrenal steroids (e.g., DOC, corticosterone) is relatively low ($<0.01\%$). Nevertheless, the concentration of potentially cross-reacting steroids sometimes is very high, requiring some purification of aldosterone before measurement. Unconjugated plasma aldosterone will extract into an organic solvent and can be isolated by chromatography. The addition

Fasiculata and reticularis

Fig. 41.5 Urinary metabolites generated from steroids involved in cortisol and adrenal androgen synthesis.

of tritiated aldosterone as an internal standard corrects for incomplete extraction in radioimmunoassay methods for aldosterone. In urine, unconjugated steroids are first extracted into an organic solvent such as ethyl acetate or methylene chloride after acid hydrolysis of the conjugates. The solvent is evaporated, and the dried extract is reconstituted in a buffer before analysis. Whether the specimen requires purification depends on the diagnostic kit being used and the type of patient being evaluated. For example, specificity is not a significant concern in hypertensive adults without adrenal disease, whereas greater specificity may be needed for newborns and young infants, patients with adrenal disease, and pregnant women, in whom high concentrations of potentially interfering steroids are likely.

Measurement of 17-Hydroxyprogesterone

Measurement of serum or plasma 17-OHP can be used to diagnose almost all cases of CYP21 deficiency, the most common cause of CAH. In this disorder, 17-OHP concentrations may reach several hundred times the upper limit of normal.

Radioimmunoassays for 17-OHP that use antibodies against 17-hydroxyprogesterone-3-carboxymethyloxime-BSA are available; these methods can be used with serum, plasma, saliva, and amniotic fluid. Monoclonal antibody-based methods have also been described. In addition to radioiodinated tracers, nonisotopic labels used in 17-OHP immunoassays include enzymes with photometric, fluorescent, or chemiluminescent substrates, and fluorescence-based immunoassays using fluorescein or streptavidin-europium labels, and chemiluminescent labels. Despite the use of highly specific antisera, most immunoassays are susceptible to interference by other corticosteroids that may be present in neonatal and infant plasma specimens. Methods for measuring 17-OHP in serum by GC/MS and LC/MS-MS are also available.

Measurement of 11-Deoxycortisol

Serum or plasma 11-deoxycortisol (compound S) measurements are used to detect 11 β -hydroxylase (or C-11 hydroxylase) deficiency or as part of the metyrapone stimulation test. Metyrapone inhibits the 11 β -hydroxylase enzyme, and a 40- to 80-fold increase in plasma 11-deoxycortisol is observed after metyrapone stimulation in patients with normal pituitary-adrenal reserve. As a consequence, analytical methods for 11-deoxycortisol in metyrapone stimulation tests do not require particularly high sensitivity.

Nonisotopic methods for measuring 11-deoxycortisol in serum have been described, including enzyme immunoassays, fluorometric methods, and fluorescence polarization.

LC/MS-MS methods for measuring 11-deoxycortisol have been described, mostly as part of corticosteroid profiles. These methods typically involve liquid-liquid extraction into an organic solvent, although solid-phase extraction has been used as well.

Measurement of Urinary Metabolites of Adrenocortical Steroids

Measurement of the urinary excretion of adrenocortical steroids and their metabolites is common in the laboratory assessment of adrenal disease. Immunoassays for the major circulating steroid hormones are widely available.

Measurement of 17-OHCS has been used to differentiate CYP21 deficiency from CYP11B1 deficiency. In CYP21 deficiency, 17-OHCS would not be elevated because both 11-deoxycortisol and cortisol are low. However, because CYP11B1 deficiency increases 11-deoxycortisol (the metabolic block is between 11-deoxycortisol and cortisol), 17-OHCS would be elevated in untreated or undertreated CYP11B1 deficiency. Also, CYP11B1 deficiency and CYP21 deficiency are differentiated by elevated plasma 11-deoxycortisol concentrations in the former.

17-Hydroxyprogesterone is metabolically reduced to pregnanetriol, which can be measured in urine. The urinary metabolites of 11-deoxycortisol and cortisol are classified as

POINTS TO REMEMBER

- The adrenal gland is the exclusive source of cortisol and aldosterone and is a minor source of sex hormones.
- Cortisol is synthesized and released by the adrenal gland in response to adrenocorticotrophic hormone (ACTH) secreted by the anterior pituitary gland, which in turn is stimulated by corticotropin-releasing hormone (CRH) secreted by the hypothalamus.
- Aldosterone is synthesized and released by the adrenal gland in response to several factors, including angiotensin II and III, ACTH, and increased plasma potassium concentration.
- Overproduction of cortisol results in various symptoms collectively termed *Cushing syndrome*.
- Adrenal insufficiency can precipitate a life-threatening condition known as Addisonian crisis, due to inadequate secretion of cortisol and aldosterone.
- Cushing syndrome is most often caused by corticosteroid therapy, but it may also be caused by cortisol-, ACTH-, or CRH-secreting tumors.
- Chronic adrenal insufficiency (Addison disease) can be caused by autoimmune, infectious, and metastatic diseases.
- Provocative tests are often required to determine whether adrenal disease is primary (dysfunction of the adrenal gland) or secondary (dysregulation of adrenocortical-stimulating hormones).

17-OHCS. Analytically, 17-OHCS can be photometrically measured by the reaction of 17,21-dihydroxy-20-oxosteroids with a phenylhydrazine-ethanol-sulfuric acid reagent, producing yellow phenylhydrazones termed *Porter-Silber chromogens*.

Urinary metabolites of 17-hydroxyprogesterone, 11-deoxycortisol, and cortisol are 17-ketogenic steroids (17-KGS). Ketogenic steroids have been measured using the Zimmermann reaction, in which an alkaline solution of meta-dinitrobenzene reacts with methylene groups at carbon-16 of the 17-ketosteroids. In CYP17 deficiency, 17-KGS is not elevated. However, in both CYP21 and CYP11B1 deficiencies, when untreated or undertreated, 17-KGS are elevated.

DHEA and androstenedione metabolites are measured in the same way as 17-ketosteroids because both have ketone groups in the C-17 position. Testosterone has a hydroxyl group at the C-17 position, and therefore is not a 17-ketosteroid. DHEA and androstenedione are elevated in untreated and undertreated CYP21 and CYP11B1 deficiencies. [Fig. 41.5](#) summarizes these urinary steroid metabolites.

Measurement of Renin

Circulating concentrations of prorenin may be as many as 100-fold greater than the concentration of renin (although a 10:1 ratio of prorenin to renin is more common); therefore even minimal cross-reactivity of prorenin with renin antibodies used in immunoassays to measure renin can be problematic. Assays exist to measure PRA (by monitoring the production of angiotensin I) or the mass of renin by immunoassay. Each approach has advantages and disadvantages.

Measuring renin activity. Measuring plasma renin activity (PRA) provides an indication of the biologically active fraction of renin in the specimen because it measures the primary function of the enzyme, which is the conversion of angiotensinogen to angiotensin I. Renin activity measurements, however, are difficult to standardize, and two general approaches are used to measure renin activity. In the classic PRA method, first described in 1975, inhibitors of angiotensinase and ACE are added to prevent the conversion of angiotensin I to angiotensin II (some methods “trap” angiotensin I with an antibody to prevent its conversion to angiotensin II), the specimen is incubated at 37°C, and production of

angiotensin I is measured. The rate of the reaction is influenced by pH, incubation time, and, most important, the endogenous angiotensinogen concentration in the specimen (which can be increased in pregnancy, glucocorticoid excess, and estrogen administration). Because the angiotensinogen concentration in blood does not ordinarily exceed the K_m for the renin-angiotensinogen complex, its concentration is rate-limiting. Therefore the classic PRA method produces results that vary significantly, depending on the endogenous concentration of angiotensinogen.

A second approach to measuring renin activity uses exogenous angiotensinogen as substrate and thereby avoids the variability associated with endogenous angiotensinogen concentrations. (This approach is sometimes called *plasma renin concentration assay*, which is a confusing term in that the assay still involves the measurement of activity, rather than concentration. Furthermore, the term is not consistently applied; *plasma renin concentration* has been used in reference to immunoassays that measure the renin concentration, rather than activity.) These renin activity methods use angiotensinogen derived from plasma collected from nephrectomized sheep; it is added at a concentration that is several times the K_m for the renin-angiotensinogen complex, ensuring that the reaction rate is limited by renin activity alone. The advantage of using a consistent source of angiotensinogen is that the activity assays can be calibrated against renin reference materials; an international reference preparation of human renin, validated by bioassay, has been available since 1975.

Care must be taken when measuring and interpreting renin activity in patients who are taking renin inhibitors, a relatively new class of drugs used to treat essential hypertension. Aliskiren was the first member of this class of drugs to be approved by the US Food and Drug Administration. Renin activity will be suppressed in these patients, although renin and prorenin concentrations will be high.

Measuring renin concentration. As an alternative to the PRA assay, the concentration of renin can be measured by immunoassay or mass spectrometry. Immunoassays for renin cross-react with prorenin. A variety of monoclonal immunoradiometric assays (IRMAs) for renin have been developed, some of which measure renin and prorenin.

Immunochemiluminometric (ICL) methods for renin are also available, and the results of these assays have been correlated with IRMA results.

Aldosterone/renin ratio. Primary aldosteronism is characterized by nonsuppressible aldosterone secretion. Normally plasma aldosterone concentration and renin activity are inversely related, but their short half-lives (<20 minutes) make their measurements highly variable. A more useful

parameter is the ratio of plasma aldosterone concentration to renin activity (aldosterone-renin ratio; ARR). ARR is used as a screening test for primary aldosteronism. When the units of plasma aldosterone concentration are ng/dL and plasma renin activity is expressed in ng/mL·h, an ARR cutoff of 23.6 has a sensitivity of 97% and specificity of 94% for primary aldosteronism.

REVIEW QUESTIONS

- Measurement of urinary free cortisol (UFC) is typically used as a screening test for
 - hyperaldosteronism.
 - cortisol hypersecretion.
 - adrenal insufficiency.
 - congenital adrenal hyperplasia (CAH).
- Glucocorticoids _____ blood glucose concentrations by altering synthesis of gluconeogenic enzymes.
 - increase
 - decrease
 - do not affect
- The primary mineralocorticoid is
 - cortisol.
 - dehydroepiandrosterone (DHEA).
 - 11-deoxycortisol.
 - aldosterone.
- The major site of steroid hormone metabolism that involves the P450 enzyme systems is the
 - liver.
 - kidney.
 - gastrointestinal tract.
 - adipose tissue.
- The stimulation test that is used to assess the ability of the adrenal glands to synthesize cortisol is referred to as the
 - dexamethasone test.
 - metapyrone test.
 - cosyntropin test.
 - salt-loading test.
- Primary adrenal insufficiency is referred to as
 - Cushing syndrome.
 - Addison disease.
 - Conn syndrome.
 - congenital adrenal hyperplasia (CAH).
- The adrenocortical disorder that results from loss-of-function mutations in specific adrenocortical enzymes responsible for the synthesis of cortisol is
 - Cushing syndrome.
 - Addison disease.
 - Conn syndrome.
 - congenital adrenal hyperplasia (CAH).
- The anterior pituitary hormone that is responsible for increasing the size and number of adrenocortical cells and for eventual cortisol synthesis is
 - corticotropin.
 - growth hormone.
 - corticotropin-releasing hormone (CRH).
 - aldosterone.
- One of the main functions of the mineralocorticoids is
 - increasing blood glucose.
 - increased fat breakdown.
 - sodium retention.
 - glycogen synthesis.
- Which one of the following disorders is the result of autonomous excessive production of cortisol?
 - Cushing syndrome
 - Addison disease
 - Conn syndrome
 - Congenital adrenal hyperplasia (CAH)

Thyroid Disorders

Danielle B. Freedman, David Halsall, William J. Marshall, Christina Ellervik

OBJECTIVES

1. Define the following:
 - Colloid
 - Cretinism
 - Euthyroid
 - Follicle
 - Goiter
 - Iodide
 - Reverse T3 (rT3)
 - Thyroglobulin (Tg)
 - Thyroid storm
 - Thyrotoxicosis
 - Thyrotropin-releasing hormone (TRH)
2. Describe the structure and function of the thyroid gland, including cell types, internal location of key hormone precursors and proteins, regulation of the thyroid gland, and functions of the hormones synthesized and secreted.
3. Describe the metabolism of thyroid hormones, including synthesis, peripheral deiodination, specific effects on target tissues, and catabolism; state the full names of the thyroid hormones.
4. State the effects of increased and decreased thyroid hormones on thyroid-stimulating hormone (TSH), TRH, and target tissues.
5. For the following disorders, state the cause(s), symptoms, laboratory analyses, and lab results used to diagnose:
 - Autoimmune hypothyroidism
 - Graves disease
 - Hashimoto thyroiditis
 - Myxedema
 - Primary and secondary hyperthyroidism
 - Primary and secondary hypothyroidism
 - Sick euthyroid syndrome
 - T3 thyrotoxicosis
6. Name and describe the thyroid autoantibodies associated with thyroid disease, including mechanism of action, specificity of autoantibody to each disease, methods of detection, and interferences.
7. State the methods, specimen requirements, and problems with methods used to assess total and free thyroid hormones, thyroxine-binding globulin (TBG), Tg, and TSH.
8. State the formulae for estimation of free thyroid hormone concentration; given appropriate information, calculate estimates of free hormone concentration.
9. Analyze and solve case studies related to thyroid disease and laboratory analysis of these conditions.

KEY WORDS AND DEFINITIONS

Autoimmune thyroid disease (AITD) Diseases in which the immune system attacks or stimulates the body's own thyroid gland.

Central hypothyroidism Refers to thyroid hormone deficiency due to a disorder of the (1) pituitary, (2) hypothalamus, or (3) hypothalamic-pituitary portal circulation.

Colloid An amorphous material found in the follicular lumen of the thyroid gland. A critical component is *thyroglobulin* (Tg).

Congenital hypothyroidism A pathological condition resulting from severe thyroid insufficiency, which may lead to cretinism or myxedema.

Cretinism An archaic term for the clinical consequences of untreated congenital hypothyroidism

caused by a deficiency of thyroid hormone during prenatal development and infancy; characterized in childhood by short stature, developmental delay, dystrophy of the bones, and a low basal metabolism. It is also called *congenital myxedema*, which is also an archaic term.

Euthyroid Having normal thyroid function.

Goiter An enlargement of the thyroid gland that causes a swelling in the front part of the neck.

Graves disease A disorder of the thyroid of autoimmune etiology that causes hyperthyroidism. Characterized by having at least two of the following conditions: hyperthyroidism, goiter, and exophthalmos. It is also known in Europe as *Basedow disease*.

Hashimoto thyroiditis An autoimmune disorder in which the thyroid gland is attacked by a cell-mediated autoimmune process. Also known as *Hashimoto disease* and *chronic lymphocytic thyroiditis*, it is marked by (1) goiter, (2) chronic inflammation of the thyroid (*thyroiditis*), and (3) often hypothyroidism.

Hyperthyroidism A condition caused by excessive production of iodinated thyroid hormones. Symptoms and signs include increased basal metabolic rate, enlargement of the thyroid gland, rapid heart rate, high systolic blood pressure, and a number of secondary symptoms.

Hypothyroidism A condition of deficient thyroid gland activity leading to lethargy, muscle weakness, and intolerance to cold.

Myxedema A severe form of hypothyroidism in which there is accumulation of mucopolysaccharides in the skin and other tissue, leading to a thickening of facial features and a doughy induration of the skin.

Organification A process in the thyroid gland whereby iodide is oxidized and incorporated into tyrosyl residues (tyrosine) of thyroglobulin (Tg). Organification is catalyzed by the enzyme thyroperoxidase (TPO).

Primary hypothyroidism A condition that develops when the thyroid gland fails to produce or secrete as much thyroxine (T₄) as the body needs.

Reverse T₃ (rT₃) A biologically inert metabolite of thyroxine (T₄) with three iodine molecules attached in a configuration (1-3,3',5'-triiodothyronine) different from that of the active thyroid hormone triiodothyronine (T₃).

Secondary (central) hypothyroidism Hypothyroidism that arises as a consequence of inadequate secretion of thyroid stimulating hormone (TSH or *thyrotropin*) by the anterior pituitary gland.

Sick euthyroid syndrome Abnormalities of T₄, free T₄, T₃, and TSH concentrations that are seen in people with severe illness. In general, treatment with replacement thyroid hormone is not indicated.

Subclinical hyperthyroidism A biochemical condition with normal concentrations of serum thyroid hormones when the serum TSH concentration is repeatedly low in the absence of hypothalamic or pituitary disease.

T₃ thyrotoxicosis A hyperthyroid condition in which T₃, but not T₄, is elevated.

Thyroglobulin (Tg) An iodine-containing glycoprotein of high molecular weight (663 kDa) present in the colloid of the follicles of the thyroid gland.

Thyroid follicle The secretory unit of the thyroid gland consisting of an outer layer of epithelial cells that enclose an amorphous material called colloid.

Thyroid-stimulating hormone (TSH) A polypeptide hormone synthesized by the anterior pituitary gland that promotes the growth of the thyroid gland and stimulates the synthesis and release of thyroid hormones by the thyroid gland. Also called *thyrotropin*.

Thyroid storm A life-threatening condition that develops in a minority of cases of untreated thyrotoxicosis (hyperthyroidism, or overactive thyroid).

Thyroiditis A condition characterized by inflammation of the thyroid gland.

Thyrotoxicosis A toxic condition resulting from excessive amounts of thyroid hormones in the body.

Thyrotropin-releasing hormone (TRH) A tripeptide produced in the hypothalamus that stimulates the synthesis and release of TSH from the anterior pituitary.

Thyroxine (T₄) The major hormone synthesized and released by the thyroid gland that contains four iodine molecules (1-3,5,3',5'-tetraiodothyronine).

Thyroxine-binding globulin (TBG) One of three major plasma thyroid hormone binding proteins (TBG, transthyretin [TTE], and albumin).

Toxic multinodular goiter A condition in which the thyroid gland contains multiple lumps (nodules) that are overactive and that produce excess thyroid hormones. Also known as *Parry disease* and *Plummer disease*.

Transthyretin (TTR) A protein found in serum and cerebrospinal fluid that binds to and transports thyroxine (T₄). TTR complexes with retinol-binding protein (RBP) to prevent its loss through the glomerulus by filtration. It was once called *prealbumin*, because it travels faster than albumin on electrophoresis gels.

Triiodothyronine The biologically active form of thyroid hormone formed primarily outside of the thyroid gland by the peripheral deiodination of thyroxine (T₄). It has three iodine molecules attached to its molecular structure (1-3,5,3'-triiodothyronine).

ANATOMY

The thyroid consists of two lobes connected by an isthmus and is like a butterfly in shape with the right lobe being slightly larger than the left. It is in the front of the neck just above the trachea. The gland synthesizes thyroid hormones and calcitonin through two distinct cell types: the epithelial or follicular cells and the parafollicular (or C) cells, respectively. The normal adult thyroid gland weighs 15 to 25 g, but in specific disease states, it can attain a weight of several hundred grams.

The thyroid gland is composed of follicles or acini (Fig. 42.1). In the center of the **follicle** is the lacuna, which contains **colloid**

composed predominantly of **thyroglobulin (Tg)**. The parafollicular (or C) cells have been shown to produce the polypeptide hormone *calcitonin*.

Thyroid Morphogenesis and Dysmorphogenesis

Thyroid dysgenesis is a collective designation for thyroid agenesis (or athyreosis; i.e., the complete lack of thyroid tissue), hypoplasia, hemiagenesis (lacking one lobe), and thyroid ectopia (complete or coexisting with normal positioned tissue; i.e., the aberrant location of thyroid tissue along its embryological descent). The developmental defects have

Fig. 42.1 (A) Basic unit of the thyroid gland. The follicle is the basic unit of the thyroid gland. It is composed of thyroid follicular cells surrounding the colloid. Outside the follicular cells is a basal lamina. (B) Apical and basolateral poles of the follicular cells and tight junctions between the follicular cells. Parafollicular (C cells) that secrete calcitonin can be found beneath or outside the basal lamina. Not pictured between the follicles are capillaries and fibroblasts.

considerable phenotypic variations. Ectopic tissue may coexist with a normally positioned gland. It is important to localize ectopic thyroid tissue before thyroidectomy.

Fetuses are dependent on thyroid hormones for normal growth and organ development, especially brain development and maturation.

THYROID HORMONES

The thyroid gland secretes two hormones, **thyroxine** (3,5,3',5'-L-tetraiodothyronine) and **triiodothyronine** (3,5,3'-L-triiodothyronine), which are commonly known as T4 and T3, respectively (Table 42.1). In addition, the thyroid gland secretes very small amounts of biologically inactive 3,3',5'-L-triiodothyronine (**reverse T3** [rT3]) and minute quantities of monoiodotyrosine (MIT) and diiodotyrosine (DIT), which are precursors of T3 and T4. The structures of these compounds are shown in Fig. 42.2.

Biological Function

The functions of thyroid hormones include (1) control of the basal metabolic rate and calorogenesis, (2) enhancement of mitochondrial metabolism, (3) stimulation of neural development and normal growth, (4) promotion of

TABLE 42.1 Nomenclature and Abbreviations for Thyroid Tests

Name	Abbreviation
Hormones	
Total thyroxine	T4
Total triiodothyronine (3,5,3'-triiodothyronine)	T3
Free thyroxine	FT4
Free triiodothyronine	FT3
Thyrotropin (thyroid-stimulating hormone)	TSH
Reverse T3 (3,3',5'-triiodothyronine)	rT3
Serum-Binding Proteins	
Thyroid-hormone binding proteins	TBP
Thyroxine-binding globulin	TBG
Transthyretin (thyroxine-binding prealbumin)	TTR
Albumin	Alb
Tests for Autoimmune Thyroid Disease	
Autoimmune thyroid disease	AITD
Thyroglobulin autoantibodies	Anti-Tg
Thyroperoxidase autoantibodies	Anti-TPO
TSH receptor autoantibodies	Anti-TSHR
TSH receptor antibodies	TRAb
TSH receptor blocking antibodies	Anti-TSHRB
TSH receptor stimulating antibodies	Anti-TSHRS
Other Hormones, Thyroid-Related Proteins, and Conditions	
Thyroid peroxidase	TPO
Thyrotropin-releasing hormone	TRH
Thyroglobulin	Tg
Thyroid hormone receptor	THR
Deiodinase 1,2,3	D1, D2, D3
Iodotyrosine dehalogenase 1	DEHAL
Sodium/iodide symporter	NIS
TSH receptor	TSHR
Dual oxidase 1 and 2	DUOX1 and DUOX2
Thyroid hormone receptor- α	THR α
Thyroid hormone receptor- β	THR β

sexual maturation, (5) stimulation of adrenergic activity with increased heart rate and myocardial contractility, (6) stimulation of protein synthesis and carbohydrate metabolism, (7) increasing the synthesis and degradation of cholesterol and triglycerides, (8) increasing the requirement for vitamins, (9) increasing calcium and phosphorus metabolism, and (10) enhancing the sensitivity of adrenergic receptors to catecholamines. These effects are typically magnified in patients with either an overactive thyroid gland (e.g., in **hyperthyroidism**), or reduced in patients with reduced thyroid function (e.g., **hypothyroidism**).

Biochemistry

Approximately 40% of secreted T4 is deiodinated in peripheral tissues by enzyme deiodinases to yield T3, and about 45% is deiodinated to yield rT3, a biologically inactive metabolite.

Therefore, with normal T4 production of 100 nmol (80 µg) daily, approximately 40 nmol (26 µg) of T3 and 45 nmol (29 µg) of rT3 are produced by peripheral deiodination.

From the estimated daily production rates for T3 (30 µg) and rT3 (30 µg) in a normal (**euthyroid**) state, at least 85% of T3 production and essentially all rT3 production are accounted for by peripheral deiodination of T4 rather than by direct secretion from the thyroid gland. T3 is at least four to five times more potent in biological systems than T4. Because one-third of all T4 is converted to T3 during the course of its metabolism, T4 may be considered to be a prohormone for

Fig. 42.2 Chemical structures of thyroxine (T4), triiodothyronine (T3), and **reverse T3 (rT3)**.

T3. The biosynthesis of thyroid hormones occurs by a process termed **organification**. It involves the (1) trapping of circulating iodide by the thyroid gland, (2) incorporation of iodine into Tg tyrosines producing monoiodinated tyrosines and di-iodinated tyrosines, and (3) coupling of two iodinated tyrosyl residues to form the thyronines (T4 and T3) within the protein backbone of the Tg protein in the follicular lumen (**Fig. 42.3**). Endocytosis followed by proteolytic cleavage of Tg releases the iodothyronines into the circulation.

Dietary iodine is the basic element involved in the synthesis of thyroid hormones. It is normally ingested in the form of iodide. Iodide transport to the follicles is the first and rate limiting step in the synthetic process. The follicular cells of the thyroid concentrate iodide to some 30 to 40 times the normal plasma concentration by means of an energy-dependent pump mechanism, the sodium-iodide symporter (approved gene name: solute carrier family 5 [sodium/iodide cotransporter], member 5; approved symbol *SLC5A5*; chromosome 19p13.11).

The synthesis of MIT and DIT (**Fig. 42.4**), T4 (**Fig. 42.5**), and T3 (**Fig. 42.6**), occurs mainly at the follicular cell–colloid interface but also within the colloid (see **Fig. 42.3**).

Tg is present in highest concentrations within the colloid, where it is stored. The follicular cells engulf colloid globules by endocytosis; these globules then merge with lysosomes in the follicular cell. Lysosomal proteases break the peptide bonds between iodinated residues of Tg, and MIT, DIT, T4,

Fig. 42.3 Synthesis of thyroid hormones begins with absorption of iodide by the thyroid follicular cell and the Na^+/I^- symporter. From the cytoplasm, iodide moves into the lacunae via pendrin. Within the lacunae, thyroperoxidase (TPO) and the dual oxidases (DUOX [not depicted]) convert iodide to iodine, leading to iodination of tyrosine residues on thyroglobulin (Tg). Tg is synthesized in the cell and exported to the lacunae. TPO is responsible for the coupling of monoiodotyrosine (MIT) and di-iodotyrosine (DIT) to form T3, and di-iodotyrosine and di-iodotyrosine to form T4. Upon the uptake of iodinated Tg (containing T4 and T3) and the fusion of this phagosome-like vesicle with a primary lysosome, Tg is degraded in a secondary lysosome, releasing T4 and T3 into the circulation and MIT and DIT undergo deiodination via a dehalogenase to recycle the iodine for new thyroid hormone synthesis. RER, Rough endoplasmic reticulum.

Fig. 42.4 Monoiodination and diiodination of tyrosine. *Tg*, Thyroglobulin.

Fig. 42.5 Chemical coupling of two molecules of diiodotyrosines to produce a molecule of thyroxine (T4). The reaction is catalyzed by thyroperoxidase. *Tg*, Thyroglobulin.

Fig. 42.6 Chemical coupling of one molecule of monoiodotyrosine and one molecule of diiodotyrosine to produce one molecule of T3. The reaction is catalyzed by thyroperoxidase. *Tg*, Thyroglobulin.

and T3, are released into the cytoplasm of the follicular cell. T4 and T3 diffuse into the systemic circulation after their liberation from *Tg*. DIT and MIT are deiodinated by an intracellular microsomal iodotyrosine dehalogenase (approved gene name iodotyrosine deiodinase, approved symbol *IYD*; chromosome 6q25.1). The freed iodide is then reused for thyroid hormone synthesis.

Each step in the synthesis of thyroid hormones is regulated by pituitary **thyroid-stimulating hormone (TSH)**. TSH (also known as **thyrotropin**) stimulates (1) the “iodide pump,” (2) *Tg* synthesis, and (3) colloidal uptake by follicular cells. TSH also regulates the rate of proteolysis of *Tg* for the liberation of T4 and T3. In addition, TSH induces an increase in the size and number of the thyroid follicular cells. Prolonged TSH stimulation leads to increased vascularity and eventual hypertrophic enlargement of the thyroid gland (**goiter**). Initially, it was believed that both T4 and T3 entered cells by passive diffusion across the plasma membrane. However, researchers have

now shown that thyroid hormones cross plasma membranes using specific transporters. One important thyroid hormone transporter is monocarboxylate transporter 8 (MCT8; gene symbol *SLC16A2*; chromosome Xq13.2). MCT10 (*SLC16A10*; chromosome 6q21–q22) transports iodothyronines and aromatic amino acids across membranes, and MCT10 is likely more preferential than MCT8 in transporting T3 over T4 across plasma membranes. Organic anion transporting polypeptide 1C1 (OATP1C1) also has high affinity for thyroid hormone and may be an important component of the transport of T3 and T4.

Metabolism

Free (unbound) T4 (FT4) is the primary secretory product of the normal thyroid gland. T4 undergoes peripheral deiodination of the outer ring at the 5' position to yield T3. This deiodination occurs in a number of tissues but primarily in the liver. rT3, produced by removal of one iodine from the inner ring of T4, is metabolically inactive and is an end-product of T4 metabolism. Peripheral deiodination is a rapidly responsive mechanism of control for thyroid hormone balance. Acute or chronic stress or illness causes a shift in the direction of this deiodination, favoring formation of rT3 rather than T3. Various medications also shift peripheral deiodination toward the inactive product rT3.

T4 and T3 in the circulation are bound reversibly and almost completely to carrier proteins. These carrier proteins are (1) **thyroxine-binding globulin (TBG)**, (2) thyroxine-binding prealbumin (TBPA; **transthyretin [TTR]**), and (3) albumin. Collectively, these proteins bind 99.97% of total T4 and 99.7% of total T3. Thus, only a very small fraction of each of these hormones is unbound and free for biological activity. Because a wide variation exists in the concentration of thyroid hormone binding proteins, even under normal circumstances, a wide variation also exists in T4 concentrations among individuals with normal (euthyroid) thyroid function. Total T3 concentrations also vary with alterations in binding proteins, although usually to a lesser degree than T4 concentrations. Circumstances in which thyroid hormone-binding protein concentrations are increased or decreased are shown in [Box 42.1](#).

Regulation and Control

Thyroid hormone synthesis and secretion are controlled by a negative feedback system ([Fig. 42.7](#)) involving (1) **thyrotropin-releasing hormone (TRH)** from the hypothalamus, (2) TSH from the pituitary, and (3) thyroid hormones from the follicular cells of the thyroid glands.

BOX 42.1 Alterations in the Concentration or Affinity of Thyroid Hormone-Binding Proteins

Increases In

- A. TBG concentration (or affinity)
 1. Genetic (inherited) causes
 2. Nonthyroidal illness (human immunodeficiency virus infection, infectious and chronic active hepatitis, estrogen-producing tumors, acute intermittent porphyria)
 3. Normal physiology (pregnancy, newborn)
 4. Drug use (oral contraceptives, estrogens, tamoxifen, methadone)
- B. Prealbumin binding (familial euthyroid thyroxine excess)
- C. Albumin binding (familial dysalbuminemic hyperthyroxinemia)
- D. Thyroxine binding by autoantibodies (autoimmune thyroid disease, hepatocellular carcinoma)

Decreases In

- A. TBG concentration
 1. Genetic (inherited) causes
 2. Nonthyroidal illness (major illness or surgical stress, chronic liver disease, protein-losing enteropathy, nephrotic syndrome)
 3. Drug use (androgens, anabolic steroids, large doses of glucocorticoids)
- B. TBG-binding capacity (drugs bound to TBG, such as salicylates and phenytoin)
- C. Prealbumin concentration

TBG, Thyroxine-binding globulin.

Fig. 42.7 Metabolic control of thyroid hormones. **Thyrotropin-releasing hormone (TRH)** from the hypothalamus enters the hypothalamic-pituitary portal system to release thyroid stimulating hormone (*TSH*; thyrotropin) from anterior pituitary thyrotrophs. TSH stimulates the release of **thyroxine (T4)** and triiodothyronine (T3) from the thyroid gland, although most T3 (~80%) comes from peripheral monodeiodination of T4 to T3. More than 99% of T4 and T3 is bound to various thyroid hormone-binding proteins (*TBP*). T4 and T3 negatively feedback on the hypothalamus and, more powerfully, the pituitary. T4 and T3 enter into target tissues, where T4 is converted to T3 with T3 binding to the thyroid hormone receptor (*TR*).

Fig. 42.8 Chemical structure of thyrotropin-releasing hormone (*TRH*). Note that TRH is a tripeptide (L-pyroglutamyl-L-histidyl-L-prolinamide).

Biochemistry

TRH is the modified tripeptide L-pyroglutamyl-L-histidyl-L-prolinamide secreted by the paraventricular nuclei (PVN) in the hypothalamus (Fig. 42.8). Its concentrations rise in thyroid hormone deficiency with TRH declining when thyroid hormone is in excess. TRH is delivered to the anterior pituitary gland via the hypothalamic-pituitary portal system. TSH (also known as *thyrotropin*) is secreted by anterior pituitary cells known as *thyrotrophs*. In relative terms, TRH has a greater effect on TSH glycosylation than hormone release. However, glycosylation of TSH is necessary for normal TSH bioactivity. When TRH is deficient, TSH may lack potency as the result of insufficient glycosylation, yet nonglycosylated TSH may retain much of its immunoreactivity. Chemically, TSH is a 30 kDa heterodimeric glycoprotein that shares the 14.7 kDa alpha subunit (gene location: chromosome 6q21.1–q23) with (1) luteinizing hormone (LH), (2) follicle-stimulating hormone (FSH), and (3) human chorionic gonadotropin (hCG), whereas each hormone has a unique beta subunit (see Chapters 40 and 44).

Function

The effects of TSH on the thyroid follicular cell are mediated through the TSH receptor. At physiological TSH concentrations, the second messenger system involves G_s proteins, adenylate cyclase, and the formation of cyclic adenosine monophosphate. At supraphysiologic concentrations (100X normal), TSH signals through the inositol-phosphate diacylglycerol cascade. The 743-amino acid glycosylated thyroid-stimulating hormone receptor (TSHR/≈100 kDa) may be in either the “on” conformation, with active signaling, or the “off” conformation, where signaling does not occur.

TSH binding to the TSHR places the TSHR in the “on” conformation, leading to stimulation of the thyroid gland. Within the TSH-stimulated thyroid follicular cell, the (1) activity of the sodium-iodine symporter increases; (2) synthesis of Tg and thyroperoxidase (TPO) increases; and (3) release of T4 and T3 increases. TSH stimulation increases the size and number of thyroid follicular cells.

IODINE AND THYROID DISORDERS

Iodine (or iodide [I^-] in its ionized form) is a trace element and an essential nutrient (see [Chapter 27](#)). Iodine is an indispensable component of the thyroid hormones T3 and T4, respectively. These hormones, together with the thyronamines, are the only iodine-containing hormones in vertebrates. Without iodine, there is no biosynthesis of thyroid hormones. Thus, thyroid function requires an adequate supply of iodine to the thyroid gland.

Geography and Iodine Supply

Iodide ions in seawater and coastal seaweed beds are oxidized to elemental iodine, which then volatilizes into the atmosphere and is returned to the soil by rain. This process (the iodine cycle) is slow and incomplete in many regions, thus leaving soils and drinking water iodine depleted.

Most iodine is found in the oceans. The major source of iodine in industrialized countries is iodized salt, and if that is not available, then dairy products.

Cruciferous vegetables, such as cabbage, kale, cauliflower, and broccoli, contain glucosinolates, and their metabolites compete with iodine for thyroidal uptake. Cassava, linseed, and sweet potato contain cyanogenic glucosides, which can be metabolized to thiocyanates and compete with iodine for thyroidal uptake.

Pregnant and lactating women have higher demands for iodine because of an increase in maternal T4 production to maintain maternal euthyroidism and the transfer of thyroid hormone to the fetus early in the first trimester.

Iodine-Containing Products and Goitrogens

Exposure to iodine also can occur from iodine-containing products, such as disinfectants, amiodarone, radiology contrast agents, and topical antiseptics (e.g., the surgical scrub povidone-iodine). The iodine content of these agents is several thousand-fold higher than iodine appearing in naturally occurring foods. Iodine deficiency is the major cause of endemic goiter, but naturally occurring compounds and environmental pollutants may also be goitrogenic. Goitrogens can be either agents acting directly on the thyroid gland or cause a goiter by indirect action. Interestingly, cigarette smoking is associated with high plasma concentrations of thiocyanate, which can compete with iodine for uptake into the thyroid.

Public Health Programs

There are two kinds of public health programs for securing optimal thyroid function. One is newborn screening for thyroid function (see section on congenital hypothyroidism); the other is iodization of salt.

Biochemistry

Dietary iodine controls its own absorption through post-transcriptional regulation of the intestinal Na^+/I^- symporter (NIS). The thyroid gland has autoregulatory mechanisms to handle excess iodine intake involving the sodium iodide symporter. Excess iodine has an inhibitory effect on thyroxine

synthesis in intact thyroids. In conditions of adequate dietary iodine supply, the healthy thyroid usually takes up less than 20% of absorbed iodine. However, in chronic iodine deficiency, this fraction can be more than 80%. The thyroid is thus able to adapt to low intakes of dietary iodine by marked modification of its activity. The metabolism of circulating thyroid hormones in peripheral tissues releases iodine that enters the plasma iodine pool, which in turn can be taken up by the thyroid or excreted by the kidney. Approximately 90% of ingested iodine is excreted in the urine and approximately 10% in feces.

Iodine Deficiency

Both deficient and excessive intakes of iodine can impair thyroid function. The clinical presentations of iodine deficiency are largely age dependent. In fetuses, deficiency may cause abortion, stillbirth, and congenital anomalies. In neonates, deficiency may cause infant mortality and endemic **cretinism**. In children and adolescents, deficiency may cause impaired mental function, delayed physical development, and low IQ. In adults, deficiency may cause impaired cognitive function, reduced work productivity, thyroid autoimmunity, toxic nodular goiter, and hypothyroidism. In all ages, goiter is the most visible sign of iodine deficiency but is not specific to it.

Iodine Excess

Thyroid dysfunction may occur in vulnerable patients if exposed to excess iodine. These patients include those with preexisting thyroid disease, older adults, pregnant and lactating women, fetuses, and neonates. Iodine excess can result in adverse thyroidal effects after only a single exposure to iodine-containing substances. Excess dietary iodine intake in pregnant and lactating women in iodine-replete areas may lead to an increase in plasma TSH concentrations and thus to **subclinical hypothyroidism (SCH)**.

EXTRATHYROIDAL FACTORS THAT AFFECT THYROID FUNCTION

Epidemiologic Factors

Concentrations of thyrotropin, thyroid hormones, thyroid antibodies, and thyroid-binding proteins are to varying degrees determined genetically and by epidemiologic factors such as age, gender, ethnicity, body mass index, smoking, pregnancy, nutritional iodine, season, nonthyroidal disease, radiation, and medication.

Drugs

Many drugs, other than those used for treatment of thyroid disorders, interfere with thyroid hormone homeostasis ([Table 42.2](#)) through actions on thyroid hormone synthesis, secretion, transport, metabolism, and absorption.

Lithium

Lithium, which is still a widely used drug for the treatment of bipolar disorder, is associated with subclinical and

TABLE 42.2 Effects of Some Drugs on Tests of Thyroid Function

Cause	Drug	Effect
Inhibit TSH secretion	Dopamine	↓ T4; ↓ T3;
	L-dopa	↓ TSH
	Glucocorticoids	
	Somatostatin	
Inhibit thyroid hormone synthesis or release	Iodine	↓ T4; ↓ T3;
	Lithium	↑ TSH

	Cholestyramine	
	Colestipol	
	Iron sucralfate	
	Soybean preparations	
	Kayexalate	
Increase in concentration of T4-binding proteins	Estrogen	↑ T4; ↑ T3;
	Clofibrate	⇌FT4;
	Opiates (heroin, methadone)	⇌TSH
	5-Fluorouracil	
	Perphenazine	
Decrease in concentration of T4-binding proteins	Androgens	↓ T4; ↓ T3;
	Glucocorticoids	⇌FT4; ⇌TSH

↓, Reduced serum concentration; ↑, increased serum concentration; ⇌, no change; FT4, free thyroxine; NSAID, nonsteroidal antiinflammatory drug; rT3, reverse triiodothyronine; T3, triiodothyronine; T4, thyroxine; TSH, thyroid-stimulating hormone.

Data obtained from Smallridge, R. D. (1995). Thyroid function tests. In K. L. Becker (Ed.), *Principles and practice of endocrinology and metabolism* (7th ed., pp. 299–306). Philadelphia: JB Lippincott.

overt hypothyroidism in up to 34% and 15% of patients, respectively. These may develop even after many years of treatment. Patients should have regular thyroid function tests, at least once or twice per annum. Lithium primarily inhibits thyroid hormone secretion, although it appears also to have effects on iodine trapping, release, and coupling.

Amiodarone

Amiodarone is an antiarrhythmic drug that comprises 37% iodine by weight and has structural similarities with thyroid hormones. The drug has a long half-life, large distribution volume, and wide tissue distribution. The mechanisms of amiodarone injury are multifactorial and involve the accumulation of iodine, the formation of free radicals, and immunologic damage. The effects of amiodarone can be divided into effects occurring in everyone treated with amiodarone, resulting in changes in thyroid function tests (“obligatory effects”), and effects only occurring in some people treated with amiodarone (“facultative effects”), resulting in clinically overt thyrotoxicosis or hypothyroidism. It may take several months for normalization of thyroid function tests after discontinuation of amiodarone treatment.

Amiodarone-induced thyrotoxicosis (AIT) is particularly prevalent (10%) in iodine-deficient regions, in men, and in patients with underlying thyroid disease (e.g., nodular goiter or Graves disease). Amiodarone-induced hypothyroidism occurs primarily in iodine-sufficient regions and in women with preexisting anti-TPO antibodies.

Nonthyroidal Illness

Many disorders are associated with variation in the concentration of thyroid hormones in the absence of definable thyroid disease (Table 42.3). For example, (1) significant nutritional deprivation, (2) acute severe illness, or (3) chronic illness often result in changes in thyroid function. Collectively they are characterized as *nonthyroidal illnesses* (NTI; **sick euthyroid syndrome**). A progressive spectrum of thyroid test result anomalies often accompanies nonthyroidal illnesses in euthyroid patients. The earliest and most common changes that occur are a reduction in the serum concentrations of total and free T3, sometimes to extremely low concentrations, and an elevation in the serum concentration of rT3 (the “low T3 state”). These changes have been ascribed to a block in the 5′-deiodinases that convert T4 to T3 in peripheral tissue. This conversion is inhibited in patients with (1) acute and chronic nutritional problems, (2) poorly controlled diabetes mellitus, and (3) the use of drugs such as hydrocortisone and beta blockers.

Serum TSH concentrations are usually normal in euthyroid sick patients, but may be mildly to moderately depressed with moderate to severe NTI or slightly elevated during recovery from a severe illness (Fig. 42.9). Causes of these transient abnormal TSH concentrations are not fully understood, but may relate to the effects of endogenous or exogenous hormones, such as glucocorticoids or dopamine, which independently suppress secretion of pituitary TSH concentrations. Other possible causes include altered nutrition or altered biological activity of immunoreactive TSH. Decreased T4 levels (both total and free) may result from T4 displacement from thyroid hormone binding proteins. As patients recover from NTIs, many of the thyroid test abnormalities revert to normal. T4 concentrations will be corrected first, followed by a rise in the concentration of T3. Serum TSH may also transiently rebound to high concentrations for several days or weeks before returning to normal.

TABLE 42.3 Nonthyroidal Illness

Hormone	Initial	Midcourse	Prolonged	Resolution
TSH	Normal	Normal to decreased	Decreased	Increases
T4	Normal	Normal to decreased	Decreased	Increases
T3	Decreased (–)	Decreased (––)	Decreased (–––)	Increases
rT3	Increased (+)	Increased (++)	Increased (+)	Decreases

Note: The severity of decreased T3 is proportional to the number of (–) signs. The degree of increase in rT3 is proportional to the number of (+) signs.

T3, Triiodothyronine; rT3, reverse T3; T4, thyroxine; TSH, thyroid-stimulating hormone.

Fig. 42.9 Effects of altered deiodination. In states of nonthyroidal illness (e.g., the sick euthyroid syndrome), thyroid hormone deiodination patterns are altered with reduced T3 concentrations and elevated concentrations of reverse T3 (rT3).

EVALUATION OF THYROID FUNCTION

In clinical practice, thyroid function tests are routinely measured to diagnose disorders of the thyroid. For example, in combination with information obtained from (1) history, (2) physical, and (3) laboratory results, patients are classified as (1) hypothyroid, (2) hyperthyroid, or (3) euthyroid (Fig. 42.10). Almost all laboratory tests for thyroid function are commercially available on automated immunoassay instruments. The following is a brief description of tests that are used for the evaluation of thyroid status. Package inserts that accompany commercial products are also a source of additional information. Reference intervals for the analytes, discussed later, are found in the Appendix.

Measurement of Thyroid Stimulating Hormone

Immunoassay is the method of choice for the measurement of serum TSH in the clinical laboratory. Human TSH is a 28 to 30 kDa dimeric glycoprotein consisting of a 92-amino acid alpha subunit (identical to the alpha subunit of hCG, FSH, and LH)

and a 112 to 118 amino acid beta subunit. Current third-generation TSH assays distinguish mild to modest TSH suppression (due to, e.g., overtreatment of hypothyroidism) from severely suppressed TSH levels as observed in Graves disease. All assays in clinical practice should be “third generation”; that is, they should have a coefficient of variation (CV) of less than 20% (functional sensitivity) at a concentration of 0.01 mIU/L.

Principles of Thyroid-Stimulating Hormone Immunoassays

Most TSH methods currently used in clinical laboratories are two-site “sandwich” heterogeneous immunoassays involving (1) enzyme, (2) fluorometric substrate, or (3) chemiluminescent labels. Heterogeneous immunoassays differ in the method used to separate bound and free fractions before application of the signal antibody. Immunometric assays generate a proportional dose-response calibration curve with higher signals corresponding to increased concentrations of analyte. Because the physiological interval of TSH concentrations is typically less than three orders of magnitude, high-dose hook effects are rarely encountered with TSH immunoassays.

Specimen Collection and Storage

Both serum and plasma are used for TSH measurements. TSH is stable for 5 days at 2°C to 8°C, and for at least 1 month when stored frozen. For newborn screening, whole blood may be collected by heel puncture 48 to 72 hours after birth.

Comments on Thyroid-Stimulating Hormone Measurements

Secretion of TSH is circadian with peak concentrations of TSH occurring between 0200 and 0400 hours, and the lowest between 1700 and 1800 hours. Low-amplitude oscillations occur throughout the day. TSH surges immediately after birth, reaching a peak of 25 to 160 mIU/L within 30 minutes and declining back to cord blood concentrations by postpartum day 3. TSH concentrations stabilize to near adult concentrations within the first few weeks of life. In the first trimester of pregnancy, TSH concentrations decline as hCG stimulates the maternal thyroid gland to produce thyroid hormone, sometimes leading to a TSH concentration that is just below the lower reference limit. Reference intervals for adult TSH concentrations are the same for men and women (generally near 0.4 to 4.5 mIU/L). However, there is active discussion that the upper limit of the reference interval may be as low as

Fig. 42.10 Suggested algorithm for the laboratory evaluation of thyroid function. *TSH*, Thyroid-stimulating hormone.

2.5 to 3.5 mIU/L if people with thyroid autoantibodies and/or abnormal thyroid ultrasound findings are excluded from the reference population.

Measurement of Total Thyroxine

T4 is the principal hormone secreted by the thyroid, and its circulating concentration is under the control of TSH. The hormone is synthesized from tyrosine residues on Tg in the colloid of the thyroid gland. Circulating T4 is highly (>99.9%) protein bound, and the fraction that is bound to protein is biologically inactive. Immunoassays and instrument-based methods are used to measure total T4 in biological fluids, predominantly serum or plasma.

Immunoassays

Many clinical laboratories measure T4 by using an automated competitive immunoassay. Most of these T4 immunoassays use high-affinity polyclonal antibodies produced against an albumin-T4 conjugate. These polyclonal antibodies are highly specific and display minimal cross-reactivity with T3. Tg sometimes has been used as the immunogen, because it contains iodinated tyrosine residues that are the precursors of T4 and T3. Monoclonal antibodies against T4 have also been developed.

Immunoassays of T4 measure both free and protein-bound hormone. Accurate measurement of T4 therefore requires dissociation of the hormone from serum proteins, such as (1) TBG, (2) albumin, and (3) TTR, which bind more than 99.9% of circulating T4. Various blocking agents have been used to dissociate T4 from TBG. The most common of these blocking agents is (1) 8-anilino-1-naphthalene-sulfonic acid (ANS), although (2) salicylate, (3) thimerosal, and (4) phenytoin have also been used for this purpose. Barbitol is used to dissociate T4 from TTR.

Nonisotopic assays for T4 are widely available for use on various automated immunoassay systems, or adaptable to automated chemistry platforms. Chemiluminescent and electrochemiluminescent assays also have been adapted for use on automated platforms.

OTHER METHODS

Other instruments used to measure T4 in human serum include (1) electron capture gas chromatography, (2) high-performance liquid chromatography, and (3) isotope dilution tandem mass spectrometry. The latter method has been suggested as a reference method for assay of T4.

Specimen Collection and Storage

Serum is the preferred specimen for the measurement of T4, but plasma with ethylenediaminetetraacetic acid (EDTA) or heparin as an anticoagulant has also been used. If plasma is used, repeated freeze-thaw cycles should be avoided as fibrin clots may form producing potentially spurious results due to changes in specimen viscosity. Gel barrier collection devices do not have any apparent adverse effect on T4 methods. T4 is a stable analyte with no appreciable change in concentration for up to 7 days at room temperature, or 30 days when frozen. Mild to moderate hemolysis and lipemia do not significantly affect most T4 immunoassays; however, grossly hemolyzed specimens should be avoided because of dilutional effects. T4 autoantibodies interfere with some immunoassays and may produce erroneously low or high results, depending on the method. Such interferences should be considered when there is discordance between the clinical and laboratory findings. Heel-stick capillary specimens have been used for T4 measurement, as have dried blood specimens collected on filter paper. Dried blood specimens are stable and easily

transported and are widely used in the United States to screen neonates for **congenital hypothyroidism**. T4 is extracted from a punched-out disk of blood saturated filter paper into a buffer before assay. The filter paper should not be exposed to extreme heat or light.

Comments on Total Thyroxine Measurements

Because it reflects mostly inactive (protein-bound) hormone, the quantity of total T4 alone provides limited clinical information. For this reason, FT4 measurements are preferred over total T4 measurements for routine testing. Cord blood T4 concentrations are lower in preterm than in full-term neonates, and they correlate positively with birth weight in full-term infants. At birth, serum total T4 concentrations are higher in neonates because of the maternal estrogen-induced increase in serum TBG; FT4 concentrations are near adult concentrations. The concentration of total T4 rises abruptly in the first few hours after birth and declines gradually until adolescence.

Measurement of Triiodothyronine

T3 is the principal active thyroid hormone with approximately 20% of circulating T3 secreted by the thyroid gland, and the remainder is produced by deiodination of T4 in the peripheral tissues. Like T4, T3 is highly bound to protein with less than 1% of the total concentration as free active hormone. However, compared with T4, it is less tightly bound to serum proteins by about an order of magnitude. Consequently, the displacement of bound T3 from proteins is essentially complete in the presence of conventional blocking agents, such as ANS. Also, T3 does not ordinarily displace T4 from thyroid hormone-binding proteins.

Immunoassays are the techniques of choice to measure T3 in body fluids, predominantly serum or plasma.

Nonisotopic Immunoassays

Nonisotopic immunoassays for T3 are similar to total T4 methods. Many of the T3 methods have been developed for use on automated immunoassay systems, and some are compatible with chemistry platforms. Many commercial methods use enzyme labels, such as peroxidase or alkaline phosphatase, conjugated to T3 or anti-T3 antibodies. Enzyme activity is determined by using a variety of sensitive (1) photometric, (2) fluorescent, or (3) chemiluminescent substrates. Automated platforms that employ chemiluminescent labels are the analytical systems of choice to measure T3. Both heterogeneous and homogeneous immunoassays for T3 have been described (see [Chapter 15](#)).

Specimen Collection and Storage

Serum is the preferred specimen, but plasma with EDTA or heparin as an anticoagulant may be used. Serum specimens should be tested within 24 hours of collection, or stored at 2°C to 8°C if tested beyond 24 hours. Frozen specimens are stable for at least 30 days. Turbid samples may require centrifugation before testing.

Comments on Total Triiodothyronine Measurements

Significant discrepancies have been observed when the results of different T3 immunoassays were compared using reference sera. Interlaboratory quality assurance (proficiency testing) results also demonstrate higher analytical variance for T3 compared with T4 methods. Among the factors that have been suggested to account for the poorer analytical performance of T3 immunoassays are the (1) lower concentration of T3 in serum, (2) greater antibody cross-reactivity, (3) protein interferences, and (4) different limits of detection for T3 methods. Total T3 measurements are useful in the diagnosis and monitoring of hyperthyroid patients with suppressed TSH and normal FT4 concentrations (**T3 thyrotoxicosis**); T3 measurements have only limited value in euthyroid and hypothyroid patients. Thyroid hormone replacement in hypothyroid patients is monitored by TSH and FT4 measurements, and is not monitored by measuring T3.

Measurement of Reverse Triiodothyronine

Several radioimmunoassay (RIA) methods for measuring rT3 have been developed and commercial assays are available. However, none of these assays have been adapted to automated platform because rT3 measurement has limited diagnostic value. The diagnosis of NTI can usually be established without measuring rT3.

Measurement of Free Thyroid Hormones

Numerous methods have been developed for assessing the concentrations of FT4 and FT3 in serum. These methods include (1) direct assays that currently serve as reference methods, and (2) indirect or estimate assays that are more widely available for general laboratory use.

Direct Reference Methods

Direct measurement of FT4 (and FT3) in serum is a technical challenge as the quantity of free hormone in normal serum is exceedingly low—typically less than 100 pmol/L (7.8 ng/dL).

Reliable methods for measuring FT4 and FT3 in serum include those that separate free and bound hormone fractions by (1) direct equilibrium dialysis or (2) ultrafiltration. After separation, the free concentration is measured by a sensitive analytical method, such as immunoassay or mass spectrometry.

Direct equilibrium dialysis. In this procedure isotopically labeled T4 or T3 “tracer” is added to the specimen before dialysis is performed. When equilibrium is established, concentrations of the tracer on both sides of the dialysis membrane are used to calculate the ratio of bound to free hormone, so the FT4 (or FT3) concentration can be calculated based on the total T4 or T3 concentration.

If the amount of tracer added to the specimen is small in comparison with the endogenous hormone concentration, minimal disruption of free/bound hormone is noted.

Ultrafiltration. The ultrafiltration procedure for FT4 determination in serum is significantly less time-consuming than dialysis. In this method, the serum specimen is (1) adjusted to a pH of 7.4, (2) incubated for 20 minutes at 37°C

(to achieve equilibrium of the binding at this temperature), and then (3) applied to an ultrafiltration device for centrifugation for 30 minutes at 37°C and $2000 \times g$ (using a fixed-angle rotor). Subsequently the ultrafiltrate is analyzed for T4 by immunoassay.

Free T4 assays based on ultrafiltration measure free hormone without the need for total hormone measurements. Direct equilibrium dialysis and ultrafiltration methods are unaffected by either variation in serum binding proteins or thyroid hormone autoantibodies. Mean values obtained in euthyroid healthy subjects are reported to be slightly higher when using ultrafiltration methods than when using equilibrium dialysis.

Indirect Methods for Estimating Free Thyroid Hormones

Two-step and one-step immunoassays estimate free hormone concentrations by using antibody extraction techniques. They are subdivided into *sequential two-step assays* and *simultaneous one-step ("analogue") assays*. The analogue methods are no longer used, and the sequential two-step assays are preferred. Each procedure involves the direct incubation of serum with a specific anti-T4 or anti-T3 antibody, during which thyroid hormones reach a new equilibrium with all of the binders present. A slight decrease in free hormone concentration occurs, but is insignificant if the antibody sequesters less than 5% of the total amount of hormone present in the specimen. Thus, the amount of immunoextracted T4 or T3 closely approximates the undisturbed free hormone concentration that preexists in serum at equilibrium.

Estimates of FT4 and FT3 generally give reliable results in (1) healthy subjects, (2) hyperthyroid and hypothyroid patients, and (3) patients with only mild binding protein abnormalities. Results are comparable with those of reference methods, such as those that use direct equilibrium dialysis. In certain clinical conditions, free hormone estimate methods may give abnormal results that differ from the generally accepted reference limits. These abnormalities are commonly encountered in euthyroid patients who show significant changes in T4 or T3 binding to serum proteins.

Measurement of Thyroxine-Binding Globulin

Modern TBG methods measure its concentration directly using a variety of immunochemical approaches. For example, one competitive, heterogeneous method measures the competition between endogenous TBG and labeled TBG for binding to an immobilized anti-TBG antibody. Another assay utilizes a solid-phase second antibody; bound conjugate that is measured by chemiluminescence after the addition of Luminol and hydrogen peroxide. A third immunoassay is based on enhanced microparticle turbidimetry, in which the presence of endogenous antigen inhibits the cross-linking of antigen-microparticle complexes by anti-TBG antibody, reducing the turbidity of the reaction mixture.

Measurement of Thyroglobulin

Tg is detectable in the plasma, and as such acts as a marker for the presence of active thyroid tissue. Tg concentrations are

determined by thyroid mass, TSH stimulation, and thyroid manipulation including surgery, fine-needle aspiration, or thyroid injury. The primary use of serum Tg measurement is as a tumor marker in patients with differentiated thyroid cancer (DTC) who have undergone thyroidectomy. It is difficult to measure Tg owing to the heterogeneity of the molecule, largely because of different glycoforms, and to the prevalence of endogenous anti-Tg or anti-reagent antibodies that interfere with the immunoassay. Current practice for thyroidectomized thyroid cancer patients is to withdraw thyroxine replacement to stimulate endogenous TSH secretion or to use recombinant human TSH to stimulate any residual or neoplastic thyroid tissue. This can be inconvenient, unpleasant, and expensive. Consequently, a Tg assay with the sensitivity to detect Tg in the absence of TSH stimulation (i.e., suppressed) is desirable. Three methods are in current use, each with its own advantages and limitations.

Competitive immunoassays have lower sensitivity (~5 ng/mL), are more labor intensive, but are robust to antibody interference compared to immunometric assays.

Immunometric assays are very sensitive (0.1 ng/mL or lower), amenable to automation, but prone to antibody interference. Immunometric Tg assays should be reported together with anti-Tg results.

Peptide mass spectrometric assays are limited by the relatively poor analytical sensitivity and low available mass range of mass spectrometric methods. However, they offer the promise of robustness to antibody interference.

Measurement of Thyroid Autoantibodies

Increased circulating concentrations of thyroid autoantibodies are found in a variety of thyroid disorders and in other autoimmune diseases and certain malignancies. These autoantibodies are directed against several thyroid and thyroid hormone antigens, including (1) Tg (TgAb), (2) thyroid peroxidase antibody (TPOAb), (3) the TSH receptor (TRAb), (4) TSH, (5) T4, and (6) T3. Of these autoantibodies, measurement of TPOAb is the test most often used to evaluate thyroid autoimmune diseases. TPOAb and TgAb are detected by a variety of methods, including (1) indirect immunofluorescence, (2) the agar gel diffusion precipitin technique, (3) agglutination (hemagglutination or latex particle agglutination), (4) RIA, (5) complement fixation, (6) ELISA techniques, and (7) chemiluminescence-based immunometric assays.

Measurement of Urinary Iodine Concentration

Because most of the body's iodine is excreted in urine, urinary iodine concentration (UIC) is considered a reliable and valid biomarker of the iodine intake and iodine deficiency of the population. Secondary measurements for estimating iodine deficiency are thyroid size, TSH concentration, and thyroid hormones.

THYROID DISEASE

Thyroiditis

Thyroiditis means inflammation of the thyroid. It encompasses many thyroid disorders, some of which have an

TABLE 42.4 Types of Autoimmune Thyroiditis

	Course	Features
Goitrous (Hashimoto) thyroiditis	Chronic	Goiter, lymphocytic infiltration, fibrosis, thyroid cell hyperplasia
Atrophic thyroiditis (primary myxedema)	Chronic	Atrophy, fibrosis
Juvenile thyroiditis	Chronic (may disappear)	Usually lymphocytic infiltration
Postpartum thyroiditis	Transient: may progress to chronic thyroiditis	Small goiter; some lymphocytic infiltration
Silent (painless) thyroiditis	Transient	Small goiter; some lymphocytic infiltration
Focal thyroiditis	Progressive in some patients	Present in the thyroid glands of 20% of people at autopsy

Reproduced from Weetman, A. P. (2012). Chronic autoimmune thyroiditis. In L. E. Braverman, & D. S. Cooper (Eds.), *Werner & Ingbar's the thyroid* (10th ed., p. 56). Philadelphia: Lippincott, Williams & Wilkins. Copyright Lippincott, Williams & Wilkins.

autoimmune etiology, including Hashimoto thyroiditis, painless sporadic thyroiditis, and painless postpartum thyroiditis (Table 42.4). The prevalence of individuals with high serum concentrations of thyroid antibodies varies with gender, age, and ethnicity; the prevalence is higher in women, in people older than 60 years of age, and in whites. It has been suggested that dietary iodine deficiency may be protective against certain types of thyroiditis because of the geographical variations in incidence seen in Hashimoto thyroiditis, painless postpartum thyroiditis, and painless sporadic thyroiditis.

The different types of thyroiditis may cause thyrotoxicosis, hypothyroidism, or both. All types of thyroiditis may eventually progress to permanent hypothyroidism, and the risk is higher in patients with high serum thyroid antibody concentrations. As thyroid function declines, TSH secretion increases, resulting in SCH (elevated TSH, normal T4 and T3), and later in overt hypothyroidism with clearly elevated TSH and a preferential expression of T3 but low T4, and finally, in thyroid failure, also low T3.

Autoimmune Thyroid Disease

Autoimmune thyroid disease comprises two main diseases, Hashimoto thyroiditis and Graves disease. The prevalence is estimated to be 5%, but the prevalence of thyroid antibodies in the general population is 10% to 20%. **Autoimmune thyroid disease (AITD)** is a T-cell-mediated disorder leading to an immune attack of the thyroid in an individual with genetic susceptibility accompanied by environmental factors. Examples of factors that increase the risk of AITD include ethnicity, pollutants (smoking, radioiodine), dietary (iodine excess, selenium deficiency), endocrine (female gender, parity, postpartum, oral contraceptives), infections, drugs, and trauma. Pathologically, AITD is characterized by lymphocyte infiltrates within the thyroid. AITD is associated with other autoimmune diseases, either organ specific (autoimmune polyglandular syndromes) or systemic (type 1 diabetes, rheumatoid arthritis, systemic lupus erythematosus, Sjögren syndrome, systemic sclerosis, cryoglobulinemia, sarcoidosis, psoriatic arthritis); these associations reflect common genetic susceptibilities and common pathogenic mechanisms. AITD is also associated with papillary thyroid cancer.

Hypothyroidism

Hypothyroidism is defined as a deficiency in thyroid hormone production or secretion producing a variety of clinical signs and symptoms of hypometabolism. The term *myxedema* is used in severe or complicated cases but strictly refers only to the appearance of the skin as it becomes infiltrated with glycosaminoglycans. Hypothyroidism is a common endocrine disorder that is often overlooked but often may present with serious signs and symptoms. The disorder is treatable with a good prognosis. Thyroid hormones affect the function of most of the organs and tissues of the body (Box 42.2). The clinical features of thyroid hormone deficiency are therefore quite diverse and may involve multiple systems. The thyroid gland itself may be enlarged as a goiter; either firm or granular in texture; tender or nontender, or normal, small, or impalpable, depending on the etiology of the hypothyroidism. Importantly, hypothyroidism may be overt or subclinical. Overt hypothyroidism is defined by a high serum TSH concentration and low serum FT4; SCH is defined by a high serum TSH (but usually <10 mIU/L) and a normal serum FT4 concentration.

Epidemiology

Worldwide, the most common cause of hypothyroidism is still iodine deficiency. However, in developed countries where iodine fortification is widespread, the most common cause of **primary hypothyroidism** is Hashimoto thyroiditis. Hypothyroidism is more common in women than men, increases with age, and is higher in whites than in blacks or Hispanics.

Etiology

Hypothyroidism has many etiologies (some of which are described in other sections of this chapter), including thyroiditis, particularly of autoimmune origin, postpartum phase, drugs, previous thyroid injury, hypothalamic or pituitary disorders in **central hypothyroidism**, and iodine deficiency (Boxes 42.3 and 42.4). Congenital hypothyroidism is discussed in a separate section.

Hashimoto thyroiditis. Hashimoto thyroiditis was first described in 1912 by Hakaru Hashimoto, a Japanese physician.

BOX 42.2 Clinical Manifestations of Hypothyroidism

Symptoms

Fatigue
Lethargy
Sleepiness
Mental impairment
Depression
Cold intolerance
Hoarseness
Dry skin
Hair loss
Decreased perspiration
Weight gain
Decreased appetite
Constipation
Menstrual disturbances (typically menorrhagia) and infertility
Arthralgia
Paresthesia

Signs

Goiter (may be present)
Slow movements
Slow speech
Hoarseness
Bradycardia
Dry skin
Loss of outer lateral eyebrow
Nonpitting edema (myxedema) (caused by accumulation of glycosaminoglycans in subcutaneous and other interstitial tissue)
Carpal tunnel syndrome
Psychosis
Galactorrhea
Hyporeflexia
Delayed relaxation of reflexes
Myopathy
Congestive cardiac failure (severe hypothyroidism)
Coma (severe hypothyroidism)
Growth failure and mental retardation (undetected congenital hypothyroidism)
Prolonged jaundice (neonatal hypothyroidism) (as a result of immaturity of uridine diphosphate glucuronyltransferase)

BOX 42.3 Causes of Hypothyroidism

Primary Hypothyroidism

Thyroid dysgenesis
Chronic autoimmune thyroiditis: atrophic and goitrous forms
Defective thyroid hormone biosynthesis
Congenital defects in thyroid hormonal biosynthesis
Iodine deficiency

Central Hypothyroidism

Pituitary disease
Hypothalamic disease

Transient Hypothyroidism

Silent (painless) thyroiditis including postpartum thyroiditis
Subacute thyroiditis (De Quervain syndrome)

BOX 42.4 Other Causes of Primary Hypothyroidism

Thyroid ablation
Subtotal and total thyroidectomy
Radioactive iodine therapy or surgery for
Graves disease
Thyrotoxicosis
Toxic nodular goiter
External radiotherapy for
Hodgkin and non-Hodgkin lymphoma
Solid cancers of the head and neck
Aplastic anemia
Leukemia
Pharmacologic agents
Lithium carbonate
Cytokines (interferon- α , interleukin-2)
Tyrosine kinase inhibitors
Iodine and iodine-containing drugs (e.g., amiodarone)
Other drugs: aminogluthethimide, ethionamide, sulfonamides
Infiltrative disorders
Riedel (invasive fibrous) thyroiditis
Amyloidosis
Sarcoidosis
Hemochromatosis
Scleroderma
Cystinosis
AIDS (including *Pneumocystis* infection)
Primary thyroid lymphoma
Toxic substances
Cigarettes
Industrial and environmental agents
Embryological variants
Lingual thyroid

Reproduced from Singer, P. A. (2013). Primary hypothyroidism due to other causes. In L. E. Braverman, & D. S. Cooper (Eds.), *Werner & Ingbar's the thyroid* (10th ed., p. 552). Philadelphia: Lippincott, Williams & Wilkins. Copyright Lippincott, Williams & Wilkins.

Also known as chronic lymphocytic thyroiditis, Hashimoto thyroiditis is the most common type of thyroiditis, and in iodine-sufficient areas it is also the most frequent cause of hypothyroidism and goiter. It leads to the destruction of thyroid follicular cells through a T-cell-mediated autoimmune process. Histologically, the gland is infiltrated with lymphocytes and plasma cells, which can lead to the development of secondary lymphoid follicles within the gland, which are similar to the secondary follicles observed in normal lymph nodes. The initial finding is usually a firm, symmetric goiter, but over time, the gland can atrophy, reflecting destruction of the gland. The gland may often be lobulated, which sometimes makes it difficult to distinguish from multinodular goiter. Although atrophy may occur in Hashimoto thyroiditis, atrophic thyroiditis may also occur when autoantibodies against the TSHR bind to the receptor and block the action of endogenous TSH. TSHR-blocking autoantibodies can cross the placenta during pregnancy, causing transient hyperthyrotropinemia in infants (elevated TSH with a normal T₄) or even

transient congenital hypothyroidism. Therefore, atrophic thyroiditis falls into the spectrum of AITDs.

The diagnosis of Hashimoto thyroiditis is supported by recognition of autoantibodies against TPO (anti-TPO) or Tg (anti-Tg). Ninety percent of patients with chronic lymphocytic thyroiditis (the histologic description of Hashimoto thyroiditis) have anti-TPO at presentation, and 20% to 50% have anti-Tg autoantibodies, making these autoantibodies excellent markers for the condition. The thyroid is hypoechogenic on ultrasound examination.

If overt hypothyroidism is present or SCH with high serum thyroid antibody concentrations, patients should be treated with levothyroxine with the goal of normalizing TSH. TSH-suppressing doses can be used short term to reduce goiter size. TSH should be used for monitoring. Serum thyroid antibody concentrations do not decrease with treatment.

There is a strong association between Hashimoto thyroiditis and primary B-cell lymphoma of the thyroid, although this is a rare condition. It is thought that prolonged stimulation of the intrathyroid B cells results in the emergence of a malignant clone. In addition, the frequency of papillary carcinoma may be increased in chronic autoimmune thyroiditis, particularly in women. Pain may indicate the presence of lymphoma. Fine-needle aspiration (FNA) biopsy or surgical biopsy may be required to distinguish between these conditions.

Central hypothyroidism. Central hypothyroidism is caused by an insufficient stimulation by TSH of an otherwise normal thyroid gland. The prevalence is estimated to be 1 in 20,000 to 1 in 80,000 in the general population, accounting for 1 in 1000 hypothyroid patients. Neonatal screening programs have shown a prevalence of congenital hypothyroidism of central origin of 1 in 160,000. In the Netherlands, the neonatal screening program using a combined TBG, TSH, and T4 strategy has shown that central hypothyroidism is diagnosed earlier with milder forms with an incidence of 1 in 16,000.

Central hypothyroidism may arise from pituitary disorders (secondary) or hypothalamic (tertiary) disorders including the pituitary stalk (Box 42.5). Tertiary hypothyroidism is a result of insufficient TSH stimulation by TRH.

Central hypothyroidism can be classified into invasive or compressive lesions, iatrogenic factors (e.g., cranial surgery or irradiation), injuries (e.g., head traumas), vascular accidents (e.g., pituitary apoplexia, postpartum pituitary [Sheehan] syndrome), autoimmune disease (e.g., polyglandular autoimmune diseases), infiltrative lesions (e.g., iron overload, sarcoidosis), inherited diseases, and infectious diseases (e.g., tuberculosis). Invasive or compressive lesions include pituitary macroadenomas, craniopharyngiomas, meningiomas or gliomas, Rathke cleft cysts, metastases, empty sella syndrome, and carotid aneurysms. The inherited forms are rare and may include TSH β mutations or TRH receptor mutations or pituitary transcription factor defects (mutations in *POU1F1*, *PROP1*, *HESX1*, *LHX3*, *LHX4*, or *LEPR*) with combined pituitary hormone deficiencies including TSH deficiency.

Transient or reversible forms of central hypothyroidism can be observed with drugs affecting the neuroendocrine TSH regulation, such as somatostatin analogs, glucocorticoids,

BOX 42.5 Possible Causes of Central Hypothyroidism

Invasive lesion: pituitary macroadenomas, craniopharyngiomas, meningiomas, gliomas, Rathke cleft cysts, metastases, carotid aneurysms

Iatrogenic: cranial surgery or irradiation, drugs

Injury: head traumas, traumatic delivery

Infarction: postpartum necrosis (Sheehan syndrome), pituitary apoplexy, ictus

Immunologic disease: lymphocytic hypophysitis, circulating anti-POU1F1 antibodies

Infiltrative lesion: sarcoidosis, hemochromatosis, histiocytosis X

Infectious disease: tuberculosis, syphilis, mycoses

Inherited: pituitary transcription factor defects (occasionally with childhood onset), TSH β and TRHR mutations

Idiopathic: Other unknown causes

Empty sella syndrome

TRHR, Thyrotropin-releasing hormone (TRH) receptor (TRHR) gene; *TSHB*, thyroid-stimulating hormone-beta (TSHB) gene.

Reproduced from Persani, L., & Beck-Peccoz, P. (2013). Central hypothyroidism. In L. E. Braverman, & D. S. Cooper (Eds.), *Werner & Ingbar's the thyroid* (10th ed., p. 561). Philadelphia: Lippincott, Williams & Wilkins. Copyright Lippincott, Williams & Wilkins.

or dopaminergic compounds acutely inhibiting TSH secretion; however, the thyroid stimulation may be inadequate to maintain a euthyroid status because the reduction in TSH and thyroid hormone concentrations activates the feedback mechanism. Transient or reversible forms may also occur during recovery from prolonged thyrotoxicosis or severe chronic diseases. Transplacental passage to the fetus of TSH receptor-stimulating antibodies or thyroid hormones from a thyrotoxic mother or corticosteroids or dopamine given to mothers during complicated delivery may also transiently affect neonates' suppression of TSH secretion and central hypothyroidism.

The clinical manifestations of central hypothyroidism (caused by either pituitary or hypothalamic disease) are similar to those of primary hypothyroidism but tend to be less severe (unless diagnosed in infancy). If a mass is taking up space in the cranium, headache, visual field disturbances, and hypopituitarism may develop. Nonthyroidal illness may have a similar picture as central hypothyroidism because of suppression of the hypothalamic-pituitary axis. Undiagnosed central hypothyroidism in infancy leads to cretinism.

The laboratory diagnosis is based on demonstration of low, normal, or slightly elevated TSH concentrations combined with low T4 or FT4 concentrations. In neonatal screening programs, central hypothyroidism can only be identified if TSH and T4 are both measured.

Subclinical hypothyroidism. SCH can be classified as mild (TSH between 4 and 9.9 mIU/L) or severe (TSH $\geq$ 10 mIU/L); the trimester of pregnancy and age-dependent cutoffs differ and should be applied as appropriate. The elevation in TSH should have persisted for 6 to 12 weeks or longer in the setting of FT4 concentrations that are repeatedly found within the reference interval. The prevalence increases with

TABLE 42.5 Patterns of Thyroid Dysfunction

	TSH	FT4	Comments
Primary hypothyroidism	Increased	Decreased	—
Subclinical primary hypothyroidism	Increased	Normal	—
Primary hyperthyroidism	Decreased	Increased	T3: increased
T3 toxicosis	Decreased	Normal	T3: increased
Subclinical primary hyperthyroidism	Decreased	Normal	T3: normal
Thyroid hormone resistance due to defects in the thyroid hormone receptor	Normal to increased	Increased	T3: increased; rT3: increased
Thyroid hormone resistance due to defects in thyroid hormone metabolism of T4 converted to T3	Mildly increased	Increased	T3: decreased; rT3: increased
Thyroid hormone resistance due to defects in thyroid hormone transport into cells	Normal to increased	Normal to decreased	T3: increased; rT3: decreased

T3, Triiodothyronine; rT3, reverse T3; FT4, free T4; T4, thyroxine; TSH, thyroid-stimulating hormone.

age and is higher in women than in men. Population prevalence differs; in the United States, it is estimated to be 4% to 9% in individuals without known thyroid disease.

Myxedematous coma. Patients with severe hypothyroidism may present with myxedematous (hypothyroid) coma, a syndrome of decreased consciousness, hypothermia, and other features of hypothyroidism. This condition has a high mortality and requires aggressive treatment in a critical care facility with facilities for mechanical ventilation if required.

Laboratory Diagnosis of Hypothyroidism

Serum TSH is the first-line measurement with an age-dependent reference interval usually between 0.4 and 4.2 mIU/L (see Appendix for reference intervals). *Overt hypothyroidism* is defined as increased TSH and low FT4 (Table 42.5). Autoantibodies should also be measured, indicating an autoimmune etiology. The British Thyroid Association recommends the combination of TSH and T4 (FT4 or total T4) as the first-line measurement.

Patients diagnosed with SCH (defined as increased TSH but FT4 within the reference interval) should be followed up with repeat measurements together with the measurement of TPO antibodies preferably after a 2- to 3-month interval. The presence of antibodies indicates increased risk of progression to overt hypothyroidism. Other conditions in which TSH is elevated but FT4 is normal encompass the recent institution of thyroid hormone replacement therapy (FT4 returns to normal before TSH declines), poor compliance with treatment in primary hypothyroidism, recovery from nonthyroidal illness, positively interfering heterophilic antibodies, (e.g., human antimouse antibodies) in double-antibody immunoassays, and thyroid hormone resistance.

In central hypothyroidism, the laboratory diagnosis is based on low, normal, or slightly elevated TSH combined with low total or free T4 concentrations.

Treatment

Levothyroxine sodium (thyroxine) is the treatment of choice for hypothyroidism with few adverse events if used appropriately.

Thyrotoxicosis

The term **thyrotoxicosis** refers to a condition with excess thyroid hormone. The term *hyperthyroidism* refers to a sustained increase in thyroid hormone biosynthesis and secretion by the thyroid gland. The term *thyrotoxicosis* relates to its clinical manifestations: a syndrome of hypermetabolism and hyperactivity resulting from an elevation of plasma T4 or T3 concentration (most usually both). The terms *thyrotoxicosis* and *hyperthyroidism* are not entirely synonymous. For example, thyrotoxicosis can occur as a result of excessive hormone release from the thyroid in the absence of increased synthesis, as may occur in thyroiditis. Excessive intake of thyroid hormones can also cause thyrotoxicosis but not hyperthyroidism. Box 42.6 summarizes the clinical manifestations of thyrotoxicosis.

Thyrotoxicosis can affect any physiological system in the body with the frequency and severity of signs and symptoms varying considerably among patients. Some of the causes produce characteristic clinical signs; for example, orbital and cutaneous manifestations, *which is unique to Graves disease*. The age of the patient and presence of concomitant disturbances may have an impact on the clinical features of hyperthyroidism, either exaggerating or diminishing them. For example, older patients may have less marked evidence of sympathetic activation, such as anxiety, hyperactivity, or tremor, and less weight loss but marked features of cardiovascular dysfunction such as congestive cardiac failure and atrial fibrillation.

Graves disease—the most common cause of hyperthyroidism—affects approximately 0.4% of the US population and occurs more often in women than in men (5:1). It is frequently associated with other autoimmune disorders. There is a genetic susceptibility to Graves disease, as shown by a sibling occurrence risk of 11.6% and a heritability of 75% in twin studies; the rest is environmental with smoking being a significant risk factor.

The causes of thyrotoxicosis are listed in the “Points to Remember” section. Thyrotoxicosis is usually associated with hyperthyroidism but not always. Common causes for

BOX 42.6 Clinical Manifestations of Thyrotoxicosis

Symptoms

Nervousness, stroke, agitation, or irritability
 Fatigue, lethargy
 Weakness
 Increased perspiration
 Heat intolerance
 Tremor
 Hyperactivity
 Palpitation
 Appetite change (usually increase)
 Weight change (usually weight loss)
 Increased bowel movement
 Menstrual disturbances

Signs

Hyperactivity
 Tachycardia or atrial arrhythmia
 Systolic hypertension
 Warm, moist, smooth skin
 Stare and eyelid retraction
 Tremor
 Hyperreflexia
 Muscle weakness
 Goiter
 Thyroid bruits (with Graves disease, exophthalmos, pretibial myxedema, onycholysis, thyroid acropachy)
 Digital clubbing, swelling of digits and toes
 Periosteal reaction at extremities of bones

thyrotoxicosis *not* associated with hyperthyroidism include (1) *thyroiditis* (silent painless thyroiditis, postpartum thyroiditis, subacute thyroiditis), and (2) *excess exogenous thyroid hormone* (iatrogenic or factitious).

The prevalence of the causes varies with iodine intake, such that in iodine-sufficient areas, Graves disease is the most common cause of thyrotoxicosis, accounting for 60% to 90% of cases. But in iodine-deficient areas, thyroidal autonomy is more common. Thyroiditis accounts for about 10% of all causes of thyrotoxicosis. Iodine fortification induces a temporary, modest increase in the incidence of hyperthyroidism in mild to moderate iodine-deficient regions.

Thyroid (Thyrotoxic) Storm

Thyroid storm (also known as thyrotoxic crisis) is a rare, severe, exaggerated, and life-threatening condition of thyrotoxicosis, which is triggered by precipitating factors (e.g., intercurrent illness or surgery). Thyroid storm is most often seen in the context of underlying Graves hyperthyroidism but can complicate thyrotoxicosis of any etiology.

Graves Disease

Graves disease results from an autoantibody that binds to and activates the TSHR, producing excessive release of thyroid hormone and clinical hyperthyroidism. In patients with Graves disease, the thyroid gland is no longer under the control of pituitary TSH but is constantly stimulated by the circulating

antibodies with TSH-like activity. Both B and T lymphocytes are known to be directed at three well-characterized thyroid autoantigens, namely Tg, TPO, and TSHR. However, the majority of the evidence suggests that TSHR is the primary autoantigen of Graves disease and that the immune response to the other two thyroid antigens is reflective of the resulting thyroiditis.

Graves ophthalmopathy has an autoimmune pathogenesis, with important genetic and environmental influences, particularly smoking. Orbital muscle, connective tissue, and adipose tissue are infiltrated by lymphocytes and macrophages. The extracellular compartment of extraocular muscles and orbital fibroadipose tissue becomes edematous, secondary to the deposition of hydrophilic glycosaminoglycans.

The diagnosis of Graves disease is based on laboratory demonstration of thyrotoxicosis, clinical features (particularly Graves disease-specific extrathyroidal manifestations, including ophthalmopathy and dermatopathy), and the presence of a moderate, diffuse, and soft goiter over which a vascular bruit may be detectable. Ophthalmopathy, thyroid dermatopathy, and acropachy occur in 25%, 1.5%, and 0.3 % of patients with Graves disease, respectively. Patients with ophthalmopathy who are smokers have a higher risk of developing or worsening of the condition (6% in nonsmokers vs. 23% in smokers).

Treatment of Graves disease includes antithyroid drugs (thionamides), radioiodine therapy, and thyroidectomy.

Toxic Adenomas and Toxic Multinodular Goiter

Toxic adenomas and **toxic multinodular goiter** are conditions in which thyrocytes function and produce thyroid hormones independently of thyrotropin (TSH) and TSHR-stimulating antibody. This autonomous secretion of thyroid hormones leads to TSH suppression and ultimately results in thyrotoxicosis. Such thyroid autonomy is a common finding in iodine-deficient areas, where it accounts for up to 60% of cases of thyrotoxicosis. However, thyroid autonomy is rare in regions with sufficient iodine supply (3% to 10% of cases with thyrotoxicosis).

Gain-of-Function Mutations of the Thyroid-Stimulating Hormone Receptor

A familial autosomal dominant form of hyperthyroidism has been described that is caused by gain-of-function mutations in the TSH receptor. The gain-of-function mutation places the TSHR in the “on” position in the absence of ligand (TSH) binding. In infants homozygous for such mutations, neonatal thyrotoxicosis, so severe as to require emergency thyroidectomy, has been observed. Certain heterozygous mutations have been reported to cause infantile hyperthyroidism.

Central Hyperthyroidism

Central hyperthyroidism is rare but is most frequently caused by nearly always benign thyroid-stimulating hormone-secreting pituitary adenomas. A total of 75% of the tumors are macroadenomas, having a diameter larger than 10 mm at the time of diagnosis, but microadenomas (diameter <10 mm) are increasingly recognized owing to earlier

diagnosis with improved imaging techniques. Patients with TSH-secreting tumors present with signs and symptoms of thyrotoxicosis, but extrathyroidal manifestations (i.e., ophthalmopathy, pretibial **myxedema**, and acropachy) are absent. Goiter is a common finding as a consequence of chronic TSH hyperstimulation. Patients may also have symptoms related to the mass effect of the pituitary adenoma such as visual field defects, headache, or loss of other anterior pituitary function (menstrual disorders, galactorrhea, acromegaly).

The laboratory diagnosis is based on a nonsuppressed TSH in the presence of high levels of free thyroid hormones (FT3 and FT4). Other diagnostic criteria include evidence of a pituitary mass on computed tomography or magnetic resonance imaging. There are both clinical situations (in particular) and possible laboratory artifacts that may cause a biochemical profile that is characteristic of patients with TSH-secreting tumors; these include thyroid hormone resistance, binding protein abnormalities, falsely high FT4 results, and falsely high TSH concentrations. The molar ratio of α -subunit to TSH may serve as a useful tumor marker in the differential diagnosis; in case of a TSH-secreting pituitary adenoma, the ratio of α -subunit to TSH concentration is typically larger than 1 ng/mL; in thyroid hormone resistance syndrome, the ratio is less than or equal to 1 ng/mL.

Subclinical Hyperthyroidism

The laboratory diagnosis of subclinical hyperthyroidism is defined by a low plasma TSH with normal concentrations of T4 and T3. The condition is classified as mild if TSH is in the range 0.1 to 0.4 mIU/L.

Persistent subclinical hyperthyroidism may be caused by exogenous iatrogenic overdose of levothyroxine or by endogenous causes as in primary hyperthyroidism such as Graves disease, toxic multinodular goiter, or solitary autonomous nodule. Exogenous subclinical hyperthyroidism is the most common and is reversible by reduction of levothyroxine dose.

Transitory subclinical hyperthyroidism may be caused by treatment with radioiodine or antithyroid drugs in patients previously with overt hyperthyroidism or as part of thyroiditis.

Diagnosis and Differential Diagnosis of Thyrotoxicosis

The diagnosis of Graves disease may be obvious if the patient has other clinical signs, such as exophthalmos. The laboratory diagnosis of thyrotoxicosis is based on a suppressed or low TSH and increased FT4 or increased FT3 or total T3. TSH is the most sensitive biomarker. A total of 2% to 4% of patients with hyperthyroidism have increased concentration of FT3 or total T3 but normal concentration of FT4 (T3 thyrotoxicosis). However, low TSH can also be caused by other conditions relevant for the diagnosis. Subclinical hyperthyroidism is defined as low TSH with normal circulating concentrations of T4 and T3. Low TSH may also be drug induced (glucocorticoids and dopamine) or caused by nonthyroidal illness.

In pituitary adenoma (secondary hyperthyroidism), TSH can be inappropriately normal or high for an elevated concentration of peripheral thyroid hormones.

If the etiology of thyrotoxicosis is uncertain, a radioactive iodine uptake test should be performed; iodine uptake of the thyroid gland is low in thyroiditis and high in Graves disease and autonomous nodules (single or multiple).

The presence of TRAB (TSHR-stimulating antibodies) effectively confirms a diagnosis of Graves disease. The likelihood of Graves disease is 1000- to 3000-fold greater if TRAB are present. Sensitivity and specificity for third-generation TRAB assays are high. A total of 75% of patients with Graves disease have TPO antibodies, an observation that may help differentiate this disease from toxic nodular hyperthyroidism if necessary.

Due to the side-effects of antithyroid drugs, patients with Graves disease should have a baseline complete blood count, including a white blood cell (WBC) count with differential, and a liver profile, including bilirubin and transaminases, before antithyroid drug therapy is initiated.

POINTS TO REMEMBER: CAUSES OF HYPERTHYROIDISM

Endogenous Thyroid Disorders

Autoimmune thyroid disease
Graves disease
Hashitoxicosis
Postpartum thyroiditis
Toxic multinodular goiter
Toxic adenoma
Struma ovarii
hCG-induced hyperthyroidism
Gestational hyperthyroidism

hCG-secreting tumors (trophoblastic tumor)
Atopic thyroid tissue
Secondary hyperthyroidism (pituitary tumor secreting TSH)

Exogenous Disorders

Thyroid destruction from viral or bacterial thyroiditis (e.g., de Quervain)
Iodine-induced hyperthyroidism (e.g., miodarone)
Thyroid hormone ingestion (thyrotoxicosis factitia)

hCG, Human chorionic gonadotropin; *TSH*, thyroid-stimulating hormone.

THYROID DISORDERS IN PREGNANCY AND POSTPARTUM

It is estimated that approximately 4% of pregnant women have a history of thyroid disease, develop thyroid disease during pregnancy, or are diagnosed for the first time with thyroid disease 5 years after a pregnancy.

Physiological Changes

Plasma T3 and T4 concentrations increase during pregnancy owing to an increase in TBG concentration. This increase is caused by enhanced hepatic synthesis and reduced metabolism (a result of increased estrogen levels) early in pregnancy, resulting in a 1.5-fold increase in TBG by 6 to 8 weeks of gestation. TBG remains elevated throughout pregnancy.

Placental hCG shares the same α subunit with TSH but has a unique β subunit and acts in early pregnancy as a TSH agonist by binding to TSH receptors on the thyroid gland. The physiological consequences of the mild hCG stimulation of the thyroid in early pregnancy leads to a physiological rise in T4 and T3, which, by the hypothalamic-pituitary-thyroid (HPT) axis feedback mechanism, inhibits TSH secretion, which causes TSH to fall. Serum TSH decreases in the first trimester and then rises during the second and third trimesters in response to falling hCG concentrations, but does not exceed pre-pregnancy values. There is transient rise in FT4 during the first trimester owing to the relatively high circulating concentration of hCG, and FT4 gradually falls in the second and third trimesters. Changes in FT3 concentrations broadly parallel those of FT4.

Concentrations of hCG are higher in a twin pregnancy, which causes a more pronounced transient TSH suppression in the first trimester relative to a singleton pregnancy.

Hypothyroidism in Pregnancy

A total of 2% to 3% of all iodine-sufficient pregnant women have undiagnosed hypothyroidism, mostly SCH. Overt hypothyroidism is estimated to occur in 0.5% of all pregnant women. Worldwide, the most common cause is endemic iodine deficiency. The main cause of hypothyroidism in iodine-sufficient populations is chronic autoimmune thyroiditis. Two percent have isolated hypothyroxinemia (e.g., low thyroid hormone without plasma TSH elevation and without the presence of autoantibodies). About 10% to 20% of women in the childbearing years have detectable autoantibodies (TPO or Tg autoantibodies).

The diagnosis of hypothyroidism in pregnancy is based, as in nonpregnant subjects, on the finding of an elevated serum TSH concentration with low concentrations of FT4, using trimester-specific reference intervals (see Appendix). Untreated overt maternal hypothyroidism is associated with adverse maternal and fetal outcomes. There is an increased risk of miscarriage, preterm delivery, and preeclampsia in the mother. In the newborn, there is an increased risk of neonatal mortality caused by preterm delivery, risk of low-for-gestational-age birth weight, and decreased IQ. The complications are similar in SCH, but occur at a lower frequency. Also, in euthyroid pregnant women, positive for thyroid peroxidase and Tg antibodies, the risks of miscarriage, preterm delivery, and postpartum thyroiditis are increased.

Thyrotoxicosis in Pregnancy

Graves disease occurs in 0.1% to 1% of all pregnancies. Gestational transient hyperthyroidism usually occurs in the first trimester with a prevalence of 2% to 3% in Europeans.

The causes of thyrotoxicosis in pregnancy are the same as for thyrotoxicosis generally; however, gestational transient hyperthyroidism is pregnancy specific. Thyrotoxicosis may be present before pregnancy or be diagnosed in pregnancy or postpartum.

The diagnosis of thyrotoxicosis in pregnancy is made by finding a low plasma TSH concentration and elevated concentrations of FT3 and/or FT4, compared to trimester-specific reference intervals. Subclinical hyperthyroidism in pregnancy is defined as a low plasma TSH concentration with normal concentrations of FT4 or FT3. In patients with Graves disease, TSH and thyroid hormones should be measured every 4 to 6 weeks during pregnancy.

The measurement of TSH receptor stimulating antibodies (TRAb) should be reserved for patients with Graves disease who become pregnant or if Graves disease is suspected during pregnancy. In the former, TRAb should be measured at diagnosis and at 24 to 28 weeks' gestation because these antibodies can cross the placenta, starting in the late second trimester. Testing for other thyroid autoantibodies is not required, although these are typically present in high titers.

GRAVES DISEASE IN PREGNANCY

Uncontrolled, untreated Graves disease is associated with adverse pregnancy outcomes during and following pregnancy. Risks for the mother include fetal loss, preeclampsia, miscarriage, premature labor, thyroid storm, and congestive heart failure. Risks for the fetus and neonate include hyperthyroidism caused by TSH receptor stimulating antibodies (TRAb) crossing the placenta (fetal tachycardia, accelerated bone maturation, fetal goiter, intrauterine growth restriction, and signs of congestive heart failure, low birthweight for gestational age, poor Apgar scores, and respiratory distress syndrome), risk of hypothyroidism caused by treatment with antithyroid drugs, and congenital abnormalities caused by hyperthyroidism and the teratogenic effects of antithyroid drugs. Neonatal hyperthyroidism is infrequent and occurs in 1 in 50,000 neonates born to mothers with Graves disease. However, if it is not recognized and treated properly, the mortality rate can be as high as 30%.

Gestational Transient Hyperthyroidism and Hyperemesis Gravidarum

Gestational transient thyrotoxicosis is a nonautoimmune hyperthyroidism occurring in pregnant women with a spectrum ranging from no emesis, to emesis, to hyperemesis gravidarum (when dehydration could be so severe that intravenous fluid replacement may be required). Gestational transient thyrotoxicosis occurs in 2% to 3% of all pregnancies and results from activation of TSH receptors by hCG. Serum hCG concentrations are positively correlated with the severity of nausea and vomiting. The thyrotoxicosis of hyperemesis gravidarum usually resolves spontaneously within several weeks as the vomiting disappears. The degree of hyperthyroidism is typically mild.

Postpartum Thyroiditis

Postpartum thyroiditis may be difficult to differentiate from Graves disease. The differences between the two include the presence of goiter, ophthalmopathy, and TRAb in Graves disease; these are usually not present in thyroiditis. Approximately

4% to 9% of unselected postpartum women develop postpartum thyroiditis, although the incidence varies with geographical location. Postpartum thyroiditis often recurs in subsequent pregnancies, and 50% of women eventually develop hypothyroidism.

Thyroid Function Testing in Pregnancy

TSH is a reliable indicator of thyroid function during pregnancy in most cases. Trimester-specific reference intervals for TSH and thyroid hormones should be applied (see Appendix). International guidelines recommend that trimester- and assay-specific reference intervals should be established or verified in each laboratory. If that is not possible, then reference intervals from the American Thyroid Association (ATA) should be applied.

Serum FT₄ and FT₃ are in the picomolar range, and to be valid, they are technically difficult to measure because they must be free from interference by the much higher total hormone concentrations (in the nanomolar range). The reliability of immunoassays for the measurement of FT₃ and FT₄ is decreased in pregnancy owing to higher TBG but lower albumin concentrations. Liquid chromatography–tandem mass spectrometry combined with equilibrium dialysis or ultrafiltration methods are more reliable for both total and free hormone measurements during pregnancy.

THYROID NEOPLASIA

The prevalence of palpable thyroid nodules in adults is about 5%, the prevalence of nodules found on ultrasonography is 13% to 30%, and the prevalence of nodules found on autopsy is 49% to 57%. The prevalence of cancer in single nodules has been estimated to be 5% and may be less frequent in multinodular goiter. Cancer risk depends on age, sex, radiation exposure, history, family history, and other factors.

There are four main types of thyroid cancer (listed from the most common to the least common): DTC, including (1) papillary, and (2) follicular thyroid cancer, accounting for more than 90% of thyroid cancers in United States; (3) medullary thyroid cancer (MTC) (<5%); and (4) anaplastic thyroid cancer, accounting for about 2%. Parafollicular or C cells secrete calcitonin and give rise to MTC, with an intermediate prognosis. About 80% of MTC is sporadic (i.e., not genetically inherited and occurs randomly), and the rest is hereditary.

The main role for the clinical biochemist is the monitoring of TSH suppression therapy, the determination of cancer ablation, the detection of recurrence in patients given definitive treatment, such as thyroidectomy, and the prognosis.

Diagnosis

Differentiated Thyroid Cancer

Patients with DTC have a favorable prognosis. Tg is not a diagnostic marker, but it is a useful marker for disease recurrence in thyroidectomized patients because it should be undetectable. Tg should not be used as a tumor marker in the presence of anti-Tg antibodies owing to measurement interference. Thyroid stimulation either by temporarily ceasing thyroid

hormone replacement or by the administration of recombinant TSH greatly increases the sensitivity of Tg measurement, but this may not be necessary using more sensitive Tg assays. The optimal cut-off for Tg for predicting recurrence is not known. There is a general agreement that a stimulated Tg less than 1 ng/mL, with no other radiologic or clinical evidence of disease and in the absence of autoantibodies, suggests no evidence of disease, although recurrence has been described below this cut point. Newer Tg assays have a functional sensitivity of 0.1 ng/mL or less (compared to older assays with 1 ng/mL); this allows for earlier identification of recurrence and helps avoid the use of TSH stimulation. As described earlier, immunometric assays for Tg and TgAbs are prone to interferences.

Medullary Thyroid Cancer

Calcitonin, produced by C cells, is a valuable blood tumor marker for MTC. Calcitonin is a 32-amino-acid monomeric peptide—the result of cleavage and the posttranslational processing of procalcitonin, which is itself a product of preprocalcitonin. Serum calcitonin can be used as a screening test in patients with a family history of MTC, who are at risk of developing the disease. The use of calcitonin as a screening marker in patients with nodular goiter and with no family history is debatable. Calcitonin also is used diagnostically as an immunohistochemical marker. Basal serum calcitonin and carcinoembryonic antigen (CEA) should be measured concurrently. CEA is not a specific biomarker for MTC and is not useful in the early diagnosis of MTC. However, CEA is useful for evaluating disease progression in patients with clinically evident MTC and for monitoring patients after thyroidectomy. All patients diagnosed with MTC should be tested for the genetic mutations associated with hereditary forms of the disease. To predict outcome and plan long-term follow-up in patients treated by thyroidectomy for MTC, tumor, node, metastasis classification, the number of lymph node metastases, and postoperative serum calcitonin and CEA should be used. Genetic status also determines the prognosis in patients with hereditary MTC.

Measurements of calcitonin also may be used to monitor for persistent or recurrent disease after surgery because the concentrations correlate with tumor burden. The MTC growth rate can be determined by measuring serum levels of calcitonin or CEA over multiple time points to determine the rate at which each marker's value doubles. Furthermore, serum TSH and serum calcium should be measured postoperatively. The goals are to get patients euthyroid and to prevent hypocalcemia.

Blood samples should be drawn in the fasting state. Calcitonin has a low stability in serum at room temperature, so the sample must be immediately separated and then frozen and transported on ice to the laboratory. The measurement of calcitonin is by immunoassay (e.g., immunochemiluminometry), which is prone to interferences. Because of inter-method differences, concentrations pre- and post-thyroidectomy and during treatment should be measured using the same assay and instrument in the same laboratory. Calcitonin values are

higher in men than in women, which is likely because of a higher C-cell mass. Calcitonin may also be high during the first week of life and in low-birthweight children and premature infants. Besides gender and age, pregnancy, lactation, and growth in children may also influence circulating concentrations of calcitonin. Calcitonin may be increased in nonthyroidal cancer, inflammation and sepsis, acute and chronic renal failure, hypercalcemia, pulmonary disease, and hypergastrinemia.

THYROID DISEASE IN CHILDREN

Thyroid disease can occur at any age; however, some characteristics in newborns, children, and adolescents are worth mentioning. The consequences of a hypofunctioning thyroid in developing and maturing children may be long lasting if not diagnosed and treated early. Neonatal hyperthyroidism may be caused by the transplacental passage of thyroid-stimulating maternal immunoglobulins (due to active maternal Graves disease) or by activating TSH receptor mutations (see subsequent text). In older children and adolescents, the most common cause of hyperthyroidism is Graves disease, and the most common cause of hypothyroidism in iodine-replete areas is Hashimoto thyroiditis.

Congenital Hypothyroidism

Before the introduction of newborn screening programs, the incidence of congenital hypothyroidism was estimated to be 1 in 7000 newborns. However, recent surveys estimate the incidence to be 1 in 2000 to 1 in 4000 newborns; the incidence is higher in Asians and Hispanics than in whites and blacks. The incidence is higher in older compared with younger mothers, and in preterm infants versus term infants. Incidence rates are dependent on TSH screening cut-offs.

Congenital hypothyroidism can be categorized into *permanent* and *transient* forms, which again can be divided into *primary* (thyroid disorder), *secondary* (i.e., central hypothyroidism; see earlier discussion), and *peripheral*. Permanent congenital hypothyroidism (75% to 86%) needs lifelong replacement treatment, but transient forms resolve within weeks to months after birth. Permanent primary congenital hypothyroidism may be caused by defects in thyroid development, thyroid dysgenesis (85%), or dyshormonogenesis (15%)—a biosynthesis defect of thyroid hormone production in a structurally normal gland. Thyroid dysgenesis may consist of either thyroid agenesis, failure of the gland to descend normally during embryologic development with or without ectopy, or hypoplasia of a normal localized gland. Central hypothyroidism occurs in 1 in 25,000 to 1 in 50,000 newborns.

Transient congenital hypothyroidism is most commonly caused by inadequate maternal iodine intake in areas of endemic iodine deficiency. It may also be caused by maternal antithyroid medication during pregnancy, transfer of maternal blocking antibodies, maternal iodine exposure (e.g., amiodarone), liver hemangiomas causing increased production of deiodinase 3, and genetic defects.

Unless born with thyroid agenesis, most newborns with congenital hypothyroidism have some thyroid function. Many newborns, even those with thyroid agenesis, do not present with classic symptoms and signs of hypothyroidism owing to transplacental passage of maternal thyroid hormones. Early symptoms and signs of congenital hypothyroidism include a lethargic infant with increased sleep, prolonged jaundice, myxedematous facies, large fontanelles, macroglossia, distended abdomen, hypothermia, and hypotonia. Later symptoms and signs include poor sucking effort leading to feeding difficulties, constipation, developmental delay with cognitive and growth retardation, myxedema, umbilical hernia, and decreased activity. Ten percent of children born with congenital hypothyroidism have other congenital birth defects, and 50% of them have congenital heart defects.

Levothyroxine is the treatment of choice with treatment goals to raise serum T4 and normalize serum TSH. Levothyroxine treatment can prevent mental retardation in the majority of children (>90%) if commenced within the first 2 weeks of life.

Laboratory Diagnosis of Congenital Hypothyroidism

Newborn screening for congenital hypothyroidism is a successful public health program for secondary prevention of mental retardation. Worldwide it is estimated that 25% of the newborn population undergoes screening for congenital hypothyroidism.

Screening strategies differ between countries, with some countries measuring TSH initially with a reflex T4 if TSH is abnormal. Others measure T4 as a first-line test, and if T4 is below a certain cut-off, they reflex test for TSH or measure a combination of TSH, T4, and Tg to differentiate between primary and secondary causes. The disadvantage of screening programs only measuring TSH with a reflex T4, is the inability to detect central hypothyroidism. The initial screening occurs on the second to fifth day of life; children discharged from the hospital on the first day of life may have a sample taken at this time. Some programs routinely obtain a second specimen at 2 to 6 weeks of age. Some programs use cord blood at birth, and others use a heel prick on filter paper after birth. Many programs now use the initial TSH measurement from heel prick blood on filter cards. Filter cards are mailed to a central laboratory. Each program has its own cut-offs for test results. Thyroid hormone levels and TSH are higher in the first days of life but have usually fallen to concentrations typically seen in infancy within the 2 to 4 weeks.

An abnormal result on screening should lead to a confirmatory test in a serum sample, but this should not delay treatment. Confirmatory testing includes TSH and free or total T4, and should be compared with appropriate age-dependent reference intervals (see Appendix for reference intervals). Further diagnostic tests may include radionuclide thyroid uptake and scanning, thyroid sonography, and serum Tg to determine the subtype of congenital hypothyroidism, but again these investigations should not delay the initiation of treatment.

False-positive elevations in TSH within the first 2 days of life may be revealed after repeated confirmatory testing. Transplacental transfer of heterophile antibodies is well described as a false-positive interference in blood spot TSH, and maternal thyroid function tests need to be checked in this context. Preterm infants with an immature HPT axis and acutely ill term infants may have a late rise in TSH and may not show elevated TSH on the first screening test; many programs have a second screening test for these babies. Dopamine used in the treatment of ill premature neonates can also attenuate TSH release. Seasonal variations in TSH occur with an increased false-positive rate of congenital hypothyroidism in the winter (0.9%) compared with the summer (0.6%); this is in accordance with globally conducted previous studies that have identified an increased prevalence of suspected and confirmed cases of congenital hypothyroidism in the winter months.

GENETICS

Evidence from twin studies has shown that about 65% of baseline TSH and thyroid hormone concentrations are genetically determined, with about 20% of the variability coming from common genetic variation at the population level. This suggests a genetic basis for narrow intraindividual variation in these hormone concentrations. Several loci have been identified in genome-wide association studies (GWAS) for the circulating concentrations of TSH, thyroid hormones, thyroid autoantibodies, and deiodinases.

Autoimmune susceptibility against the thyroid gland is estimated to affect 5% of the general population, and about 80% of this susceptibility can be explained by genetic factors.

Genetics in Congenital Hypothyroidism

Thyroid dyshormonogenesis is inherited in an autosomal recessive pattern. Thyroid dysgenesis, on the other hand, is inherited in only approximately 2% of cases; the rest are considered to be sporadic.

Thyroid-Stimulating Receptor Mutations and Resistance to Thyroid-Stimulating Hormone

Cases of familial thyrotoxicosis with no evidence of autoimmunity and children with persistent isolated neonatal hyperthyroidism should be evaluated for familial nonautoimmune autosomal dominant hyperthyroidism (FNAH) and persistent sporadic congenital nonautoimmune hyperthyroidism (PSNAH) caused by rare germline mutations in the *TSHR* gene.

Thyroid Hormone Receptor Mutations and Resistance to Thyroid Hormone

Two different thyroid hormone receptors are known; thyroid hormone receptor α ($THR\alpha$) and β ($THR\beta$), which are encoded by the *THRA* and *THRB* genes, respectively. Patients with mutations in *THRB* present with resistance to thyroid hormone β ($RTH\beta$) characterized by raised levels of thyroid hormone, normal or elevated levels of TSH, and goiter, suggesting a critical role for *THRB* in negative-feedback regulation.

Only a few patients with resistance to thyroid hormone α ($RTH\alpha$) have been described.

REVIEW QUESTIONS

- What is the most common type of laboratory assay that is widely used to assess thyroid hormone concentrations?
 - Ultrafiltration
 - Immunoassay
 - Potentiometry
 - Estimation from using a formula
- What stimulates the uptake of iodide by the thyroid gland for thyroid hormone synthesis?
 - Thyroid-stimulating hormone (TSH)
 - Thyroxine (T₄)
 - Tyrosine
 - Thyroiditis
- What causes primary hypothyroidism?
 - The absence or dysfunction of the thyroid gland
 - Increased TSH
 - A pituitary disorder
 - A hypothalamus disorder
- Hyperthyroidism is also referred to as
 - Athyreosis
 - Myxedema
 - Thyrotoxicosis
 - Exophthalmos
- What is the function of thyroid hormones?
 - Inhibit the secretion of growth hormone
 - Solely regulate reproductive processes in male and females
 - Maintain water homeostasis
 - Regulate carbohydrate, lipid, and protein metabolism within cells
- Secondary (or central) hypothyroidism* is indicated by which of the following sets of lab results?
 - Increased T₄, and decreased TSH
 - Increased T₄, and increased TSH
 - Decreased T₄, and increased TSH
 - Decreased T₄, and decreased TSH
- The thyroid gland produces all of the following hormones *except* which of the following hormones?
 - TSH
 - Calcitonin
 - Thyroxine (T₄)
 - Triiodothyronine (T₃)
- What is the amino acid precursor of T₄?
 - Threonine
 - Tyrosine
 - Thyronine

- d. Alanine
9. What is the technique of choice to measure T3 in body fluids?
- Nephelometry
 - Potentiometry
 - Immunoassay
 - Atomic absorption
10. Which of the following analytes is most sensitive for the early detection of primary thyroid gland failure?
- Thyroxine (T4)
 - TSH
 - Thyroglobulin (Tg)
 - Thyroid-binding globulin (TBO)

Reproduction-Related Disorders

Robert D. Nerenz, Emily Jungheim, Ann Gronowski

OBJECTIVES

1. Identify hormonal factors that determine male and female reproductive function.
2. Describe clinical symptoms associated with states of reproductive dysfunction.
3. Explain pathologic mechanisms responsible for infertility.
4. Describe laboratory tests used in the evaluation of reproductive disorders.

KEY WORDS AND DEFINITIONS

Amenorrhea The absence of menstruation.

Dehydroepiandrosterone (DHEA) The most abundant adrenal androgen.

Estradiol The predominant female sex steroid.

Follicle A pouch-like sac on the surface of the ovary that contains the maturing ovum (egg).

Follicle-stimulating hormone (FSH) A heterodimeric glycoprotein secreted by the pituitary gland that stimulates ovarian follicle maturation and sperm production.

Gonad A gamete-producing gland.

Gonadotropin-releasing hormone (GnRH) A hypothalamic polypeptide hormone that stimulates LH and FSH release by the pituitary gland.

Hypothalamus The portion of the brain just above the pituitary gland that regulates its endocrine functions.

Luteinizing hormone (LH) A heterodimeric glycoprotein secreted by the pituitary gland that stimulates gonadal sex steroid production and triggers ovulation.

Menopause Cessation of menstruation, which usually occurs around the age of 50.

Menses The monthly flow of blood from the female genital tract.

Pituitary The master regulatory endocrine gland located at the base of the brain.

Polycystic ovary syndrome (PCOS) A female condition that is characterized by multiple ovarian follicles, ovulatory dysfunction, and increased androgen production.

Progesterone A steroid hormone secreted by the corpus luteum and placenta with a primary role in maintaining pregnancy.

Ovary Female gonad.

Ovulation The process of ovarian egg release.

Sex hormone-binding globulin A circulating plasma protein that binds estradiol, testosterone, and dihydrotestosterone.

Testis Male gonad.

Testosterone The predominant male sex steroid.

Virilization The induction or development of male secondary sex characteristics; especially the induction of such changes in females.

BACKGROUND

The field of reproductive endocrinology encompasses the hormones of the hypothalamic-pituitary-gonadal axis and the adrenal glands; these hormones are crucial for reproductive function. Hypothalamic **gonadotropin-releasing hormone (GnRH)** directs the **pituitary** to synthesize and release **follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH)**, which in turn stimulate gonadal synthesis of the sex steroids that govern the development and maintenance of secondary sex characteristics. In states of reproductive health, serum concentrations of these hormones rise and fall in a tightly regulated and well-characterized pattern.

In states of reproductive dysfunction, measurement of these hormones in the clinical laboratory often provides the necessary information to identify the underlying abnormality and guide appropriate treatment.

MALE REPRODUCTIVE BIOLOGY

The mature **testes** synthesize both sperm and androgens. The testes contain a structured network of tightly packed seminiferous tubules, the lumina of which are lined by maturing germ cells and Sertoli cells. Sertoli cells play a crucial role in sperm maturation and secrete *inhibin*, a 32-kDa glycoprotein

that inhibits the pituitary secretion of FSH. Surrounding the seminiferous tubules are the interstitial Leydig cells, the primary site of androgen production. The principal androgen in humans is **testosterone**, which serves a central role in reproductive physiology. Testosterone is required for sexual differentiation, spermatogenesis, and the promotion and maintenance of sexual maturity at puberty. At the cellular level, these effects are mediated by binding of testosterone or its more potent metabolite dihydrotestosterone (DHT) to the androgen receptor or via aromatization to estradiol and subsequent binding to the estrogen receptor. Testicular function is under the control of the hypothalamic-pituitary-gonadal axis.

HYPOTHALAMIC-PITUITARY-GONADAL AXIS

GnRH is a decapeptide synthesized in the **hypothalamus** and transported to the anterior pituitary gland, where it stimulates the release of both FSH and LH.

In adult men, GnRH and thus LH and FSH are secreted in pulsatile patterns. A circadian rhythm is present, with higher concentrations found in the early-morning hours and lower concentrations in the late evening. LH acts on Leydig cells to stimulate the conversion of cholesterol to pregnenolone. FSH acts on Sertoli cells and spermatocytes and is central to the initiation (in puberty) and maintenance (in adulthood) of spermatogenesis. Sex steroids and inhibin provide negative feedback control of LH and FSH secretion, respectively.

Androgens

Androgens are a group of C-19 steroids (Fig. 43.1) responsible for masculinization of the genital tract and development and maintenance of male secondary sex characteristics. Testosterone is the principal androgen secreted in men.

Biosynthesis of Testosterone

Testosterone is synthesized primarily by the Leydig cells of the testes (95%) and, to a lesser extent ($\approx 5\%$), via peripheral conversion from the precursors **dehydroepiandrosterone (DHEA)** and androstenedione, which are synthesized in the zona reticularis of the adrenal glands (see Fig. 43.1).

Androgen Transport in Blood

Testosterone and DHT circulate in plasma freely ($\approx 2\%$ to 3%) or bound to plasma proteins. Binding proteins include the specific **sex hormone-binding globulin** (SHBG) and nonspecific proteins such as albumin. SHBG is an α -globulin that has low capacity for steroids but binds with very high affinity ($K_a = 1 \times 10^8$ to 1×10^9), whereas albumin has high capacity but low affinity ($K_a = 1 \times 10^4$ to 1×10^6). SHBG has the highest affinity for DHT and the lowest for estradiol.

The biologically active fraction includes free testosterone; some have suggested that albumin-bound testosterone may also be available for tissue uptake. Therefore the bioavailable testosterone is equal to approximately 35% of the total quantity (free + albumin-bound).

Testosterone and SHBG exhibit rhythmic variation in their circulating concentrations. Testosterone concentrations peak at approximately 0400 to 0800 hours, and nadir concentrations occur at between 1600 and 2000 hours. Daily variations in SHBG concentrations are similar to those of other proteins and albumin in serum, with major changes related to posture. Concentrations of SHBG are elevated with hyperthyroidism and in hypogonadal men.

Metabolism of Testosterone

Circulating testosterone serves as a precursor for the formation of two additional active metabolites: DHT and estradiol. In one pathway, 5α -reductase converts 6% to 8% of testosterone to DHT. Both testosterone and DHT bind the androgen receptor, but DHT binds with higher affinity. In an alternative pathway, testosterone and androstenedione are converted to estrogens ($\approx 0.3\%$) through aromatase (CYP19). DHT is formed in androgen target tissues such as the skin and prostate, whereas aromatization occurs in many tissues, especially the liver and adipose tissue. Peripheral aromatization occurs primarily in adipose tissue (of both men and women) because of the high concentration of aromatase in this tissue. The rate of extraglandular aromatization therefore increases with body fat.

The main excretory metabolites of androstenedione, testosterone, and DHEA are shown in Fig. 43.2. Except for epitestosterone, these catabolites constitute a group of steroids known as **17-ketosteroids** (17-KS); they are excreted primarily in the urine.

Testosterone Concentrations

Testosterone is required for proper sexual development and function throughout all stages of life: fetal, pubertal, and adult (Fig. 43.3). Fetal testes produce testosterone around the seventh week of gestation, with peak serum concentrations of approximately 250 ng/dL (8.7 nmol/L) observed at the beginning of the second trimester, and with concentrations gradually returning to baseline by birth. Shortly after birth, the concentration of testosterone begins to increase, peaking again at approximately 250 ng/dL (8.7 nmol/L) at 2 to 3 months of age, and then falling to baseline again by 6 to 12 months. The concentration of testosterone remains low (<50 ng/dL, 1.7 nmol/L) until puberty, when the concentration of testosterone rises to 500 to 700 ng/dL (17.3 to 24.3 nmol/L). Testosterone remains elevated through adulthood until around the third to fourth decade.

Men beyond 30 to 40 years of age experience an age-dependent decrease in circulating testosterone concentration, estimated at 0.5% to 2% per year from about the fourth decade onward. This decline in testosterone is thought to be due to (1) a decrease in Leydig cell numbers, (2) decreased GnRH pulse amplitude, and (3) increases in SHBG. In the past, these decreases in circulating concentrations of testosterone were viewed as a normal part of the aging process. Now, however, these decreases, when accompanied by symptoms of decreased libido, sexual dysfunction, decreased energy levels, and decreased muscle mass, are regarded as a syndrome

Fig. 43.1 Biosynthesis of androgens (adrenal glands and testis). The heavy arrows indicate the preferred pathway. The circled area represents the site of chemical change. *Denotes androgens.

Fig. 43.2 Catabolism of C19O2 androgens. The circled area represents the site of chemical change.

Fig. 43.3 Schematic diagram of different phases of male sexual function during life as indicated by mean plasma testosterone concentration and sperm production at different ages. (From Griffin, J. E., & Wilson, J. D. [1980]. The testis. In P. K. Bondy, & L. E. Rosenberg [Eds.], *Metabolic control and disease* [8th ed., pp. 1535–1578]. Philadelphia: WB Saunders.)

with a variety of names, such as androgen deficiency in the aging male (ADAM), partial androgen deficiency of the aging male (PADAM), late-onset hypogonadism (LOH), and, erroneously, andropause. The name *andropause* is inaccurate and misleading, given that in contrast to menopause in women, concentrations of sex steroids in men do not decrease sharply with secondary cessation of reproductive function. A name put forward more recently is *testosterone deficiency syndrome* (TDS), highlighting a specific deficit in testosterone as part of the clinical picture.

Diagnosis of LOH (TDS) should be based on both clinical and laboratory assessment. Clinically, patients should exhibit symptoms suggestive of testosterone deficiency, such as decreased libido, erectile dysfunction, decreased muscle mass and strength, decreased bone mineral density, and changes in mood. Patients should exhibit one to three of these symptoms with a concomitant low concentration of serum testosterone to fit various diagnostic criteria. Total serum testosterone is the most widely used biochemical parameter for assessment of hypogonadism, but measurement of free or bioavailable testosterone should be considered when total testosterone is not diagnostic despite the clinical presentation of hypogonadism.

Male Reproductive Abnormalities

A wide variety of abnormalities can affect the male reproductive system before birth, in childhood, or in adulthood. For the purposes of this chapter, they have been divided into categories of (1) hypogonadotropic hypogonadism, (2) hypergonadotropic hypogonadism, (3) defects in androgen action (Box 43.1), (4) erectile dysfunction, and (5) gynecomastia.

Hypogonadotropic Hypogonadism

Hypogonadotropic hypogonadism occurs when defects in the hypothalamus or pituitary prevent normal gonadal stimulation. Causative factors include congenital or acquired panhypopituitarism, hypothalamic syndromes, GnRH deficiency, hyperprolactinemia, malnutrition or anorexia, and iatrogenic causes. All of these abnormalities are associated with decreased testosterone and gonadotropin concentrations.

Kallmann syndrome, the most common form of hypogonadotropic hypogonadism, results from a deficiency of GnRH in the hypothalamus during embryonic development. It is characterized by hypogonadism and anosmia (loss of the sense of smell) in male or female patients and is inherited as an autosomal dominant trait with variable penetrance.

Hypergonadotropic Hypogonadism

Hypergonadotropic hypogonadism results from a primary gonadal disorder. Patients with primary testicular failure have increased concentrations of LH and FSH and decreased concentrations of testosterone. Causes of primary hypogonadism are categorized as (1) acquired causes (irradiation, castration, mumps orchitis, or cytotoxic drugs), (2) chromosomal defects (Klinefelter syndrome), (3) defective androgen synthesis (20 α -hydroxylase deficiency), (4) testicular agenesis, (5) seminiferous tubular disease, and (6) other miscellaneous

BOX 43.1 Male Reproductive Abnormalities

Hypogonadotropic Hypogonadism

Panhypopituitarism (congenital or acquired)
Hypothalamic syndrome (acquired or congenital)
Structural defects (neoplastic, inflammatory, and infiltrative)
Prader-Willi syndrome
Laurence-Moon-Biedl syndrome
GnRH deficiency (Kallmann syndrome)
Hyperprolactinemia (prolactinoma or drugs)
Malnutrition and anorexia nervosa
Drug-induced suppression of luteinizing hormone (androgens, estrogens, tranquilizers, antidepressants, antihypertensives, barbiturates, cimetidine, GnRH analogs, and opiates)

Hypergonadotropic Hypogonadism

Acquired (irradiation, mumps orchitis, castration, and cytotoxic drugs)
Chromosome defects
Klinefelter syndrome (47,XXY) and mosaics
Autosomal and sex chromosomes, polyploidies
True hermaphroditism
Defective androgen biosynthesis
20 α -Hydroxylase (cholesterol 20,22-desmolase) deficiency
17,20-Lyase deficiency
3 β -Hydroxysteroid dehydrogenase deficiency
17 α -Hydroxylase deficiency
17 β -Hydroxysteroid dehydrogenase deficiency
Testicular agenesis
Selective seminiferous tubular disease
Miscellaneous
Noonan syndrome (short stature, pulmonary valve stenosis, hypertelorism, and ptosis)
Streak gonads
Myotonia dystrophica
Acute and chronic disease

Defects in Androgen Action

Complete androgen insensitivity (*testicular feminization*)
Partial androgen sensitivity
5 α -Reductase deficiency

GnRH, Gonadotropin-releasing hormone.

causes. Aging is associated with gonadal failure, specifically, decreased Leydig cell mass and reserve capacity with reduction in pulsatile secretion of GnRH by the hypothalamus, leading to decreased testosterone secretion.

Defects in Androgen Action

The most common and severe defect in androgen action is *androgen insensitivity syndrome* (AIS), a disorder arising from mutations in the androgen receptor gene (AR). AIS may be classified as complete (CAIS) or partial (PAIS), depending on the amount of residual receptor function. Individuals with complete AIS (formerly known as testicular feminization) have a male karyotype (46,XY) with female external genitalia (labia, clitoris, and vaginal opening). The testes are present intra-abdominally,

and because they produce anti-Müllerian hormone (AMH), no uterus, fallopian tubules, or proximal vagina is present. The circulating concentration of testosterone in these patients is greater than or equal to that of a healthy male. Concentrations of LH are increased, presumably because of resistance of the hypothalamic-pituitary system to androgen inhibition.

Males with *5 α -reductase deficiency* (5-ARD) do not convert testosterone to the more potent DHT. Because DHT leads to masculinization of external genitalia in utero, males are born with ambiguous genitalia. High ratios of the circulating concentrations of testosterone to DHT are indicative of 5-ARD. Moreover, evidence indicates that DHT formation is deficient in the tissues of the urogenital tract in these patients.

In patients with cryptorchidism or ambiguous genitalia, identification of abdominal gonads is essential for proper diagnosis and treatment. The presence of testicular tissue has traditionally been detected by the measurement of Leydig cell testosterone production after stimulation with human chorionic gonadotropin (hCG). A growing appreciation of the assessment of Sertoli cell function has been noted. Inhibin and AMH reflect Sertoli cell function and may offer a noninvasive evaluation of the integrity of the seminiferous tubules.

Erectile Dysfunction

Erectile dysfunction (formerly referred to as *impotence*) is the persistent inability to develop or maintain a penile erection that is sufficient for intercourse and ejaculation in 50% or more of attempts. A wide variety of organic and psychologic abnormalities may cause changes in sexual drive and in the ability to have an erection or to ejaculate. Psychogenic erectile dysfunction is the most common diagnosis. Other causes include vascular disease, diabetes mellitus, hypertension, uremia, neurologic disease, hypogonadism, hyperthyroidism and hypothyroidism, neoplasms, and drugs. If no obvious explanation for erectile dysfunction can be found, measurement of morning serum testosterone, LH, and thyroid-stimulating hormone (TSH) concentrations has been suggested. Elevated gonadotropin concentrations indicate primary hypogonadism.

Gynecomastia

Gynecomastia, the benign growth of glandular breast tissue in men, is a common finding among males of various ages. This condition, which is related to an increase in the estrogen/androgen ratio, is commonly associated with three distinct periods of life. First, transient gynecomastia can be found in 60% to 90% of all newborns because of the high estrogen concentrations that cross the placenta. The second peak occurs during puberty in 50% to 70% of normal boys. It is usually self-limited and may be due to low serum testosterone, low DHT, or a high estrogen/androgen ratio. The last peak is found in the adult population, most frequently among men aged 50 to 80 years. Gynecomastia may be due to testicular failure, resulting in an increased estrogen/androgen ratio, or to increased body fat, resulting in increased peripheral aromatization of testosterone to estradiol. It is important to note that prolactin plays an important role in *galactorrhea* (milk production) but only an indirect role in gynecomastia.

POINTS TO REMEMBER

- GnRH stimulates LH and FSH release, which increase testosterone and sperm production, respectively.
- LH secretion is inhibited by testosterone and FSH secretion is inhibited by inhibin.
- Testosterone is transported in blood tightly bound to SHBG and loosely bound to albumin.
- Free testosterone is biologically active and represents 2% to 3% of total testosterone.
- Pituitary defects result in hypogonadotropic hypogonadism.
- Primary gonadal defects result in hypergonadotropic hypogonadism.

FEMALE REPRODUCTIVE BIOLOGY

The ovaries produce ova and secrete the sex hormones progesterone and estrogen. Every healthy female neonate possesses approximately 400,000 primordial follicles, each containing an immature ovum. During the reproductive life span of an adult woman, 300 to 400 follicles will reach maturity. A single mature **follicle** is produced during each normal menstrual cycle at approximately day 14. Surrounding the oocyte of the mature follicle are three distinct cell layers: *theca externa*, *theca interna*, and *granulosa cells*. The theca interna cells are the primary source of androgens, which are transported to adjacent granulosa cells, where they are aromatized to estrogens.

The mature follicle undergoes ovulation by the process of rupture, thereby releasing the oocyte into the proximity of the fallopian tubes. The follicle then fills with blood to form the corpus hemorrhagicum. The granulosa and theca cells of the follicle lining quickly proliferate to form lipid-rich luteal cells, replacing the clotted blood and forming the *corpus luteum* (yellow body). The luteal cells produce estrogen and progesterone. If fertilization and pregnancy occur, the corpus luteum persists and continues to produce estrogen and progesterone. If no pregnancy occurs, the corpus luteum regresses, and the next menstrual cycle begins.

The uterine cavity is lined by the endometrium. The endometrium undergoes cyclic changes in preparation for implantation and pregnancy in response to cyclic changes in estrogen and progesterone. During the follicular phase, the endometrial lining increases in thickness and vascularity in response to increasing circulating concentrations of estrogen; after regression of the corpus luteum, menstruation begins, and the endometrium is shed in response to the withdrawal of progesterone.

Hypothalamic-Pituitary-Gonadal Axis

In adult women, a tightly coordinated feedback system exists between the hypothalamus, anterior pituitary, and ovaries to orchestrate menstruation. FSH serves to stimulate follicular growth, and LH stimulates ovulation and progesterone secretion from the developing corpus luteum.

Fig. 43.4 Biologically active estrogens.

Estrogens

Estrogens are responsible for the development and maintenance of female sex organs and female secondary sex characteristics. In conjunction with progesterone, they participate in regulation of the menstrual cycle and of breast and uterine growth as well as in the maintenance of pregnancy.

Estrogens affect calcium homeostasis and have a beneficial effect on bone mass. They decrease bone resorption and accelerate linear bone growth in prepubertal girls, resulting in epiphyseal closure. Long-term estrogen depletion is associated with loss of bone mineral content, an increase in stress fractures, and postmenopausal osteoporosis.

Estrogens also have well-established effects on plasma proteins that influence endocrine testing. They increase concentrations of SHBG, corticosteroid-binding globulin, and thyroxine-binding globulin. Hence boys and girls have comparable concentrations of SHBG, but adult men have SHBG concentrations that are about half those of adult women. Concentrations of plasma proteins that bind copper and iron are also elevated in response to estrogen, as are those of high-density and very high-density lipoproteins. In addition, estrogens are believed to play a preventive role in coronary heart disease.

Chemistry

The three most biologically active estrogens in order of potency are estradiol (E₂), estrone (E₁), and estriol (E₃) (Fig. 43.4).

Biosynthesis

The biochemical pathway illustrating aromatization of testosterone to estradiol and androstenedione to estrone is shown in Fig. 43.5.

Estrogens are secreted primarily in healthy women by the ovarian follicles and the corpus luteum and during pregnancy by the placenta. The adrenal glands and testes (in men) are also believed to secrete minute quantities of estrogens. The **ovary** synthesizes estrogens via aromatization of androgens. Synthesis of estrogens begins in the theca interna cells with the enzymatic synthesis of androstenedione from cholesterol.

Androstenedione is then transported to the granulosa cells, where it is further metabolized directly to estrone (androstenedione → estrone), or first to testosterone and then to estradiol (androstenedione → testosterone → estradiol). These conversions are catalyzed by the enzyme aromatase. The healthy human ovary produces all three classes of sex steroids: estrogens, progestagens, and androgens; however, estradiol and progesterone are its primary secretory products. The most potent estrogen secreted by the ovary is 17β-estradiol. Because it is derived almost exclusively from the ovaries, its measurement is often considered sufficient for the evaluation of ovarian function.

Estrogens are also produced by the peripheral aromatization of androgens, primarily androstenedione. In healthy men and women, approximately 1% of secreted androstenedione is converted to estrone. Although the ovaries of postmenopausal women do not secrete estrogens, these women have significant blood concentrations of estrone originating from the peripheral conversion of adrenal androstenedione. Because a major site of this conversion is adipose tissue, estrone is increased in obese postmenopausal women, sometimes yielding enough estrogen to produce bleeding.

Biosynthesis During Pregnancy

Estrogen biosynthesis differs qualitatively and quantitatively in pregnant women compared with nonpregnant ones. In pregnant women the major source of estrogens is the placenta, whereas in nonpregnant women the ovaries are the main site of synthesis. In contrast to the microgram quantities secreted by nonpregnant women, the quantity of estrogens secreted during pregnancy increases to milligram amounts. The major estrogen secreted by the ovary is **estradiol** (E₂), whereas the major product secreted by the placenta is estriol (E₃). Estriol is formed in the placenta by sequential desulfation and aromatization of plasma dehydroepiandrosterone sulfate (DHEA-S). Except during pregnancy, measurements of E₃ have little clinical value.

Transport in Blood

More than 97% of circulating E₂ is bound to plasma proteins. It is bound specifically and with high affinity to SHBG and nonspecifically to albumin. SHBG concentrations are increased by estrogens and therefore are higher in women than in men. They are also increased during pregnancy, oral contraceptive use, hyperthyroidism, and administration of certain antiepileptic drugs such as phenytoin (Dilantin). SHBG concentrations may decrease in hypothyroidism, obesity, or androgen excess. Only 2% to 3% of total E₂ circulates in free form. In contrast, estrone and estrone sulfate circulate bound almost exclusively to albumin. As with testosterone, both free and albumin-bound fractions of E₂ are thought to be biologically available, but measurement of this fraction has not been shown to be clinically important.

Metabolism

The metabolism of E₂ is chiefly an oxidative process dominated by three pathways, of which the fastest is oxidation of

Fig. 43.5 Biosynthesis of estrogens. Heavy arrows indicate the Δ^5 -3 β -hydroxy pathway. The circled area represents the site of chemical change. See Fig. 43.1 for early synthetic steps.

Fig. 43.7 Structural formulas of progesterone and 19-nortestosterone.

the β-hydroxy group at C-17 to a ketone (estradiol → estrone). This process is reversible; however, equilibrium favors the estrone species (Fig. 43.6).

Progesterone

Progesterone, similar to the estrogens, is a female sex hormone (Fig. 43.7). In conjunction with estrogens, it helps to regulate the accessory organs during the menstrual cycle. This hormone is especially important in preparing the uterus for implantation of the blastocyst and in maintaining pregnancy. In nonpregnant women, progesterone is secreted mainly by the corpus luteum. During pregnancy, the placenta

becomes the major source of this hormone. Minor sources are the adrenal cortex in both sexes and the testes in men.

Biosynthesis

Biosynthesis of progesterone in ovarian tissues follows the same path, from acetate to cholesterol through pregnenolone, as it does in the adrenal cortex (see Fig. 43.1). In luteal tissue, however, low-density lipoprotein cholesterol is thought to serve as the preferred precursor despite the potential of the corpus luteum to synthesize progesterone *de novo* from acetate. Initiation and control of luteal secretion of progesterone are regulated by LH and FSH.

Fig. 43.8 Metabolism of progesterone. The circled area represents the site of chemical change.

Transport in Blood

Progesterone does not have a specific plasma-binding protein but is primarily bound to albumin with a smaller fraction bound to corticosteroid-binding globulin. Reported concentrations for plasma free progesterone vary from 2% to 10% of total concentration, and the percentage of unbound progesterone remains constant throughout the normal menstrual cycle. The production rate of progesterone during the luteal phase reaches as high as 30 mg/day (95 μ mol/day), whereas the production rate of progesterone by the placenta during the third trimester of pregnancy is approximately 300 mg/day (950 μ mol/day).

Metabolism

The important metabolic events leading to inactivation of progesterone are reduction and conjugation. The main metabolic pathway for the metabolism of progesterone is outlined

in Fig. 43.8. Reduced metabolites are eventually conjugated with glucuronic acid and excreted as water-soluble glucuronides.

Female Reproductive Development

Reproductive development begins with anatomy during the fetal period, followed by a postnatal period of adaptation to reduced maternal sex steroids, and finishes with sexual maturation during puberty. Normal females remain fertile and menstruating until menopause.

Fetal

In the genotypic female, lack of testosterone and AMH causes regression of the Wolffian ducts and maintenance of the Müllerian ducts, thus forming the female reproductive tract. Gonadotropin activity in utero is suppressed because of high concentrations of circulating estrogens derived from the mother.

Fig. 43.9 Hormonal, ovarian, endometrial, and basal body temperature changes throughout the normal menstrual cycle. E_2 , Estradiol; FSH , follicle-stimulating hormone; LH , luteinizing hormone. (From Carr, B. R., & Bradshaw, K. D. [2001]. Disorders of the ovary and female reproductive tract. In E. Braunwald, A. Fauci, D. Kasper, S. L. Hauser, D. L. Longo, & J. J. Jameson [Eds.], *Harrison's principles of internal medicine* [15th ed., p. 2158]. New York: McGraw-Hill; used with permission.)

Postnatal

When the placenta separates, concentrations of fetal sex steroids drop abruptly. Serum E_2 in neonates is decreased to basal concentrations within 5 to 7 days after birth and persists at this concentration until puberty. The negative feedback action of steroids is now removed and gonadotropins are released. Postnatal peaks of LH and FSH are measurable for a few months after birth, peaking at 2 to 5 months and then dropping to basal concentrations. During childhood, circulating concentrations of sex steroids and gonadotropins are low and are similar for both sexes. However, in patients with hypogonadism (Turner syndrome), LH and FSH concentrations are higher than in healthy children.

Puberty

The transition from sexual immaturity appears to begin with diminished sensitivity of the pituitary gland, hypothalamus, or both to the negative feedback effect of sex steroids. The mechanism for this change is unclear. As puberty approaches, nocturnal secretion of gonadotropins occurs. Concentrations of LH, FSH, and gonadal steroids rise gradually over several years before stabilizing at adult concentrations when full sexual maturity is reached. In girls, puberty is considered precocious if the onset of pubertal development (secondary sex characteristics) occurs before age 8 years and is considered delayed if no development has occurred by age 13 years or menarche has not occurred by age 16.5 years.

Adrenarche precedes puberty by a few years. In girls, the rise in adrenal androgen concentrations (DHEA, DHEA-S, and androstenedione) begins at age 6 to 7 years. This rise lasts until late puberty. In girls, puberty is associated with elevations in estrogen secretion by the ovary in response to gonadotropin concentrations that increase in response to GnRH. Estrogen secretion by the ovary increases, causing enlargement of the uterus and breasts. In the breast, estrogen enhances the growth of ducts; progesterone augments this effect. As the breast develops, estrogen increases adipose tissue around the lactiferous duct system, contributing to the further enlargement of breast tissue. These physiologic and physical processes associated with puberty in girls culminate in *menarche*—the beginning of menstrual function and the first menstrual period.

Normal Menstrual Cycle

During a normal menstrual cycle, a closely coordinated interplay of feedback effects occurs between the hypothalamus, anterior lobe of the pituitary gland, and ovaries. In addition, cyclic hormonal changes lead to functional and structural changes in the ovaries (follicle maturation, ovulation, and corpus luteum development), uterus (preparation of the endometrium for possible implantation of the fertilized ovum), cervix (to permit transport of sperm), and vagina (Fig. 43.9).

Phases. The menstrual cycle is measured beginning on day 1 as the first day of menstrual bleeding. Each cycle consists of a follicular phase followed by ovulation and then a luteal phase.

Follicular phase. The *follicular phase*—that is, the selection and growth of the dominant follicle—begins during the last few days of the previous luteal phase and terminates at ovulation (see Fig. 43.9). During the early part of the follicular phase, concentrations of FSH rise and then decline until ovulation (see Fig. 43.9). LH secretion begins to increase around the middle of the follicular phase. Just before ovulation, estrogen secretion by the follicle increases dramatically; this positively stimulates the hypothalamus and triggers the LH surge, which is a reliable predictor of ovulation, with onset of the surge for 90% of women occurring 16 to 58 hours before ovulation and the peak occurring 3 to 36 hours before ovulation. Ovulation occurs around day 14 in a 28-day menstrual cycle.

Luteal phase. The *luteal phase*, the last half of the cycle, is characterized by the increasing production of progesterone and estrogen from the corpus luteum with consequent gradual lowering of LH and FSH concentrations. The concentration of progesterone reaches a peak at about 8 days postovulation. If ovulation does not occur, the corpus luteum fails to form and the cyclic rise in progesterone is subnormal. If ovulation and pregnancy occur, hCG maintains the corpus luteum and progesterone continues to rise. In the absence of conception, the corpus luteum resolves, resulting in a decrease in estrogen and progesterone concentrations and a breakdown of the endometrium. The average duration of menstrual flow is 4 to 6 days and average menstrual blood loss is 30 mL.

Cyclic variation. Healthy women display considerable variation in cycle length ranging from 26 to 34 days (28 days on average). Much of the cyclic variation can be attributed to variation in the length of the follicular phase, while the length of the luteal phase remains relatively constant.

Gonadotropin-releasing hormone. GnRH triggers the surge of LH that precedes ovulation. There appear to be two separate feedback centers in the hypothalamus: a tonic negative feedback center in the basal medial hypothalamus and a cyclic positive feedback center in the anterior regions of the hypothalamus. Low concentrations of E_2 , such as those that are present during the follicular phase, affect the negative feedback center, whereas high concentrations of E_2 , such as those seen just before the midcycle LH peak, trigger the positive feedback center. Progesterone in combination with estrogen affects the negative feedback center in the luteal phase. GnRH is released in a pulsatile fashion and has a self-priming effect; the first dose potentiates the effects of subsequent doses. The magnitude of the LH response to GnRH increases steadily through the follicular phase and is greatest at the time of the preovulatory surge of LH, after which it declines again.

Follicle-stimulating hormone. A few days before day 1 of the cycle, FSH begins to rise (see Fig. 43.9), probably triggered by a fall in E_2 concentration that briefly eliminates the negative feedback effect. This rise in FSH initiates the

growth of a cohort of ovarian follicles. LH and FSH release is pulsatile throughout the cycle; therefore the values shown in Fig. 43.9 represent integrated concentrations. As estrogen is released from the growing follicles, FSH concentrations fall again and remain low through the follicular phase. By days 5 to 7, a single dominant follicle is selected for further growth and maturation. A rise in FSH at midcycle is triggered by progesterone. During the luteal phase, FSH is suppressed by negative feedback from E_2 until a lesser FSH peak, occurring near the end of the cycle, starts off the follicular recruitment for the next cycle.

Luteinizing hormone. LH secretion is suppressed in the follicular phase by negative feedback from E_2 . As E_2 production by the developing follicle increases, the effect of E_2 on the positive feedback center becomes important. Increasing release of GnRH from the hypothalamus and increasing sensitivity of the anterior lobe of the pituitary gland to GnRH lead to the midcycle surge of LH. Ovarian follicle receptors for LH, sensitized by FSH and E_2 , transmit the stimulus to enhance differentiation of the theca cells and production of progesterone by the developing corpus luteum. During the luteal phase, LH production is suppressed by negative feedback from progesterone combined with E_2 , but a low concentration of LH is probably necessary to prolong corpus luteum function.

Estradiol. Estradiol production by the ovary decreases near the end of a cycle but begins to increase again under the influence of FSH (see Fig. 43.9). Estradiol enhances the FSH effect on a maturing follicle through changes in FSH receptors of the follicular cells, but it suppresses pituitary FSH and LH release during the follicular phase through negative feedback. Before the mid-follicular phase, estrogen concentrations are less than 50 pg/mL (183.5 pmol/L), but they increase rapidly as the follicle matures. Estradiol production increases, reaching a midcycle peak at between 250 and 500 pg/mL (917.5–1835 pmol/L). Estradiol concentrations decrease abruptly after ovulation but increase again as the corpus luteum is formed, reaching concentrations of approximately 125 pg/mL (458.8 pmol/L) during the luteal phase. Progesterone produced by the corpus luteum combined with E_2 , exerts a negative effect on the hypothalamus and anterior lobe of the pituitary gland. As a result, the secretion of LH and FSH is again suppressed during the luteal phase. Estradiol is essential for the development of proliferative endometrium and is synergistic with progesterone for the development of changes in the endometrium that initiate shedding; the decrease in negative feedback from E_2 on the anterior lobe of the pituitary gland triggers the FSH surge that begins the development of an ovarian follicle for the next cycle.

Progesterone. Progesterone is not produced in significant amounts until the midcycle LH surge and ovulation. LH enhances theca cell differentiation and progesterone production, which increase by a factor of 10 to 20 to a maximum about 8 days after the midcycle peak of LH. Progesterone is thought to stimulate the ovulatory peak of FSH and to promote the growth of secretory endometrium, which is necessary for implantation of the fertilized ovum.

Fig. 43.10 Geometric means for follicle-stimulating hormone (FSH) and estradiol in relation to the final menstrual period (FMP). The horizontal axis represents time (years) with respect to the FMP (0); negative (positive) numbers represent time before (after) the FMP. (Modified from Burger, H. G., Dudley, E. C., Hopper, J. L., Groome, N., Guthrie, J. R., Green, A., et al. [1999]. Prospectively measured levels of serum follicle-stimulating hormone, estradiol, and the dimeric inhibins during the menopausal transition in a population-based cohort of women. *J Clin Endocrinol Metab*, 84, 4025–4030.)

Ovulation. An intricate interplay of endocrine events contributes to follicular maturation. Growth of ovarian follicles appears to be continuous. How an individual follicle is singled out for each menstrual cycle is not known; however, the late-cycle peak in FSH concentration is likely important in this process. Once a follicle has been stimulated, E_2 production causes that specific follicle to be more receptive to the effects of FSH. The high concentration of E_2 just before midcycle is responsible for triggering positive feedback in the hypothalamus, which leads to the midcycle LH surge. After ovulation, LH is suppressed by progesterone and E_2 , but the effect of LH on the corpus luteum is increased. In the event of successful fertilization and implantation, corpus luteum function is sustained by hCG produced by trophoblastic cells of the developing embryo with high molecular homology to LH and is capable of binding and stimulating LH receptors. Otherwise the declining concentration of E_2 leads to regression of the corpus luteum and the late-cycle FSH peak that starts the process again.

Menopause

Menopause is defined as the permanent cessation of menstruation resulting from loss of ovarian follicular activity. It begins with the ovaries failing to produce adequate amounts of estrogen and inhibin; as a result, gonadotropin production is increased in a continued attempt to stimulate the ovary (Fig. 43.10). The mean age of menopause in the United States is 51 years, but it varies considerably. Ovarian failure may occur at any age, but menopause before age 40 years is considered premature.

Hormonal changes begin about 5 years before the actual menopause as the response of the ovary to gonadotropins begins to decrease and menstrual cycles become increasingly irregular. At this time, FSH concentrations increase and E_2 concentrations decrease, whereas LH and progesterone

concentrations remain unchanged, indicating that menstrual cycles remain ovulatory. The decrease in estrogen concentrations gives rise to vasomotor instability and “hot flashes.”

After menopause, the ovary continues to produce androgens, particularly testosterone and androstenedione, as a result of increased LH concentrations. In addition, the adrenal gland continues to secrete androgens. The resulting decrease in the estrogen/androgen ratio is the cause of the hirsutism seen in some postmenopausal women. In general, menopause may be diagnosed in women over the age of 45 on the basis of menstrual history and age without relying on laboratory test results, although serum FSH values may be helpful. In women below age 40 with menopausal symptoms and irregular menses, other causes of menstrual irregularities should be ruled out prior to making the diagnosis of primary ovarian insufficiency (POI).

It is important to note that perimenopausal and postmenopausal women secrete pituitary hCG. Serum concentrations are generally low (<13 IU/L), but positive hCG results often cause confusion and can delay important diagnostic tests or treatments. Pituitary versus placental hCG can be confirmed by measuring serum FSH (concentrations of FSH >45 IU/L are consistent with menopause and make pregnancy unlikely) or by 2 weeks of hormone replacement therapy (hormone replacement therapy should decrease LH, FSH, and hCG concentrations).

Female Pseudohermaphroditism

In pseudohermaphroditism, the gonadal sex varies from the genital sex. The female pseudohermaphrodite is an individual who is genetically female but whose phenotypic characteristics are, to varying degrees, male. In neonates with a 46,XX karyotype and ambiguous genitalia, congenital adrenal hyperplasia (CAH) should be considered. In female fetuses, exposure to androgens before the 12th week of gestation causes

ambiguous genitalia; after 13 weeks, it results in clitoral enlargement. Because androgen excess occurs before the 12th week of gestation in those with CAH, ambiguous genitalia are almost always present. Only deficiencies of 21-hydroxylase and 11 β -hydroxylase are predominantly virilizing disorders. Deficiency of 3 β -hydroxysteroid dehydrogenase is rare, but when it occurs, affected girls may exhibit virilization.

Diagnosis of *21-hydroxylase deficiency* is made in infants and children with excess excretion of urinary 17-KS and pregnanetriol (a metabolite of 17-hydroxyprogesterone) and elevated concentrations of plasma 17-hydroxyprogesterone and androstenedione. However, sick and premature infants may have elevated concentrations of 17-hydroxyprogesterone and androstenedione. Additionally, molecular diagnostic testing is now available for detection of the mutations that account for most cases (80% to 90%) of 21-hydroxylase deficiency.

An *11 β -hydroxylase deficiency* is confirmed by finding elevated plasma concentrations of 11-deoxycortisol and deoxycorticosterone, increased concentrations of their metabolites in urine, and their suppression by glucocorticoid therapy. Plasma renin activity and aldosterone concentrations are low in this deficiency.

Elevated plasma concentrations of 17-hydroxypregnenolone, DHEA, and DHEA-S are found in patients with *3 β -hydroxysteroid dehydrogenase deficiency*. Plasma concentrations of 17-hydroxyprogesterone may be elevated as a result of peripheral conversion of 17-hydroxypregnenolone. The ratio of 17-hydroxypregnenolone to 17-hydroxyprogesterone is strikingly elevated in these patients.

Precocious Puberty

Precocious puberty is the development of secondary sexual characteristics in girls younger than 8 years old and boys younger than 9 years old. Early puberty is manifested by the appearance of secondary sexual characteristics such as premature thelarche (breast development) for girls or premature testicular enlargement for boys. When presented as isolated cases, these secondary sexual characteristics are not necessarily considered to be pathologic. However, if a child demonstrates progressive development of the characteristics and/or increased rates of bone growth and maturation, causes of true precocious puberty must be considered.

GnRH-dependent precocious puberty (also called *central precocious puberty*) is due to precocious activation of the hypothalamic-pituitary-gonadal axis. In girls, the cause is most commonly idiopathic (90%); however, idiopathic cases account for less than 10% of central precocious puberty in boys. Central nervous system tumors have also been known to cause central precocious puberty, the most common being hypothalamic hamartoma. Neurofibromatosis has been documented to lead to GnRH-dependent precocious puberty.

GnRH-independent precocious puberty (also called *pseudoprecocious puberty*) refers to precocious sex steroid secretion that is independent of pituitary gonadotropin release. CAH is a common cause of pseudoprecocious puberty. Classic forms of CAH present with virilization, growth acceleration, and accelerated bone maturation. Nonclassic

or late-onset forms usually present in childhood or adolescence with premature adrenarche and acne. In fact, 5% to 10% of children who present with premature adrenarche have late-onset adrenal hyperplasia. Tumors of the adrenal gland, ovaries, and testes that secrete androgens or estrogens may result in GnRH-independent precocious puberty.

Diagnosis of precocious puberty is based on clinical presentation, a thorough pubertal history, bone age determinations, and laboratory tests performed to assess gonadotropin concentrations and response to exogenous GnRH. The GnRH stimulation test is the gold standard for diagnosis of GnRH-dependent precocious puberty. Response to exogenous GnRH is suppressed and LH and FSH concentrations are low in individuals with GnRH-independent precocious puberty.

Irregular Menses

Amenorrhea, the absence of menstrual bleeding, is traditionally categorized as primary (women who have never menstruated) or secondary (women in whom menstruation is present for a variable time and then ceases). Amenorrhea is a relatively common disorder, with an estimated prevalence of 5% in the general population and as high as 8.5% in an unselected adolescent postpubescent population.

Primary amenorrhea. Primary amenorrhea is defined as failure to establish spontaneous periodic menstruation by the age of 16 years regardless of whether secondary sex characteristics have developed. About 40% of phenotypic females who have primary amenorrhea (nearly always associated with absence of development of secondary sex characteristics) have *Turner syndrome* (45,X karyotype) or *pure gonadal dysgenesis* (46,XX or XY karyotype). *Müllerian duct agenesis* or *dysgenesis* with absence of the vagina or uterus is the second most common manifestation, and the third most common is *androgen insensitivity syndrome* (androgen receptor deficiency and normal or elevated plasma testosterone concentrations if the patient is past puberty and is karyotype XY but has female sex characteristics).

Evaluation of primary amenorrhea. When puberty is delayed in a girl, serum gonadotropins should be measured. Low concentrations may indicate pituitary failure, whereas concentrations elevated into the postmenopausal interval indicate definite gonadal failure.

Secondary amenorrhea. Secondary amenorrhea is defined as absence of periodic menstruation for at least 6 months in women who have previously experienced menses. *Oligomenorrhea* is infrequent menstruation that occurs fewer than eight times per year. With few exceptions, the causes of primary and secondary amenorrhea overlap (Box 43.2). Pregnancy, the most common cause of secondary amenorrhea, must be considered first and ruled out. Elevated concentrations of prolactin—iatrogenic or induced by a prolactin-secreting tumor—have been found to result in oligomenorrhea or amenorrhea. About one-third of women with no obvious cause of amenorrhea have elevated prolactin concentrations. It is thought that hyperprolactinemia interferes with GnRH pulsatility, resulting in impaired release of LH and FSH.

BOX 43.2 Causes of Amenorrhea**Primary Amenorrhea**

Lower tract defects
 Vaginal aplasia
 Imperforate hymen
 Congenital vaginal atresia
 Uterine disorders
 Congenital absence of the uterus
 Endometritis
 Müllerian agenesis (Mayer-Rokitansky-Kuster-Hauser syndrome)
 Ovarian disorders
 XO gonadal and X dysgenesis and variants
 XX gonadal dysgenesis
 Turner syndrome
 17-Hydroxylase deficiency of the ovaries and adrenal glands
 Autoimmune oophoritis
 Resistant ovary syndrome
 Polycystic ovary syndrome
 Adrenal disorders (congenital adrenal hyperplasia)
 Thyroid disorders (hypothyroidism)
 Pituitary-hypothalamic disorders
 Hypopituitarism
 Constitutional delay in the onset of menses (physiologic)
 Nutritional disorders
 Kallmann syndrome

Secondary Amenorrhea

Pregnancy/lactation
 Uterine disorders
 Posttraumatic uterine synechiae (Asherman syndrome)
 Progestational agents
 Ovarian disorders
 Polycystic ovary syndrome (hypothalamic)

Ovarian tumor
 Primary ovarian insufficiency (idiopathic, autoimmune, chemotherapy, radiation, injury)
 Antimetabolite therapy
 Adrenal disorders
 Late-onset adrenal hyperplasia
 Cushing syndrome
 Virilizing adrenal tumors
 Adrenocorticoid insufficiency
 Thyroid disorders
 Hypothyroidism
 Hyperthyroidism
 Pituitary disorders
 Acquired hypopituitarism (trauma, tumor, Sheehan syndrome, lymphocytic hypophysitis)
 Physiologic or pathologic hyperprolactinemia
 Hypothalamic disorders
 Tumor and infiltrative disease
 Nutritional disorders
 Hypophysitis
 Excessive exercise
 Stress
 Iatrogenic
 Antipsychotics (phenothiazines, haloperidol, clozapine, pimozide)
 Antidepressants (tricyclics, monoamine oxidase inhibitors)
 Antihypertensives (calcium channel blockers, methyldopa, reserpine)
 Drugs with estrogenic activity (digitalis, flavonoids, marijuana, oral contraceptives)
 Drugs with ovarian toxicity (busulfan, chlorambucil, cisplatin, cyclophosphamide, fluorouracil)

Disorders of the ovary, such as *POI* and loss of ovarian function, have been known to cause amenorrhea. *POI* has been defined as failure of ovarian estrogen production occurring in a hypergonadotropic state at any age between menarche and 40 years. If the patient is younger than 25 years or shorter than 5 feet tall, karyotyping or chromosomal microarray should be performed to rule out the presence of a variety of chromosomal abnormalities involving duplications or absence of the X chromosome or the presence of a Y chromosome. Screening for the fragile X premutation (*FMR1*) should also be performed. Autoimmune disorders have been associated with 20% to 40% of cases of *POI* that result in destruction of the ovary and in amenorrhea. Other causes for ovarian failure include oophorectomy, cystic degeneration, trauma, infection, galactosemia, interference with blood supply, radiotherapy treatment, and treatment with cytotoxic chemotherapeutic agents. In rare patients, ovarian resistance to gonadotropins may be evident.

Secondary amenorrhea may also result from an issue with the outflow tract. The patient with a uterine problem is normal hormonally but does not menstruate. Endometrial damage may occur in response to a dilatation and curettage and to infection of the endometrium. Pituitary dysfunction will also cause secondary amenorrhea. This is most often due to

intrinsic pituitary tumors. However, Sheehan syndrome and pituitary apoplexy can result in panhypopituitarism. Empty sella syndrome has been reported in 4% to 16% of patients with amenorrhea and galactorrhea.

Evaluation of secondary amenorrhea. Evaluation of women with secondary amenorrhea should begin with a careful history that includes a complete description of menstrual patterns. In addition, the patient should be evaluated for galactorrhea, hot flashes, symptoms of hypothyroidism, hirsutism, prior abdominal surgery, pelvic or uterine trauma, medications prescribed, nutritional history, patterns of exercise, previous contraceptive use, weight changes, stress, and chronic disease. Serum or urine β -hCG should be measured to rule out pregnancy (Table 43.1). Because both hypothyroidism and hyperprolactinemia have been known to cause amenorrhea, they are easily excluded by measuring concentrations of serum TSH and prolactin.

A 24-hour urine sample for cortisol measurement or an overnight dexamethasone suppression test is performed in those patients suspected of having Cushing syndrome. On the basis of the preliminary assessment, magnetic resonance imaging (MRI) of the sella turcica should be performed in patients with evidence of pituitary or hypothalamic disease, or clinical hypoeestrogenism. A GnRH stimulation test with

measurement of LH and FSH concentrations in those patients with gonadotropin deficiency assists in differentiating hypothalamic disease from pituitary disease.

Progesterone challenge for evaluating amenorrhea.

When the cause of amenorrhea is unclear after the initial assessment, relative estrogen status should be determined. Serum E₂ can be measured, but results must be interpreted with caution because serum E₂ fluctuates throughout the menstrual cycle. A *progesterone challenge* may be performed as a functional assessment of relative estrogen status. Women with an estrogen-primed uterus have withdrawal vaginal bleeding after treatment with oral progestin (medroxyprogesterone acetate; Provera). If estrogen concentrations are adequate and the outflow tract is intact, menstrual bleeding should occur within a week of treatment. In patients with withdrawal bleeding, the plasma E₂ concentration is usually greater than 40 pg/mL (146.8 pmol/L). However, the progesterone challenge test is subject to false positives because up to 20% of normoestrogenic women with oligomenorrhea do not experience withdrawal bleeding. It is also subject to false negatives because up to 40% of women with oligomenorrhea and reduced plasma E₂ experience withdrawal bleeding.

If the patient demonstrates withdrawal bleeding after the progestin challenge test, this indicates that the ovaries are producing sufficient estrogen to cause endometrial proliferation and no anatomic obstruction is present. Most of these women have a history of progestin-containing contraceptive use (the progestin-dominant state can thin the endometrium), stress, weight loss, or excessive exercise.

If bleeding fails to occur after progestin challenge, then additional laboratory tests are indicated, including measurement of FSH to localize the problem to the follicle, pituitary, or hypothalamus. High FSH concentrations indicate that the ovarian follicle is not responding to gonadotropin stimulation. A single measurement of FSH greater than 50 IU/L is suggestive of ovarian failure or POI in women younger than 40 years of age.

Androgen excess. Amenorrhea due to androgen excess can stem from adult-onset CAH, corticotropin-dependent Cushing syndrome, or **polycystic ovary syndrome (PCOS)**. Patients with androgen excess will often present with acne, obesity, and variable degrees of excess hair on the face, chest, abdomen, and thighs. Some individuals with 21-hydroxylase deficiency do not manifest any developmental abnormalities or salt wasting but present with signs of androgen excess. This clinical syndrome,

TABLE 43.2 Clinical Features of the Polycystic Ovary Syndrome^a

Clinical Feature	Frequency (%)

Acne	25
Obesity	35
Infertility	50
Amenorrhea	35
Oligomenorrhea	40
Regular menstrual cycle	20

^aData were compiled from three studies. Two used ultrasonography as the primary method of diagnosis, one used ovarian histology. Total $n = 1935$.

Modified from Franks, S. (1995). Polycystic ovary syndrome. *N Engl J Med*, 333, 853.

referred to as *nonclassic adult-onset* or *late-onset CAH*, may be clinically indistinguishable from PCOS.

PCOS is characterized by infertility, hirsutism, obesity (in approximately half of those affected), and various menstrual disturbances ranging from amenorrhea to irregular vaginal bleeding (Table 43.2). Women with PCOS have an increased prevalence of diabetes, along with increased risk for coronary heart disease and endometrial cancer. PCOS patients have substantial estrogen production because of the peripheral conversion of androgens to estrogens. Abnormal bleeding patterns seen in PCOS are due to chronic anovulation and lack of progesterone stimulation and withdrawal. Chronic estrogen exposure without progesterone may predispose patients to endometrial cancer. Although this syndrome is associated with polycystic ovaries, the name is actually a misnomer in that the ovaries are covered with follicles, not cysts.

PCOS occurs in 4% to 10% of premenopausal women, and the prevalence varies depending on the diagnostic criteria used. The Rotterdam Consensus Criteria define hyperandrogenism, oligomenorrhea or amenorrhea, and polycystic ovaries by ultrasound as the characteristic signs and symptoms and require the presence of two of the three for diagnosis of PCOS. This definition has been criticized by the Androgen Excess Society (AES), which requires the presence of hyperandrogenism in conjunction with either oligomenorrhea/amenorrhea or polycystic ovaries. Despite these concerns, current Endocrine Society guidelines recommend the use of the Rotterdam Consensus Criteria.

Because the pathophysiologic mechanism is unknown, PCOS remains a diagnosis of exclusion, clinically defined by hyperandrogenism in women with chronic anovulation and no other cause. Relatively low FSH and disproportionately high LH concentrations are common in PCOS, although this ratio should not be used in a routine PCOS workup. Studies have reported higher serum AMH concentrations in women with PCOS relative to healthy women, and ongoing work is evaluating the potential utility of including AMH measurement in PCOS diagnostic criteria.

Ovarian hyperthecosis, a nonneoplastic lesion of the ovary characterized by the presence of islands of luteinized thecal cells in the ovarian stroma, is sometimes confused with PCOS. Features that distinguish it from PCOS include higher

- Phenothiazides
- Progestagens (19-nonsteroid derivatives)

concentrations of testosterone, androstenedione, and DHT derived from ovarian secretion.

Hirsutism and virilization. Hirsutism is defined as excessive growth of terminal hair in women and children in a distribution similar to that occurring in postpubertal men. True hirsutism, which is androgen responsive, has to be distinguished from hypertrichosis, which consists of excessive growth of vellus, or non-androgen-responsive hair. Women with androgen-dependent hirsutism may have exposure to excess androgens or may have heightened sensitivity to normal circulating concentrations of androgen (Box 43.3).

Virilization is characterized by clitoral hypertrophy, deepening of the voice, temporal hair recession, baldness, increased libido, decreased body fat, and menstrual irregularities or amenorrhea. Hirsutism is usually associated with normal or slightly elevated serum androgens, whereas virilization is associated with marked increases in ovarian or adrenal androgen production and is an indication for more intensive investigation.

Laboratory evaluation of hirsutism/virilization. The two most important screening tests used in the evaluation of women for hirsutism and virilization are serum total or free testosterone and DHEA-S. Elevation of DHEA-S concentration suggests an adrenal origin of androgens, whereas elevations in testosterone indicate an adrenal or ovarian source. Neoplastic disease is unlikely if the serum testosterone concentration is less than 200 ng/dL (6.9 nmol/L), the DHEA-S

concentration is less than 700 µg/dL (19 µmol/L), or 17-KS concentrations are less than 30 mg/dL (1 mmol/L).

Other factors. Hypothalamic dysfunction consists of those disorders that disrupt the frequency or amplitude of GnRH. Rarely is this due to a lesion or tumor. However, most commonly, disruption occurs in response to psychologic stress, depression, severe weight loss, anorexia nervosa, or strenuous exercise. A syndrome known as the *female athletic triad* has been described. This syndrome is prevalent in women who exercise vigorously, and it is associated with amenorrhea, disordered eating, and osteoporosis. Competitive long-distance runners, gymnasts, and professional ballet dancers appear to be at highest risk. Although the mechanism for the disturbance is unclear, symptoms and laboratory profiles are similar to those of other forms of hypothalamic amenorrhea. LH and FSH concentrations are normal or low, and E₂ concentrations are low.

Several hormone-producing tumors of the ovary, pituitary gland, and adrenal glands occur in combination with amenorrhea. This amenorrhea may be confused with pregnancy if the tumors produce hCG. Choriocarcinoma of the uterus or ovary may produce large amounts of hCG, which cause hyperthyroidism because of the slight thyrotropic action of hCG. Granulosa–theca cell tumors are usually associated with estrogen secretion resulting in amenorrhea and irregular menses and, rarely, excessive androgen with associated virilization.

Many drugs produce amenorrhea (see Box 43.2), particularly phenothiazines and other psychotropic drugs such as haloperidol, pimozide, and clozapine. Phenothiazine-induced amenorrhea is usually associated with hyperprolactinemia and galactorrhea. Drugs that affect the normal pathway of dopamine secretion will produce amenorrhea by decreasing the secretion of norepinephrine. Because norepinephrine is important in controlling the synthesis and secretion of GnRH, any alteration in its synthesis or secretion will result in menstrual abnormalities. Normal menses should resume shortly after the cessation of combined oral contraceptive pills. If menses has not resumed after ceasing the oral contraceptive pill, evaluation is warranted.

POINTS TO REMEMBER

- GnRH stimulates LH and FSH release, which control oocyte maturation and ovulation and increase estradiol and progesterone production.
- Estradiol is transported in blood tightly bound to SHBG and loosely bound to albumin, whereas progesterone is bound to corticosteroid-binding globulin.
- Estradiol and progesterone both inhibit and stimulate LH and FSH release, with the type of regulation dependent on the stage of the menstrual cycle and the serum steroid hormone concentration.
- PCOS is defined by hyperandrogenism and oligo/anovulation and remains a diagnosis of exclusion based primarily on clinical evaluation.
- Pituitary secretion of hCG is often seen in postmenopausal women, and the pituitary origin can be confirmed by the presence of concurrently elevated serum FSH.

BOX 43.4 Male Infertility Factors

Endocrine Disorders

Hypothalamic dysfunction (Kallmann syndrome)
Pituitary failure (tumor, radiation, surgery)
Hyperprolactinemia (drug, tumor)
Androgen insensitivity syndrome (AIS)
Exogenous androgens
Thyroid disorders
Adrenal hyperplasia
Testicular failure

Anatomic

Congenital absence of vas deferens
Obstructed vas deferens
Congenital abnormalities of ejaculatory system
Varicocele
Retrograde ejaculation

Abnormal Spermatogenesis

Unexplained azoospermia
Chromosomal abnormalities
Mumps orchitis
Cryptorchidism
Chemical or radiation exposure

Abnormal Motility

Absent cilia (Kartagener syndrome)
Antibody formation

Psychosocial

Unexplained impotence
Decreased libido

Modified from Morell, V. (1997). Basic infertility assessment. *Primary Care*, 24, 195–204.

INFERTILITY

Infertility is defined as the inability to conceive after 1 year of unprotected intercourse. It has been estimated that 93% of healthy couples practicing unprotected intercourse should expect to conceive within 1 year. A specific cause of infertility is identified in approximately 80% of couples: one-third are due to female factors alone, one-third to male factors alone, and one-third to a combination of problems.

Primary infertility refers to couples or patients who have had no previous successful pregnancies. Secondary infertility encompasses patients who have previously conceived but are currently unable to conceive. These types of infertility generally share common causes.

Infertility problems often arise as a result of hormonal dysfunction of the hypothalamic-pituitary-gonadal axis. This section focuses on hormonal and biochemical aspects of evaluating infertility.

Male Infertility

A list of the most common male infertility factors is given in Box 43.4. One algorithm for the evaluation of male infertility is shown in the At a Glance box. Initial evaluation of male infertility should include a detailed history and physical

examination. The physical examination should pay particular attention to (1) the external genitalia—for evidence of proper androgenization; (2) hair pattern—degree of virilization; (3) breast abnormalities—gynecomastia and/or discharge; and (4) neurologic findings—sense of smell and visual impairments. The history must include (1) reproductive history, including living children and any pregnancies that resulted in miscarriage; (2) prescribed medications; (3) use of recreational and performance-enhancing drugs and alcohol; (4) systemic illness; and (5) potential toxin exposure. Sexual history should include sexual technique, frequency of intercourse, and use of any lubricants. Issues of potency must be distinguished from those of infertility or subfertility. Testosterone should be measured, especially when the patient's history or physical examination suggests deficient development of secondary sex characteristics. Laboratory evaluation of male infertility should begin with evaluation of the semen (Table 43.3), which should be followed by evaluation of endocrine parameters.

Evaluation of Semen

Semen analysis measures ejaculate volume, pH, sperm count, motility, forward progression, and morphology. Although semen analysis is not a test for infertility, it is considered the most important laboratory test in the evaluation of male

TABLE 43.3 Normal Seminal Fluid Values

Parameter	Value
Ejaculate volume	>1.5 mL (1.4–1.7) ^a
Sperm density	>15 million/mL (12–16) ^a
Total sperm count	>39 million/ejaculate (33–46) ^a
Motility	>32% progressive motility (31–34); >40% total (38–42) ^a
Morphology	>4.0% normal (3–4) ^a
pH	7.2–8.0 ^a
Color	Gray-white-yellow
Liquefaction	Within 40 min
Fructose	>1200 µg/mL
Acid phosphatase	100–300 µg/mL
Citric acid	>3 mg/mL
Inositol	>1 mg/mL
Zinc	>75 µg/mL
Magnesium	>70 µg/mL
Prostaglandins (PGE ₁ + PGE ₂)	30–200 µg/mL
Glycerolphosphorylcholine	>650 µg/mL
Carnitine	>250 µg/mL
Glucosidase	>20 mU per ejaculate

^aValues from World Health Organization. Cooper, T. G., Noonan, E., von Eckardstein, S., Auger, J., Baker, H. W., Behre, H. M., et al. (2010). World Health Organization reference values for human semen characteristics. *Hum Reprod Update*, 3, 231.

fertility. If semen analysis is normal, it is unlikely that other laboratory testing will be useful.

Evaluation of Obstruction

Testosterone produced after administration of hCG causes the seminal vesicles, epididymis, and prostate to increase the volume of ejaculate. An appropriate increase in serum testosterone without change in the ejaculate volume may indicate mechanical blockage. Absence of or a decrease in specific biochemical markers such as acid phosphatase and citric acid (from prostate), fructose, and prostaglandins (from seminal vesicles) can assist in determining the location of blockage.

Evaluation of Endocrine Parameters

If severe oligospermia or azospermia is found, measurement of serum testosterone, LH, and FSH concentrations is warranted, with or without measurement of prolactin and TSH. Hyperprolactinemia is a cause of secondary testicular dysfunction. Prolactin excess likely causes hypogonadism by impairing GnRH release. It also leads to under androgenization and erectile dysfunction (see earlier section titled Erectile Dysfunction). If hyperprolactinemia is found, it is imperative to check for hypothyroidism because elevated TRH concentrations can result in hyperprolactinemia.

Patients with borderline or suppressed testosterone concentrations can be evaluated with an *hCG stimulation test*. With this test, an injection of 5000 IU hCG is administered intramuscularly following collection of a basal, early-morning testosterone sample. Serum testosterone is measured 72 hours later. Hypogonadal men show a depressed rise in testosterone concentration in response to this challenge. Doubling of testosterone concentration over baseline is consistent with normal Leydig cell function. As testosterone is essential for normal sperm development, any disorder that results in hypogonadism (and thus low testosterone concentrations) results in infertility.

Hypergonadotropic hypogonadism. Measurement of the concentration of FSH is indicated in men with a sperm count lower than 5 to 10 million/mL. Elevated concentrations of FSH indicate Sertoli cell dysfunction and, in azospermic men, primary germinal cell failure, Sertoli cell-only syndrome, or genetic conditions such as Klinefelter syndrome. Radiotherapy and gonadotoxic chemotherapy can also lead to testicular failure with azospermia. Elevated FSH (>120 IU/L) in the setting of decreased testosterone (<200 ng/dL, 7 nmol/L) and oligospermia indicate primary testicular failure.

Hypogonadotropic hypogonadism. Decreased concentrations of testosterone (<200 ng/dL, 7 nmol/L) and decreased concentrations of FSH (<10 IU/L) are suggestive of hypogonadotropic hypogonadism. The administration of GnRH may help to distinguish between gonadal insufficiencies caused by pituitary versus hypothalamic failure. Because the pituitary is sensitive to sex steroids for appropriate gonadotropin secretion, patients with long-standing hypogonadism should be given exogenous testosterone for 1 week before the GnRH stimulation test is administered.

BOX 43.5 Female Infertility Factors

Ovarian or Hormonal Factors

- Metabolic disease
 - Thyroid
 - Liver
 - Obesity
 - Androgen excess
 - Polycystic ovarian syndrome
- Hypergonadotropic hypogonadism
- Menopause
- Luteal phase deficiency
- Gonadal dysgenesis
- Primary ovarian insufficiency (autoimmune, cytotoxic, chemotherapy, radiation, tumor)
- Resistant ovary syndrome
- Hypogonadotropic hypogonadism
 - Hyperprolactinemia (tumor, drugs)
 - Hypothalamic insufficiency (Kallmann syndrome)
 - Pituitary insufficiency (tumor, necrosis, thrombosis, stress, exercise, anorexia)

Tubal Factors

- Occlusion or scarring
- Salpingitis isthmica nodosa
- Infectious salpingitis

Cervical Factors

- Stenosis
- Inflammation or infection
- Abnormal mucous viscosity

Uterine Factors

- Leiomyomata
- Congenital malformation
- Adhesions
- Endometritis or abnormal endometrium

Psychosocial Factors

- Decreased libido
- Anorgasmia

Iatrogenic

Immunologic (Antisperm Antibodies)

Modified from Morell, V. (1997). Basic infertility assessment. *Primary Care*, 24, 195–204.

Y-Chromosome Microdeletions

Deletions in either of the azospermia factor regions (AZF1 and AZF2) on the long arm of the Y chromosome are associated with an inability to make sperm. In addition, genes such as SRY (sex-determining region Y) are on the short arm of chromosome Y. Deletion of these regions is associated with azospermia or, less frequently, oligospermia. The incidence of Y microdeletions in idiopathic non-obstructive azospermic men is 8% to 18%. Testing for Y-chromosome microdeletions is performed to determine whether sperm might be retrieved on a testicular sperm extraction procedure.

AT A GLANCE: EVALUATING FEMALE INFERTILITY

Algorithm for the evaluation of female infertility. E_2 , Estradiol; FSH , follicle-stimulating hormone; LH , luteinizing hormone; PRL , prolactin; T , testosterone; TSH , thyroid-stimulating hormone.

Female Infertility

Evaluating female infertility is more complex than evaluating infertility in the male. A list of the most common female infertility factors is given in [Box 43.5](#). An algorithm for the evaluation of female infertility is shown in the At a Glance box.

Initial Evaluation of Female Infertility

The initial evaluation of female infertility should include a detailed history and physical examination. The physical examination should include evaluation of (1) the external genitalia and hair pattern (for signs of androgen excess, including clitoromegaly, hirsutism, and virilization), (2) the pelvis (for masses, nodularity, or tenderness), (3) the breasts (for signs of galactorrhea), (4) neurologic findings (sense of smell and visual impairments), (5) the thyroid (for enlargement or nodules), and (6) body mass index. All abnormalities in the history and physical examination should be pursued. A thorough medical and surgical history is also necessary, including an assessment of the patient's gravidity and parity, coital frequency, duration of infertility, and prior workup and treatment for infertility. History of sexually transmitted infections, assessment of previous cervical cytologic and human papillomavirus (HPV) testing and treatment, and a menstrual history should also be obtained. Concentrations of TSH, testosterone, and prolactin should be measured if menstrual cycles are absent or irregular or if signs of galactorrhea or thyroid abnormalities are present.

Evaluation of ovulation. In the menstruating woman, the next step would be to determine whether ovulation occurs. No current laboratory tests will confirm ovum release. However, measurement of the concentration of midluteal plasma progesterone does indicate that a corpus luteum has been formed. Other methods, such as measurement of the LH surge (to predict ovulation) and basal body temperature (to detect a midcycle rise in progesterone), have been used to assess ovulation.

Progesterone measurement. Measurement of the concentration of serum progesterone is the primary assay used for the evaluation of ovulation. It is important to note that an increase in progesterone concentration indicates that a corpus luteum has been formed, but it does not confirm that the oocyte was actually released. Beginning immediately after ovulation, serum progesterone concentrations rise (see [Fig. 43.9](#)); they peak within 5 to 9 days during the midluteal phase (days 21 to 23). If ovulation does not occur, the corpus luteum fails to form and the expected cyclic rise in progesterone concentration is subnormal. If pregnancy occurs, hCG maintains the corpus luteum, and progesterone production continues to rise. Midluteal progesterone concentrations greater than 300 ng/dL (9.5 nmol/L) indicate that ovulation has taken place.

Basal body temperature. Basal body temperature charts have long been accepted as simple, cost-effective indicators of ovulation. Ovulation is associated with a rapid rise in body temperature (by 0.2°F to 0.5°F, or 0.1°C to 0.3°C), which persists through the luteal phase. The rise in temperature is due

Fig. 43.11 The relationship between increasing follicle-stimulating hormone (FSH) concentrations and decreased percentage of successful pregnancies. (Modified from Jones, H., & Toner, J. P. [1993]. The infertile couple. *N Engl J Med*, 329, 1710–1715.)

to increased progesterone concentration. However, similar to progesterone, the rise in body temperature is evident only retrospectively and therefore does not predict imminent ovulation in a way helpful for timing intercourse.

Measurement of the luteinizing hormone surge. LH appears in the urine just after the serum LH surge and 24 to 36 hours before ovulation (see Fig. 43.9). Measurement of LH does not confirm ovulation or provide insight into the cause of anovulation but rather indicates when ovulation should occur and provides a guide with which to time intercourse.

Evaluation of Endocrine Parameters

Disorders of the hypothalamus, pituitary, and ovary are endocrine causes of infertility.

Hypergonadotropic hypogonadism. Premature ovarian failure is indicated by repeatedly elevated basal FSH concentrations (>30 IU/L) or a single elevation greater than 40 IU/L in a woman younger than 40 years. These patients are often hypoestrogenic (E_2 <20 pg/mL, 73 pmol/L) and do not respond to a progestin challenge because their endometrium is atrophic. A pelvic ultrasound will reveal a thin endometrium. Basal serum FSH has been used as an indicator of relative ovarian reserve. Fig. 43.11 shows the relationship between rising serum FSH and the reduced rate of successful pregnancy. A precipitous drop occurs at concentrations greater than 20 IU/L.

Assessing ovarian reserve. Women in their mid-to-late 30s and early 40s with infertility constitute the largest portion of the total infertility population. These women are also at increased risk for miscarriage. This reflects a diminished ovarian reserve as a result of follicular depletion and a decline in oocyte quality. As women age, serum FSH concentrations in the early follicular phase begin to increase. It has been suggested that this is due to a decline in the number of small follicles secreting inhibin B.

The concomitant measurement of follicular phase serum FSH and E_2 is a popular screening test for assessing ovarian reserve. In general, day 3 FSH concentrations greater than 20 to 25 IU/L are considered to be elevated and associated with a poor reproductive outcome. Concomitant measurement of serum E_2 concentration adds to the predictive power of an isolated FSH determination. Early follicular phase E_2 concentrations greater than 75 to 80 pg/mL (275 to 294 pmol/L) may be associated with a poor response to ovarian stimulation and pregnancy outcome, although these concentrations may also be slightly elevated in women with PCOS.

More recently AMH has emerged as a helpful indicator of ovarian reserve. AMH regulates follicle development and maturation as well as E_2 production. AMH is produced by small, growing follicles but ceases to be produced during FSH-dependent follicular growth or in atretic follicles. Serum AMH remains relatively constant throughout the menstrual cycle and decreases with age, leading to its promotion as a marker of ovarian reserve and reduced reproductive capacity.

Current literature suggests that the most beneficial application of AMH measurement is not in AMH's ability to predict the chance of pregnancy but rather in predicting response to controlled ovarian stimulation used in assisted reproductive techniques. Patients with elevated serum AMH concentrations are often “high responders” and at risk of ovarian hyperstimulation syndrome (OHSS) if a standard ovarian stimulation protocol is used. As a result, these women may undergo a modified stimulation protocol to minimize the risk of OHSS. At the other end of the spectrum, women with low serum AMH concentrations are considered “low responders” and often require greater ovarian stimulation to ensure successful oocyte collection.

Hypogonadotropic hypogonadism. In hypogonadotropic hypogonadism, serum E_2 concentrations are less than 40 pg/mL (147 pmol/L); therefore there is no withdrawal bleeding

with a progestin challenge because the endometrium is thin. Decreased LH (<10 IU/L) and decreased FSH (<10 IU/L) are also observed. Hyperprolactinemia can cause hypogonadotropic hypogonadic infertility. TSH should be measured to exclude hypothyroidism. Prolactin concentrations can be elevated in patients with PCOS and those taking medications such as antidepressants, cimetidine, and methyldopa as well as in stressful conditions. Prolactin concentrations can be elevated if drawn later in the day or after a meal, so they should be drawn fasting, early in the day. In cases where hyperprolactinemia is noted, radiographic imaging of the pituitary is indicated to rule out pituitary adenoma or empty sella syndrome.

Ovulatory factors. Ovulatory dysfunction is difficult to diagnose because it will manifest in the presence or absence of normal menses. Metabolic diseases of many types affect ovulatory function, including those that result in androgen excess. PCOS, which results in androgen excess, is the most common cause of anovulation. In women with hirsutism, CAH should be considered.

Historically, ovulation with inadequate luteinization and reduced progesterone secretion during the luteal phase was termed *luteal phase deficiency*. Currently, luteal phase deficiency is defined as a short luteal phase defined by less than 10 days between ovulation and menses or less than 13 days between the LH surge and menses. The clinical significance of luteal phase deficiency remains unclear.

Assisted Reproduction

Couples with a multitude of infertility problems, including unidentified causes and persistent infertility despite standard treatments, may benefit from assisted reproductive techniques (ART). If no definable cause is identified, standard initial therapy consists of ovulation induction with intrauterine insemination for three cycles before progression to more aggressive techniques such as controlled ovarian hyperstimulation (COH) with inseminations or in vitro fertilization (IVF) with or without intracytoplasmic sperm injection (ICSI).

The laboratory plays an important role in the process of COH. The principle involves the administration of gonadotropins to stimulate follicular growth, followed by hCG to stimulate follicular maturation and ovulation. Clinical, laboratory, and ultrasound monitoring of the treatment cycle is necessary to (1) identify the dose and length of therapy, (2) determine when or whether to administer hCG, and (3) obtain an adequate ovulatory response while avoiding hyperstimulation.

ANALYTIC METHODS FOR REPRODUCTIVE HORMONES

A variety of methods are available for measuring sex steroids in body fluids. Currently the most common method is nonisotopic immunoassay. However, the use of mass spectrometry to measure sex steroids is increasing.

Measurement of Sex Steroids by Mass Spectrometry

Although immunoassays are the predominant method for the detection and measurement of sex steroids (E_2 , testosterone, progesterone, etc.), they are associated with considerable analytic problems. For example, automated testosterone immunoassays (nonisotopic) perform well in healthy adult males and estradiol immunoassays perform well in healthy premenopausal females, but they are unacceptable for use in children or adult patients with low hormone concentrations due to accuracy and imprecision problems at the low end of detectability.

Tandem mass spectrometry coupled with high-performance liquid chromatography (HPLC) offers several advantages over traditional immunoassays, including lower limits of detection, enhanced specificity, small sample size, decreased lot-to-lot variability, and the possibility of analyzing multiple steroids within the same sample. This ability to simultaneously measure a variety of analytes provides the opportunity for steroid profiling, which may enhance diagnostic capabilities. Because of these advantages, the Endocrine Society has suggested using extraction and chromatography followed by mass spectrometry (MS) or MS/MS as a potential gold standard for the measurement of testosterone.

However, this technology has some disadvantages, including the requirement for highly trained personnel, high costs of equipment and maintenance, and lack of standardization. Because testosterone and estradiol assays are not standardized, observations from clinical studies that demonstrate increased disease risk at a given steroid hormone concentration cannot be transferred to other institutions that utilize different assay methods. As a result, generalized cutoffs associated with disease risk cannot be defined, universally accepted reference intervals and clinical decision points cannot be established, and patient care guidelines either do not exist or cannot be applied. These differences in assay performance are attributed to differences in assay accuracy, specificity, imprecision, and calibration that are most pronounced in steroid hormone immunoassays, but mass spectrometric assays also require standardization.

Methods for Determining Total Testosterone in Blood

Circulating testosterone comprises three different forms or pools: a non-protein-bound or “free” form, a weakly bound form, and a tightly bound form. The weakly bound form is associated with albumin, and the tightly bound form is associated with SHBG, which is also known as testosterone/estradiol-binding globulin. The term *total testosterone* refers to serum measurements of free testosterone, albumin-bound testosterone, and SHBG-bound testosterone. Bioavailable testosterone includes circulating free testosterone and albumin-bound testosterone. Testosterone bound to SHBG is not biologically active, whereas the free form is available for target

cells. Albumin-bound testosterone is also available to target tissues because testosterone can dissociate from the albumin carrier and rapidly diffuse into target cells.

Methods

Direct (no extraction required) immunoassay methods have been developed for the determination of testosterone in serum or plasma. In these methods, the steroid must be displaced from its binding proteins (albumin and SHBG), and results of the assay depend on the effectiveness of the displacement. However, most routine immunoassays are not sensitive enough to measure very low testosterone concentrations, such as those found in women, children, or hypogonadal men.

Specimen collection and storage. Serum or heparinized plasma is used to measure total testosterone. Testosterone is subject to diurnal variation, reaching a peak concentration between 0400 and 0800 hours. Therefore morning specimens are preferred. DHEA supplementation should be avoided before testing.

Comments. Estimation of SHBG in serum is useful for interpreting blood concentrations of total testosterone and for calculating androgen index and bioavailable testosterone. Immunoassays for measurement of SHBG in the routine laboratory have been developed. SHBG concentrations are increased by estradiol and decreased by testosterone and therefore change with age.

Methods for Determining Free and Bioavailable Testosterone in Blood

In cases where SHBG concentrations are altered, as in women, aging men, and illness, it has been argued that measurements of free or bioavailable testosterone more accurately reflect androgen status. The three methods routinely used in clinical practice include the following:

1. Estimation of the free testosterone fraction by equilibrium dialysis or ultrafiltration
2. Estimation of combined free and weakly bound (bioavailable) testosterone fractions by selective precipitation of the tightly bound form
3. Calculation of free and weakly bound testosterone concentrations by mathematical modeling

Methods not recommended for use in clinical practice include the following:

1. Estimation of free hormone using a direct (analog tracer) radioimmunoassay
2. Calculation of the androgen index using indices that reflect the ratios of testosterone pools

Equilibrium Dialysis/Ultrafiltration

Only a small fraction (1% to 2%) of unconjugated testosterone exists in the free state (non-protein-bound) in serum or plasma. None of the conventional assay methods, including radioimmunoassay (RIA), is sufficiently sensitive to quantify free steroid directly in a protein-free ultrafiltrate of plasma. Instead, free steroid is estimated in plasma by adding a known amount of radiolabeled compound to the sample and

allowing labeled and unlabeled compounds to reach equilibrium in their competition for the same binding sites on proteins. Bound and free radiolabeled fractions are then separated, and the ratio of free labeled to total labeled compound is determined. At equilibrium, this ratio is taken as a measure of the free testosterone fraction. An estimate of serum free testosterone can be calculated by multiplying the free testosterone fraction by the total testosterone concentration. Because of the labor-intensive nature of both equilibrium dialysis and ultrafiltration, these methods are used almost exclusively at reference laboratories.

Selective Precipitation

Selective precipitation of SHBG with ammonium sulfate is also used to measure bioavailable testosterone. With this technique, aliquots of serum or plasma are first incubated with radiolabeled testosterone. Testosterone bound to SHBG is then precipitated with 50% ammonium sulfate. The samples are centrifuged, and aliquots of the supernatant containing free and albumin-bound testosterone (also known as *non-SHBG-bound testosterone*) are radioactively counted. The percentage of radiolabel not bound to SHBG is subsequently multiplied by the total testosterone concentration to obtain the bioavailable testosterone. Similar to equilibrium dialysis and ultrafiltration methods, performance of selective precipitation is generally limited to reference laboratories.

Calculated Free Testosterone

Methods based on mathematical modeling use algorithms to derive non-SHBG-bound testosterone. These algorithms assume that when concentrations of total testosterone, SHBG, and albumin and the constants for binding of testosterone to SHBG and albumin are known, free testosterone and bioavailable testosterone can be calculated. These calculations are based on a proper estimation of the association constant for the binding of testosterone to SHBG and albumin. However, various association constants for SHBG have been reported, and conditions resulting in abnormal plasma protein concentrations—such as nephrotic syndrome, cirrhosis, and pregnancy—require adjustments in the assumption for albumin concentration.

Direct (Analog Tracer) Radioimmunoassay

Several RIA procedures are commercially available for the direct estimation of free testosterone. These assays use a labeled derivative (analog) of testosterone that, in theory, retains the ability to react with exogenous antitestosterone antibodies but is restricted from interacting with testosterone-binding proteins in the serum sample. In practice, development of an analog that does not interact with endogenous proteins has been difficult to achieve. As a result, direct RIAs have largely been replaced by calculation methods based on total testosterone, SHBG, and albumin concentrations.

Androgen Index

This index is a ratio of testosterone and SHBG multiplied by 100. Although this is only an indicator of free

testosterone, some have found it to be useful in the evaluation of hirsutism. Other reports have indicated that the free androgen index is not a reliable parameter of free testosterone because of its variability as a function of SHBG concentration.

Methods for Determining Testosterone Precursors and Metabolites in Blood

Several biosynthetic precursors and metabolites of testosterone are measured using specific immunoassays (directly or after sample extraction), chromatography, or LC-MS/MS.

Methods for Determining Dehydroepiandrosterone and Its Sulfate

Measurements of DHEA or its sulfated conjugate, DHEA-S, in serum and plasma are important for investigations of adrenal androgen production, such as assessment of adrenal hyperplasia, adrenal tumors, adrenarche, delayed puberty, or hirsutism. DHEA-S in circulation originates primarily from the adrenal glands. Although in men some may be derived from the testes; none is produced by the ovaries. DHEA is secreted almost entirely by the adrenal glands.

DHEA concentrations exhibit a circadian rhythm that reflects the secretion of adrenocorticotrophic hormone (ACTH); these concentrations vary during the menstrual cycle. DHEA-S concentrations, however, do not exhibit a circadian rhythm because of their longer circulating half-life.

DHEA-S measurement is typically performed using non-isotopic immunoassays. Other methods include competitive protein-binding assays and GC-MS. Immunoassays for DHEA-S demonstrate significant cross-reactivity with DHEA, androstenedione, and androsterone, yet the relative concentrations of these steroids have a minimal effect on assay performance.

Specimen collection and storage

Serum or plasma (preserved with ethylenediaminetetraacetic acid [EDTA]) is suitable for DHEA or DHEA-S immunoassays. Early-morning collection, before 10:30 a.m., is preferred for DHEA. DHEA-S specimens are stable for at least 1 day at room temperature.

Determining 17-Ketosteroids in Urine

The main purpose of measuring the 17-ketosteroids (KS) is to assess adrenal androgen production. However, measurement of DHEA-S in serum serves as a more convenient marker for adrenal androgen production than does urinary 17-KS excretion because 24-hour urine collection is not required and because many drugs interfere with the 17-KS assay.

Methods for Determining Estradiol in Blood

Both chromatography-mass spectrometry and immunoassay-based methods are used to measure estrogens in blood. GC-MS methods utilizing isotope dilution provide the most accurate and reliable measurement of E_2 . The main steps in these reference methods include solvent extraction, chromatographic fractionation, and chemical derivatization before analysis.

To measure E_2 directly without extraction and chromatography, the steroid must be displaced from its binding proteins. The displacing agents used in commercial methods often are not disclosed, but in some systems, effective displacement is achieved by adding 8-anilino-1-naphthalene sulfonic acid (ANS) or a large excess of a competing steroid such as DHT to the sample.

Caution should be exercised in assaying samples from subjects who are receiving oral contraceptives or estrogen replacement therapy because cross-reacting steroids may cause elevated results. Most notably, cross-reactivity with estrone is as high as 10% for some immunoassays but much lower (<1%) for others. This is likely due to a difference in the specificity of the antibody used for E_2 .

Several immunoassays for E_2 have been developed and adapted for use on fully automated immunoassay systems. All are heterogeneous assays (separation step needed), but most are direct assays and do not require preliminary extraction. Most procedures offer the convenience of solid-phase separation methods. For routine clinical applications, the greatest experience is with enzyme immunoassays.

Specimen collection and storage

Serum and plasma (with EDTA or heparin as anticoagulant) have been used. Specimens should be centrifuged and separated within 24 hours.

Methods for Determining Estriol in Blood

Except for purposes of fetal aneuploidy screening, measurement of E_3 has little clinical value because in nonpregnant women E_3 is derived almost exclusively from E_2 . Automated enzymatic immunoassay methods account for all unconjugated E_3 measurements. Several of these assays have been validated for use in maternal serum screening.

Methods for Determining Estrone in Blood

Estrone determinations have limited clinical utility. Normally, blood estrone concentrations parallel E_2 concentrations throughout the menstrual cycle, but at slightly lower concentrations.

Methods for Determining Progesterone in Blood

Enzyme immunoassays constitute the predominant method used for progesterone measurement. Initial immunoassays for serum progesterone measurement used organic solvents to remove the steroid from endogenous binding proteins such as corticosteroid-binding globulin and albumin. Direct (non-extraction) measurement of progesterone in serum or plasma is considered the method of choice for routine applications.

Several immunoassays are available on fully automated systems. All are heterogeneous assays that require separation of free and antibody-bound fractions. Although automated immunoassays are less labor-intensive than RIAs and yield results in less time without the need for radioactivity, these assays do not have adequate functional sensitivity for the measurement of low progesterone concentrations in men, postmenopausal women, and children.

Double-isotope derivative methods and competitive protein-binding assays have been applied to the measurement of serum progesterone, but these methods require extensive purification of the steroid and are labor-intensive. GC procedures using flame ionization, electron capture, or nitrogen detection have been used to improve the accuracy of progesterone analysis. However, these methods are time-consuming and often require solvent extraction, chromatography, and derivatization before the steroid is quantitated. GC-MS has been recommended as a reference method for progesterone determination.

Specimen Collection and Storage

Serum or plasma (with heparin or EDTA as anticoagulant) is used and should be separated within 24 hours. The patient need not be fasting, and no special handling procedures are necessary.

Measurement of Salivary Sex Steroids

Measurement of steroid concentrations in saliva has the potential to serve as a noninvasive and convenient procedure for the assessment of “serum free” steroid concentrations. However, primarily because of rapid fluctuations in salivary concentration necessitating the collection of multiple samples, salivary testing for sex steroids is not commonplace.

POINTS TO REMEMBER

- Measurement of total serum steroid hormone concentrations requires displacement of hormone from its binding proteins.
- Immunoassay remains the most common method of steroid hormone measurement, but mass spectrometry is becoming more widely used.
- Automated testosterone and estradiol immunoassays are acceptable for use in healthy adult men and women, respectively, but most lack sufficient accuracy and precision for use in children and adults with low steroid hormone concentrations.
- Mass spectrometry-based methods offer improved accuracy and a lower limit of detection but require highly trained personnel and increased equipment costs.
- Free testosterone is most accurately measured by equilibrium dialysis or ultrafiltration in a reference laboratory. Direct immunoassay measurement of free testosterone is not recommended.

REVIEW QUESTIONS

1. An elevated serum concentration of which of the following hormones is most useful in distinguishing between a pituitary versus placental source of hCG?
 - a. FSH
 - b. TSH
 - c. Estradiol
 - d. Progesterone
 - e. ACTH
2. Which of the following best describes the application of mass spectrometry to steroid hormone measurement?
 - a. Mass spectrometry is easily automated and does not require highly trained technologists.
 - b. All mass spectrometry-based methods generate equivalent results.
 - c. Mass spectrometry-based methods are usually more sensitive and specific than immunoassays.
 - d. Mass spectrometers do not require routine maintenance.
 - e. Mass spectrometry-based methods should not be used in women with low estradiol concentrations.
3. Which of the following laboratory tests would be most appropriate to assess anovulation?
 - a. FSH on cycle day 4
 - b. Estradiol on cycle day 10
 - c. LH on cycle day 28
 - d. Progesterone on cycle day 21
 - e. Estrone on cycle day 14
4. Which of the following accurately describes free and bio-available testosterone?
 - a. Free testosterone represents the majority of circulating testosterone.
 - b. Free testosterone provides an accurate reflection of androgen status in patients with altered SHBG concentrations.
 - c. Measurement of free testosterone using a direct immunoassay generates the most accurate results.
 - d. Free testosterone is not biologically active.
 - e. Fluctuations in circulating SHBG do not affect free testosterone concentrations.
5. Which of the following is a likely diagnosis in a female patient experiencing primary amenorrhea characterized by delayed puberty with low serum FSH and LH concentrations?
 - a. Gonadal dysgenesis
 - b. 17 α -hydroxylase deficiency
 - c. Pituitary failure
 - d. Uterine outflow abnormality
 - e. FSH insensitivity
6. What is the most common cause of secondary amenorrhea?
 - a. Prolactinoma
 - b. Fragile-X primary ovarian insufficiency
 - c. Autoimmune adrenal insufficiency
 - d. Hypothyroidism
 - e. Pregnancy

7. Which of the following correctly describes polycystic ovary syndrome?
- Women with PCOS experience hyperandrogenism and anovulation with no other known cause.
 - Women with PCOS have undetectable serum estrogen concentrations.
 - Women with PCOS have a decreased risk of developing diabetes.
 - Women with PCOS have a decreased risk of developing coronary heart disease.
 - Women with PCOS can be diagnosed with a single definitive laboratory test.

Pregnancy and Prenatal Testing

*Melanie L. Yarbrough, Ann Gronowski**

OBJECTIVES

1. Define the following:
 - Alpha fetoprotein (AFP)
 - Amnion
 - Amniotic fluid
 - Chorion
 - Ectopic pregnancy
 - Embryo
 - Gestation
 - Meconium
 - Placenta
 - Human placental lactogen (hPL), or placental lactogen (PL)
 - Preeclampsia
 - Prenatal screening
 - Surfactant
2. Outline the events in the normal development of a fetus, beginning with conception and ending with birth.
3. Describe the structure and functions of the following, including hormones synthesized (if any), effect on maternal/fetal health if dysfunctional, and laboratory analyses and results used to determine health or disease:
 - Amnion/amniotic fluid
 - Blastocyst
 - Chorionic villus
 - Corpus luteum
 - Ovaries
 - Placenta
4. List the components of amniotic fluid and state their specific functions and what laboratory analyses are used to examine amniotic fluid.
5. Describe the major biochemical changes that take place during a normal pregnancy in maternal physiological systems, including renal, hemostatic, and endocrine changes.
6. State the clinical significance of the following laboratory analytes in the assessment of maternal and fetal health:
 - Alpha fetoprotein (AFP)
 - Human chorionic gonadotropin (hCG), or chorionic gonadotropin (CG)
 - Inhibin A (inhA)
 - Placental alpha macroglobulin-1 (PAMG-1)
 - Pregnancy-associated plasma protein A (PAPP-A)
 - Unconjugated estriol (uE₃)
7. Describe the fetal renal, gastrointestinal, hepatic, pulmonary systems, including functions, development, and maturation, and how and why these systems are assessed by the laboratory.
8. For the following disorders, list the causes and symptoms, and state the laboratory analytical procedures, specimen requirements, and laboratory results used to assess and diagnose:
 - Anencephaly
 - Down syndrome
 - Eclampsia
 - Ectopic pregnancy
 - HELLP syndrome
 - Hemolytic disease of the newborn (HDN)
 - Hyperemesis gravidarum
 - Preeclampsia
 - Respiratory distress syndrome (RDS)
 - Spina bifida
9. In regard to maternal serum screening for fetal defects, describe the composition, timing during pregnancy and utility of the quadruple and integrated tests.

KEYWORDS AND DEFINITIONS

Acute fatty liver of pregnancy A rare, life-threatening complication of pregnancy that occurs in the third trimester or the immediate period after delivery characterized by fatty infiltration of hepatocytes with little inflammation or necrosis.

Alpha fetoprotein (AFP) A protein produced in the fetal liver that is measured in maternal serum for predicting risk of anencephaly, spina bifida, and Down syndrome in the fetus.

Amniotic fluid Substance derived mostly from fetal urine that protects the developing fetus.

*The authors gratefully acknowledge the original contributions of David Grenache and GERALYN Lambert-Messerlian, upon which portions of this chapter are based.

- Anencephaly** A birth defect characterized by an underdeveloped brain, skull, and scalp.
- Assisted reproductive technologies (ART)** Procedures involving the manipulation of eggs or sperm to establish pregnancy in the treatment of infertility.
- Blastocyst** A thin-walled hollow structure in early embryonic development that contains a cluster of cells called the *inner cell mass* from which the embryo arises.
- Cholestasis of pregnancy** A condition during pregnancy characterized by impaired bile flow allowing bile salts to be deposited in the skin and the placenta.
- Chorionic villi** One of the minute vascular projections of the fetal chorion that combines with maternal uterine tissue to form the placenta.
- Conception** The union of the sperm and the ovum. Synonymous with fertilization.
- Down syndrome** A birth defect characterized by having three copies of chromosome 21 rather than the normal two copies. Also known as *trisomy 21*.
- Eclampsia** Convulsions and coma occurring in a pregnant woman or a woman who recently gave birth.
- Ectopic pregnancy** An embryo developing in the fallopian tube or abdomen instead of the uterus.
- Embryo** A developing infant that has not yet finished organ development (before 10 weeks' gestation).
- Endometrium** The glandular mucous membrane that lines the uterus.
- Erythroblastosis fetalis** A severe hemolytic disease of a fetus or newborn infant caused by the production of maternal antibodies against the fetal red blood cells, usually involving rhesus (Rh) blood group incompatibility between the mother and fetus.
- Expected date of confinement (EDC)** The date at which an infant is expected to be born, calculated from the date of the last menstrual period (LMP). Also called *due date*.
- Fetal fibronectin (fFN)** A protein produced during pregnancy that is thought to function as a "glue" attaching the fetal sac to the uterine lining.
- Fetal lung maturity (FLM)** A parameter that determines the likelihood a neonate will develop respiratory distress syndrome.
- Fetus** A developing infant that has finished organ development (following 10 weeks' gestation).
- Gestation** The process, state, or period of carrying an embryo or fetus from conception until birth; by convention, the time is measured clinically from the first day of the last menstrual period (LMP) and reported in weeks.
- HELLP syndrome** A life-threatening pregnancy complication usually considered to be a variant of preeclampsia and usually occurring between 23 and 39 weeks' gestation. The name is an acronym for the diagnostic features: *H*, Hemolysis; *EL*, elevated liver enzymes; *LP*, low platelets.
- Hemolytic disease of the newborn (HDN)** A disease of the fetus and newborn caused by maternal antibody-mediated fetal erythrocyte destruction.
- Human chorionic gonadotropin (hCG)** A placental glycoprotein hormone that stimulates the ovary to produce progesterone.
- Human placental lactogen (hPL)** A placental hormone, similar in structure and function to growth hormone, that disappears from the blood immediately after delivery.
- Hydramnios (or polyhydramnios)** An abnormality of pregnancy characterized by an accumulation of excess amniotic fluid.
- Hydrops fetalis** A condition in which a fetus or newborn baby accumulates fluids, causing swollen arms and legs and impaired breathing.
- Hyperemesis gravidarum** Extreme, excessive, and persistent vomiting in early pregnancy that may lead to dehydration and malnutrition.
- In vitro fertilization (IVF)** A procedure in which (1) eggs (ova) from a woman's ovary are removed, (2) the removed eggs are fertilized with sperm in a laboratory procedure, and (3) the fertilized egg (embryo) is returned to the woman's uterus.
- Lamellar bodies** Packages of phospholipids that are produced by type II alveolar cells and represent the storage form of surfactant. They are similar in size to platelets and are present in amniotic fluid.
- Lamellar body count (LBC)** Concentration of lamellar bodies in amniotic fluid. LBC increases as gestation advances.
- Meconium** A dark green fecal material that accumulates in the fetal intestines and is discharged at or near the time of birth.
- Molar pregnancy** A type of pregnancy caused by abnormal proliferation of placental tissue in the uterus. Also known as a *hydatidiform mole*.
- Multiple of the median (MoM)** In clinical screening, the statistic used to normalize analyte values.
- Neural tube defect (NTD)** A major birth defect resulting from the abnormal development of the neural tube present during embryonic life that gives rise to the central nervous system; the two most common NTDs are *spina bifida* and anencephaly.
- Nuchal translucency (NT) test** A measurement of the size of the translucent space behind the neck of the fetus; made using ultrasound between 10 and 14 weeks of pregnancy.
- Oligohydramnios** A condition in pregnancy characterized by a deficiency of amniotic fluid.
- Omphalocele** A birth defect in which the infant's intestine or other abdominal organs protrude from the navel.
- Ovulation** The release of the ripe egg (ovum) from the ovary.
- Placenta** A membranous vascular organ that develops in female mammals during pregnancy, lining the uterine wall and partially enveloping the fetus, to which it is attached by the umbilical cord. Following birth, the placenta is expelled.
- Placental alpha microglobulin-1 (PAMG-1)** A protein present in blood and the amniotic fluid and cervico-vaginal discharge of pregnant women.

Polyhydramnios (or hydramnios) The presence of excess amniotic fluid in the uterus.

Preeclampsia A disorder of widespread vascular endothelial malfunction and vasospasm that occurs after 20 weeks' gestation and can present as late as 4 to 6 weeks postpartum. It is clinically defined by hypertension and proteinuria, with or without pathologic edema.

Pregnancy The period from conception to birth. It usually lasts 40 weeks, beginning from the first day of the woman's last menstrual period (LMP), and is divided into three trimesters, each lasting 3 months.

Pregnancy-associated plasma protein-A (PAPP-A) A protein used in screening tests for Down syndrome.

Premature rupture of membranes (PROM) Breakage of the sac containing the developing fetus and the amniotic fluid prior to the start of labor; rupture before the 37th week of gestation is called *preterm PROM (PPROM)*.

Preterm delivery The birth of an infant before 37 weeks' gestation.

Prolactin A pituitary hormone that stimulates and maintains the secretion of milk.

Puerperium The approximate 6-week period lasting from childbirth to the return of normal uterine size.

Pulmonary surfactant A fluid secreted by the cells of the alveoli that serves to reduce the surface tension of pulmonary fluids.

Respiratory distress syndrome (RDS) A disease of premature infants caused by a deficiency of lung surfactant.

Spina bifida A congenital disorder caused by the incomplete closure of the embryonic neural tube (see *neural tube defect*); the most common form is meningocele (also called *myelomeningocele*).

Triploidy A condition characterized by the individual having three times the haploid number of chromosomes in the cell nucleus.

Trisomy 18 (Edwards syndrome) A genetic disorder caused by the presence of all or part of an extra 18th chromosome (trisomy: three chromosomes).

Trophoblasts The outermost layer of cells of the blastocyst that attaches the fertilized ovum to the uterine wall and serves as a nutritive pathway for the embryo.

Umbilical cord A flexible cordlike structure containing blood vessels and attaching a human or other mammalian fetus to the placenta during gestation.

Yolk sac A membranous sac attached to an embryo that provides early nourishment in the form of yolk in many animals, including humans, where it functions as the circulatory system before internal circulation begins.

Zygote The fertilized ovum or diploid cell resulting from the fusion of two haploid gametes.

The clinical laboratory has an important role in monitoring pregnancy. In contrast to most clinical situations, clinicians must simultaneously care for more than one patient. Normal reference intervals for many clinical measurements no longer apply during pregnancy, further complicating the management of the patient. This chapter reviews the biology of pregnancy and discusses laboratory tests used to detect, evaluate, and monitor both normal and abnormal pregnancies.

HUMAN PREGNANCY

To appreciate the role of laboratory tests in pregnancy healthcare, it is necessary to understand fundamental topics, such as (1) conception, embryo development, and fetal growth; (2) the role of the placenta; (3) the importance and composition of amniotic fluid; (4) maternal physiologic adaptations to pregnancy; and (5) functional maturation of the fetus.

Conception, Embryo, and Fetus

Normal human **pregnancy** (i.e., **gestation**) lasts approximately 40 weeks, as measured from the first day of the last normal menstrual period (LMP or LNMP). The anticipated date of birth of an infant is commonly referred to as the **expected date of confinement (EDC)**. Physicians customarily divide pregnancy into four time intervals. The first three time intervals are called *trimesters*, each of which is ~13 weeks. The last time interval, 37 to 42 weeks, is coined *term*. By convention,

the first trimester, 0 to 13 weeks, begins on the first day of the last menses.

Ovulation occurs on approximately the 14th day of the menstrual cycle. If conception occurs, the ovum is fertilized, usually in the fallopian tube, and becomes a **zygote**, which is then carried down the tube into the uterus. The zygote divides, becoming a morula. After 50 to 60 cells are present, the morula develops a cavity, the primitive **yolk sac**, and thus becomes a **blastocyst**, which implants into the uterine wall about 5 days after fertilization. The cells on the exterior wall of the blastocyst, **trophoblasts**, synergistically invade the uterine **endometrium** and develop into **chorionic villi**, creating the placenta.

At this stage, the product of conception is referred to as an **embryo**. A cavity called the *amnion* forms and enlarges with the accumulation of amniotic fluid. Nourished by the placenta and protected by the amniotic fluid, an embryo undergoes rapid cell division, differentiation, and growth. From combinations of three primary cell types—ectoderm, mesoderm, and endoderm—organs begin to form through a process called *organogenesis*. At 10 weeks, an embryo has developed most major structures and is now referred to as a **fetus**. At 13 weeks, the fetus weighs approximately 13 g and is ~8 cm long.

Rapid fetal growth occurs during the 13 to 26 weeks of the second trimester. By the end of the second trimester, the fetus weighs approximately 700 g and is 30 cm long. In the third trimester fetal growth and maturation continue, and toward the

end of the third trimester there is a slight deceleration in the rate of fetal growth. By the end of the third trimester, the fetus weighs approximately 3200 g and is about 50 cm long. Term pregnancy is defined as greater than or equal to 37 weeks. Recently, the definition of term pregnancy was subdivided into early term (37 0/7 to 38 6/7 weeks), full term (39 0/7 to 40 6/7), and late term (41 0/7 to 41 6/7). Term birth is defined as delivery at or beyond 37 weeks. Normal labor, defined as rhythmic uterine contractions causing cervical dilation and eventually delivery of the fetus and placenta, normally occurs during this period.

Placenta

The **placenta** and the **umbilical cord** form the primary link between fetus and mother. The placenta grows throughout pregnancy and is normally delivered through the birth canal immediately after the birth of the infant.

Function

The placenta (1) keeps the maternal and fetal circulation systems separate, (2) nourishes the fetus, (3) eliminates fetal wastes, and (4) produces hormones vital to pregnancy. It is composed of large collections of fetal vessels called *villi*. These villi are finger-like projections that insert into blood-filled spaces called the *intervillous space*. The intervillous space contains maternal blood that bathes the fetal villi and facilitates bidirectional exchange between mother and fetus. For substances to move from maternal circulation to fetal circulation, they must cross through the trophoblasts and several membranes. The transfer of any substance depends largely on the (1) concentration gradient between the maternal and fetal circulatory systems, (2) presence or absence of circulating binding proteins, (3) lipid solubility of the substance, and (4) presence of facilitated transport, such as ion pumps or receptor-mediated endocytosis. The placenta is an effective barrier to the movement of large proteins and hydrophobic compounds bound to plasma proteins. Maternal immunoglobulin (Ig)G crosses the placenta via receptor-mediated endocytosis. Because of its long half-life, maternally produced IgG protects a newborn through passive immunity for the first 6 months of life. Antibody assays with low limits of detection may be positive in infants up to age 18 months because of the persistence of maternal antibodies.

Placental Hormones

The placenta produces several protein and steroid hormones. The major protein hormones are **human chorionic gonadotropin (hCG)** and **human placental lactogen (hPL)**. Steroid hormones including progesterone, estradiol, estriol, and estrone are synthesized in complex joint pathways involving maternal, placental, and fetal contributions. In general, hormone production by the placenta increases in proportion to the increase in placental mass (e.g., the increase in maternal serum hPL concentration with advancing gestational age is directly correlated with the increasing mass of placental tissue). hCG, which peaks at the end of the first trimester, is an exception.

Chorionic Gonadotropin

One of the most important placental hormones is hCG. It stimulates the ovary to produce progesterone by maintaining the corpus luteum that, in turn, prevents menstruation, thereby protecting the pregnancy. The chemistry, biochemistry, and methods for measuring hCG are discussed later in this chapter.

Placental Lactogen

Placental lactogen, also known as hPL and human chorionic somatomammotropin (hCS), is a single polypeptide chain of 191 amino acids with two intramolecular disulfide bridges. The structure of hPL is exceptionally homologous (96%) with growth hormone (GH) and less so with **prolactin** (67%). The placental secretion near term is 1 to 2 g/day, the largest of any known human hormone. hPL has many biological activities, including (1) lactogenic, (2) metabolic, (3) somatotropic, (4) erythropoietic, and (5) aldosterone-stimulating effects.

Placental Steroids

The placenta produces a wide variety of steroid hormones, including estrogen and progesterone, with large amounts of estrogens produced at term. Maternal cholesterol is the main precursor for placental progesterone production. Biosynthesis of estrogens by the placenta differs from that of the ovaries because the placenta has no 17 α -hydroxylase. Thus each of the estrogens—estrone (E₁), estradiol (E₂), and estriol (E₃)—must be synthesized from C-19 intermediates that already have a hydroxyl group at position 17. In nonpregnant women, the ovaries secrete 100 to 600 μ g/day of estradiol, of which about 10% is metabolized to estriol. During late pregnancy, the placenta produces 50 to 150 mg/day of estriol and 15 to 20 mg/day of estradiol and estrone. Secretion of estrogens and progesterone throughout pregnancy ensures (1) appropriate development of the endometrium, (2) uterine growth, (3) adequate uterine blood supply, and (4) preparation of the uterus for labor.

Amniotic Fluid

Throughout intrauterine life, the fetus lives within a fluid-filled compartment. The **amniotic fluid** provides a medium in which a fetus readily moves. It cushions a fetus against possible injury, helps maintain a constant temperature, and is inhaled and swallowed by the fetus during normal fetal lung development. This fluid is a dynamic medium whose volume and chemical composition are controlled within relatively narrow limits.

Volume and Dynamics

The volume of amniotic fluid increases progressively until 34 weeks' gestation, when it decreases slightly through the 40th week and then more sharply declines until the 42nd week. The volume is 200 to 300 mL at 16 weeks, 400 to 1400 mL at 26 weeks, 300 to 2000 mL at 34 weeks, and 300 to 1400 mL at 40 weeks. Pathological decreases and increases in amniotic fluid volume are encountered frequently in clinical practice. Intrauterine growth retardation and anomalies of the fetal

TABLE 44.1 Composition of Amniotic Fluid (Mean Values)

Component	GESTATIONAL AGE (WEEKS)		
	15	25	40
Sodium, mmol/L	136	138	126
Potassium, mmol/L	3.9	4.0	4.3
Chloride, mmol/L	111	109	103
Bicarbonate, mmol/L	16	18	16
Urea nitrogen, mg/dL (mmol urea/L)	11 (3.9)	11 (3.9)	18 (6.4)
Creatinine, mg/dL (μmol/L)	0.8 (71)	0.9 (80)	2.2 (194)
Glucose, mg/dL (mmol/L)	47 (2.6)	39 (2.2)	32 (1.8)
Uric acid, mg/dL (mmol/L)	4.0 (0.24)	5.7 (0.34)	10.4 (0.61)
Total protein, g/dL (g/L)	0.5 (5)	0.8 (8)	0.3 (3)

From Benzie, R. J., Doran, T. A., Harkins, J. L., Owen, V. M., & Porter, C. J. (1974). Composition of the amniotic fluid and maternal serum in pregnancy. *Am J Obstet Gynecol*, 119, 798–810.

urinary tract, such as bilateral renal agenesis or obstruction of the urethra, are associated with **oligohydramnios**, an abnormally low amniotic fluid volume. Increased fluid volume is known as **hydramnios** (also termed **polyhydramnios**). Conditions associated with hydramnios include (1) maternal diabetes mellitus, (2) severe Rh isoimmune disease, (3) fetal esophageal atresia, (4) multifetal pregnancy, (5) **anencephaly**, and (6) spina bifida.

Composition

Early in gestation, the composition of the amniotic fluid resembles a complex dialysate of the maternal serum. As a fetus grows, the amniotic fluid changes in several ways (Table 44.1). Most notably, the sodium concentration and osmolality decrease and concentrations of urea, creatinine, and uric acid increase. The activities of many enzymes in amniotic fluid have been studied with respect to both gestational age and fetal status, but have not been found to be clinically useful. The major lipids of interest are the phospholipids (PL), whose type and concentrations reflect **fetal lung maturity (FLM)** (discussed in more detail later). Numerous steroid and protein hormones are also present in amniotic fluid. The rare syndrome of congenital adrenal hyperplasia (CAH) has been diagnosed antenatally by measuring 17-hydroxyprogesterone and pregnanetriol in the amniotic fluid near term.

Early in pregnancy, little or no particulate matter is found in the amniotic fluid. By 16 weeks' gestation, large numbers of cells are present, having been shed from the surfaces of the amnion, skin, and tracheobronchial tree. These cells are of great utility in antenatal diagnosis and are the cellular source for DNA used for karyotype analysis after amniocentesis. As pregnancy continues to progress, scalp hair and lanugo (fine hair on the body of the fetus) are shed into the fluid and contribute to its turbidity. Production of surfactant particles in the lung, termed **lamellar bodies**, greatly increases the haziness of the fluid. At term, amniotic fluid contains gross particles

of vernix caseosa, the oily substance composed of sebum and desquamated epithelial cells covering the fetal skin.

Normal fetuses do not defecate during pregnancy. If severely stressed, a fetus may pass stool that is called **meconium**. This heterogeneous material contains many bile pigments and therefore stains the amniotic fluid green. Meconium-stained amniotic fluid is a sign of fetal stress.

POINTS TO REMEMBER

Placenta

- A major function of the placenta is production of several protein and steroid hormones.
- hCG is a protein hormone that maintains the corpus luteum on the ovary to produce progesterone, which protects the pregnancy by preventing menstruation. Later in pregnancy, progesterone is synthesized by the placenta.
- hPL is a protein hormone that regulates maternal and fetal metabolism to facilitate growth and development of the fetus.
- Major steroid hormones, including progesterone and estradiol, are synthesized by the fetoplacental unit.

Amniotic Fluid

- Amniotic fluid provides a medium to cushion and protect the fetus.
- Early in gestation, the composition of the amniotic fluid resembles a complex dialysate of the maternal serum.
- Toward the end of the first trimester, the fetal kidneys begin to produce urine, which becomes the main component of amniotic fluid.
- Fetal cells shed in amniotic fluid are a source of DNA for karyotype analysis for suspected aneuploidy.
- Decreases and increases in amniotic fluid volume are indicative of potential pathophysiological changes in pregnancy.

MATERNAL ADAPTATION

During pregnancy, a woman undergoes dramatic physiologic and hormonal changes. The large quantities of estrogens, progesterone, PL, and corticosteroids produced during pregnancy affect various metabolic, physiologic, and endocrine systems. In addition, the woman experiences (1) an increase in resistance to angiotensin, (2) a predominance of lipid metabolism over glucose use, and (3) increased synthesis by the liver of thyroid- and steroid-binding proteins, fibrinogen, and other proteins characteristic of pregnancy. As a result of such changes, many of the laboratory reference intervals for nonpregnant patients are not appropriate for pregnant patients. Reference intervals for more than 70 analytes in normal pregnancy have been developed. Mean values for selected tests expressed as a percentage of control means are presented in Table 44.2. It should be noted that these reference intervals will vary depending on testing method.

Hematologic Changes

Maternal blood volume increases during pregnancy by an average of 45%. Plasma volume increases more than red blood cell mass; therefore, despite augmented erythropoiesis,

Data from Lockitch, G, (Ed.), (1993). *Handbook of Diagnostic Biochemistry and Hematology in Normal Pregnancy*. Boca Raton: CRC Press.

hemoglobin concentration, erythrocyte count, and hematocrit decrease during normal pregnancy, producing the so-called physiologic anemia of pregnancy. Hemoglobin concentrations at term average 12.6 g/dL (126 g/L), compared with 13.3 g/dL (133 g/L) for the nonpregnant state.

The leukocyte count varies considerably during pregnancy, from 4000 to 13,000/ μ L. During labor and **puerperium** (the interval immediately after delivery), leukocyte counts may be markedly increased.

The concentrations of several blood coagulation factors are increased during pregnancy. For example, plasma fibrinogen increases by approximately 65%, from 275 to 450 mg/dL (8.1 to 13.2 μ mol/L); this increase contributes to the increase in sedimentation rate. Other clotting factors also increase, including factors VII, VIII, IX, and X. Prothrombin and factors V and XII do not change, whereas factors XI and XIII decrease slightly. Even though the platelet count remains unchanged in most women and the prothrombin time and activated partial thromboplastin time shorten slightly (see [Table 44.2](#)), pregnancy increases the risk of thromboembolism up to five times that of nonpregnant women.

Biochemical Changes

During pregnancy, electrolytes show little change, but an approximately 40% increase in serum triglycerides, cholesterol, PL, and free fatty acids is seen. Plasma albumin is decreased to an average of 3.4 g/dL (34 g/L) in late pregnancy; plasma globulin concentrations increase slightly. Several of the plasma transport proteins, including thyroxine-binding globulin (TBG), cortisol-binding globulin (CBG), and sex hormone-binding globulin (SHBG), increase markedly. Serum cholinesterase activity is reduced, whereas alkaline phosphatase activity in serum is tripled, mainly as the result of an increase in very heat-stable alkaline phosphatase of placental origin. In addition, creatine kinase can markedly increase upon delivery.

Renal Function

Pregnancy increases the glomerular filtration rate (GFR) to about 170 mL/min per 1.73 m² by 20 weeks, and therefore increases the clearance of urea, creatinine, and uric acid. Concentrations of these three analytes are slightly decreased in serum for much of the pregnancy. As term approaches, GFR begins to return to the nonpregnant rate. Urea and creatinine concentrations rise slightly during the last 4 weeks. During this time, tubular reabsorption of uric acid increases dramatically, which increases serum uric acid compared with the nonpregnant state. Glucosuria up to 1000 mg/day (5.55 mmol/day) may be present, owing to increased GFR, which presents more fluid to the tubules and therefore lowers the renal glucose threshold. Protein loss in the urine can increase to up to 300 mg/day.

Endocrine Changes

The action of progesterone prevents menses and thus allows pregnancy to continue. In early pregnancy, progesterone is produced by the corpus luteum of the maternal ovary in response to hCG. In later stages the placenta directly produces enough progesterone to maintain the pregnancy.

Throughout pregnancy, plasma parathyroid hormone (PTH) is increased by approximately 40%, with almost no change in the plasma free ionized calcium fraction, thus suggesting a new set point for the secretion of PTH. Calcitonin

does not increase predictably during pregnancy, whereas 1,25-dihydroxyvitamin D is increased during pregnancy and promotes increased intestinal calcium absorption to support the calcium requirements for fetal skeletal development.

Increased estrogen concentration stimulates increased hepatic production of CBG. The hepatic clearance of cortisol decreases. Thus the absolute plasma concentrations of both total and free cortisol are several times higher during pregnancy. The diurnal rhythm of cortisol, higher in the morning and lower in the evening, is maintained. Increased plasma aldosterone and deoxycorticosterone concentrations are observed.

Increasing estrogen concentrations throughout pregnancy increase the secretion of prolactin up to 10-fold. Conversely, high estrogen concentrations during pregnancy suppress the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) below the detection limit. Baseline concentrations of other pituitary hormones such as thyroid stimulating hormone (TSH) remain nearly unchanged (see Table 44.2), but the GH response to provocative stimuli is blunted.

Although normal pregnancy is a euthyroid state, many changes occur in thyroid function. High concentrations of TBG raise the concentration of total thyroxine (T_4) and triiodothyronine (T_3), but a slight decrease in free T_4 concentration occurs during the second and third trimesters. A slight reciprocal increase in TSH has been reported. Thyroglobulin is significantly increased, especially in the third trimester. Very few (<0.2%) pregnant individuals develop hyperthyroidism, and hypothyroidism is very rare. Postpartum thyroid dysfunction is common and is frequently unrecognized and misdiagnosed as routine postpartum symptoms of fatigue and weight changes. The fetal thyroid-pituitary axis functions independently from the mother's axis by the end of the first trimester. However, if the mother has preexisting Graves disease (hyperthyroidism caused by autoantibodies that stimulate the thyroid), those antibodies can cross the placenta, causing hyperthyroidism in the fetus. If the mother has anti-TSH autoantibodies, the infant can develop transient hypothyroidism.

FUNCTIONAL DEVELOPMENT OF THE FETUS

Fetal organs mature during the third trimester but not at the same rate. This section reviews the lung, liver, kidneys, and blood maturation in the fetus.

Lungs and Pulmonary Surfactant

In normal air-breathing lungs, a substance called **pulmonary surfactant** coats the alveolar epithelium and responds to alveolar volume changes by reducing surface tension in the alveolar wall during expiration. Surfactant is needed because the surface tension is an inverse function of the radius of the airway. Thus small alveoli have a higher collapsing force than larger alveoli. Surfactant opposes the force and keeps the small alveoli from collapsing. Specialized alveolar cells synthesize pulmonary surfactant and package it into laminated storage granules

called *lamellar bodies*. These storage granules are 1 to 5 μm in diameter and contain PL, cholesterol, and protein. Pulmonary surfactant production starts as early as 20 weeks' gestation, but adequate amounts do not accumulate until about 36 weeks. Exudation of pulmonary fluid (via the trachea) and fetal breathing movements transport lamellar bodies into the amniotic fluid.

Pulmonary surfactant is a complex mixture of lipids and proteins; less than 5% is composed of carbohydrates. The principal phospholipids present in surfactant are lecithin (phosphatidylcholine) and phosphatidylglycerol (PG), while phosphatidylinositol and sphingomyelin are present in much lower abundance. The synthesis of lecithin gradually increases from 28 weeks' gestation until birth, with the highest production occurring at week 36. Similarly, phosphatidylinositol first appears at 28 weeks' gestation, but reaches peak production between 32 and 35 weeks. PG is the last phospholipid to be produced, appearing in surfactant at 36 weeks and continuing to rise until birth. The protein fraction of lamellar bodies is approximately 4% and is composed of four surfactant-specific proteins: SP-A, SP-B, SP-C, and SP-D.

Liver

Hematopoiesis occurs in the liver during the first two trimesters and is transferred to the fetal bone marrow during the third trimester. The liver is also responsible for production of specific proteins (such as albumin and clotting factors), metabolism and detoxification of many compounds, and secretion of substances such as bilirubin. A clinically useful protein produced by the liver is **alpha fetoprotein (AFP)**. Bilirubin secretion and detoxification mechanisms are immature until late in pregnancy and even in the first few months after birth. Thus premature infants often have high serum bilirubin concentrations and metabolize drugs poorly.

Kidneys

Toward the end of the first trimester, the fetal kidneys begin to produce urine, which becomes the main component of amniotic fluid. Early nephrons cannot produce concentrated urine, and pH regulation is also limited. Complete maturation occurs after birth. Although kidneys are not required for fetal survival, amniotic fluid is required for normal lung development. Without fluid to breathe, the fetal lungs fail to properly develop. Thus newborns without kidneys die of pulmonary failure.

Fetal Blood Development

Fetal blood is produced first by the embryonic yolk sac, then by the liver, and finally by the fetal bone marrow. With the switch of erythropoiesis to the fetal liver and spleen, fetal hemoglobin (HbF) production begins. HbF consists of two α - and two γ -chains ($\alpha_2\gamma_2$). Small amounts of adult hemoglobin, HbA ($\alpha_2\beta_2$), are also produced, but HbF predominates during the remainder of fetal life.

As the fetal bone marrow begins red cell production, HbA production increases. At birth, fetal blood contains 75% HbF and 25% HbA. HbF production rapidly diminishes during the first year of postnatal life. In normal adults, less than 1%

of hemoglobin is HbF. The difference between fetal and adult hemoglobin is very significant, as HbF has a higher affinity for oxygen than HbA. Thus, in the placenta, oxygen is released from the maternal HbA, diffuses into the chorionic villi, and preferentially binds to the fetal HbF. In addition, 2,3-diphosphoglycerate (2,3-DPG) does not bind HbF and therefore cannot decrease its affinity for oxygen.

MATERNAL AND FETAL HEALTH ASSESSMENT

For optimum healthcare during pregnancy, a woman should consult her physician, preferably before conception. Preconception evaluation should include a medical, reproductive, and family history; physical examination; and laboratory testing.

Laboratory Testing

The following laboratory tests are recommended as part of a preconception evaluation: (1) hematocrit, (2) blood type and Rh compatibility, (3) erythrocyte antibody screen, (4) Papanicolaou smear (or human papillomavirus [HPV] test), (5) urinalysis, (6) rubella titer, (7) rapid plasma reagin test, (8) gonorrhea and chlamydia testing, (9) cystic fibrosis carrier status, (10) human immunodeficiency virus (HIV) antigen and antibody screen, and (11) hepatitis B surface antigen. Depending on demographic risks, genetic testing for disorders such as Tay-Sachs disease, thalassemia, and sickle cell disease should be offered. A careful diet history is warranted. Folic acid supplementation should be recommended to reduce the risk of **neural tube defects (NTDs)**. Women at high risk for diabetes mellitus should be screened for this disorder (see [Chapter 33](#)).

Many laboratory tests are useful for managing normal and abnormal pregnancies (see “At a Glance: Laboratory Evaluation of Maternal Health”). Screening for fetal NTDs and aneuploidy should be offered to all pregnant patients. Depending on diabetes risk, glucose tolerance testing should be performed immediately or at 24 to 28 weeks. Maternal observation and recording of fetal movements, ultrasound examination (biophysical profile), and fetal heart rate patterns (nonstress test and contraction stress tests) are the currently accepted methods for monitoring fetal well-being.

Diagnosis and Dating of Pregnancy

The most important aspects of pregnancy management are detection of pregnancy and establishing accurate estimates of gestational age. The most useful test for detecting pregnancy is the hCG test.

Qualitative tests for hCG in blood or urine are used to screen for pregnancy. In the first 8 weeks of pregnancy, the hCG concentration in maternal serum rises geometrically ([Fig. 44.1](#)). Detectable amounts (>5 IU/L) are present in the serum 8 to 11 days after conception. hCG usually becomes detectable in the urine 1 to 3 days later, although this interval is highly variable. For women aged 13 to 40 years, serum hCG

AT A GLANCE

Laboratory Evaluation of Maternal Health

First Prenatal Visit

- Complete blood count (CBC)
- Rh(D) typing and antibody screen
- Pap smear
- Urinalysis
- Rubella immunity
- Varicella immunity
- Hepatitis B screening
- HIV antibody test
- Sexually transmitted infection (STI) testing
 - Syphilis
 - Chlamydia
 - Gonorrhea

Women at increased risk may also receive testing for the following:

- Genetic testing for inherited disease
- Cystic fibrosis carrier testing
- Hemoglobinopathies
- Gonorrhea
- Tuberculosis
- Toxoplasma
- Hepatitis C

Additional testing later in pregnancy:

- Detection of fetal anomalies
 - Maternal serum screening (first and second trimester)
 - Cell free fetal DNA screening (at 10 weeks' gestation or later)
- Oral glucose tolerance testing (between 24 and 28 weeks' gestation)
- Group B *Streptococcus* screening cultures (between 35 and 37 weeks' gestation)

Fig. 44.1 Concentration of chorionic gonadotropin (hCG) in maternal serum as a function of gestational age. Lines represent the 2nd, 50th, and 97th percentiles. The maternal serum values from 14 to 25 weeks are medians calculated from 24,229 pregnancies from testing performed at ARUP Laboratories, Inc., from January to October 1997. (From Ashwood, E. R. [1992]. Evaluating health and maturation of the unborn: the role of the clinical laboratory. *Clin Chem*, 38, 1523–1529, with permission.)

concentrations of 5 IU/L or greater are consistent with pregnancy. Higher values are infrequently seen in older, nonpregnant women and are thought to be caused by hCG secreted by the pituitary gland. Concentrations in approximately half of pregnant women reach 25 IU/L on the first day of their

missed period. The peak concentration occurs at about 8 to 10 weeks and is about 100,000 IU/L. Subsequently, hCG concentrations start to decline in serum and urine, and by the end of the second trimester, a 90% reduction from peak concentration has usually occurred. The presence of twins approximately doubles hCG concentrations.

COMPLICATIONS OF PREGNANCY

Although most pregnancies progress without problems, complications can arise in the mother, placenta, or fetus.

Abnormal Pregnancies

Conditions arising primarily in the mother include (1) ectopic pregnancy, (2) hyperemesis gravidarum, (3) preeclampsia, (4) HELLP syndrome, (5) liver disease, and (6) hemolytic disease of the newborn. The clinician must distinguish abnormal changes in laboratory tests from normal physiologic changes induced by pregnancy (see Table 44.2).

Ectopic Pregnancy and Threatened Abortion

When a fertilized egg implants in a location other than the body of the uterus, the condition is called an **ectopic pregnancy**. Most abnormal implantations occur in the fallopian tube; they can also occur in the abdomen, although this is rare. Common symptoms of ectopic pregnancy include abdominal pain, vaginal bleeding, and adnexal mass. Tubal rupture from the expanding nondistensible fallopian tube can cause a life-threatening hemorrhage and is a common cause of maternal death from ectopic pregnancy. Management of ectopic pregnancy can be surgical or medical (with methotrexate). Early detection and proper management of ectopic pregnancy are the most effective means of preventing maternal morbidity and mortality.

Ultrasound examination is used to evaluate women with symptoms. When ultrasound is nondiagnostic, serial quantitative measurements of serum hCG are used to identify women with ectopic pregnancy or abnormal intrauterine pregnancy. These conditions frequently produce abnormal hCG concentrations and slow rates of increase.

Preeclampsia and Eclampsia

Preeclampsia is a pregnancy condition characterized by hypertension and other end organ involvement, including proteinuria, cerebral vasospasm, hematologic abnormalities such as hemolysis and thrombocytopenia, and elevated transaminases (see “At a Glance: Diagnostic Criteria for Preeclampsia”). It can occur any time after 20 weeks (although there are cases of preeclampsia occurring at less than 20 weeks in abnormal pregnancies, such as **molar pregnancies**). It affects 3% to 5% of pregnancies and continues to be a major cause of maternal and perinatal mortality. If the mother develops generalized seizures, the condition is called **eclampsia**. Most maternal deaths are due to central nervous system complications, but ischemic liver damage may also occur. The only cure for preeclampsia is delivery of the placenta.

AT A GLANCE

Diagnostic Criteria for Preeclampsia

Mild Preeclampsia	Severe Preeclampsia
Hypertension: Blood pressure $\geq 140/90$ mm Hg (or mean arterial pressure of ≥ 105 mm Hg)	Systolic blood pressure of ≥ 160 mm Hg and/or diastolic of ≥ 110 mm Hg on two occasions 6 h apart
AND	
Proteinuria: ≥ 300 mg of protein in 24-h urine collection or $\geq 1+$ protein on urine dipstick	Oliguria (<500 mL in 24 h)
OR	Cerebral or visual disturbances
In patients with hypertension in the absence of proteinuria, new onset of any of the following is diagnostic of preeclampsia:	Pulmonary edema or cyanosis
Platelet count $<100,000/\mu\text{L}$	Epigastric or right upper-quadrant pain
Serum creatinine >1.1 mg/dL ($97 \mu\text{mol/L}$) or doubling of serum creatinine in the absence of other renal disease	Impaired liver function
Liver transaminases elevated to twice the normal concentration	Thrombocytopenia
Pulmonary edema	
Cerebral or visual symptoms	

Modified from American College of Obstetricians and Gynecologists; Task Force on Hypertension in Pregnancy. (2013). Hypertension in pregnancy: Report of the American College of Obstetricians and Gynecologists' Task Force on Hypertension in Pregnancy. *Obstet Gynecol*, 122, 1122.

HELLP Syndrome

The **HELLP syndrome** (hemolysis, elevated liver enzymes, and low platelet counts in association with preeclampsia) is a life-threatening obstetric complication that occurs in 0.1% of pregnancies. Its most prominent features are thrombocytopenia and disseminated intravascular coagulation. Most cases occur between 27 and 36 weeks' gestation, but the syndrome also may occur postpartum. Women typically present with epigastric or right upper quadrant pain, malaise, nausea, vomiting, and headache. Jaundice occurs in 5% of patients. Lactate dehydrogenase (LD) values may be very high reflecting high levels of red blood cell hemolysis, and alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are usually 2 to 10 times their upper reference limits. Treatment for HELLP is delivery of the fetus.

Liver Disease

Several liver disorders are unique to pregnancy. These include (1) hyperemesis gravidarum, (2) **cholestasis of pregnancy**, and (3) fatty liver of pregnancy. These disorders must be

distinguished from the normal physiological changes of pregnancy (see Table 44.2). Significant changes normally seen in pregnancy include a dilutional decrease in serum albumin and an increase of alkaline phosphatase (from the placenta). Notably, total bilirubin, 5'-nucleotidase, gamma-glutamyl transpeptidase (GGT), ALT, and AST are unchanged in mothers with a normal pregnancy. Changes in these analytes reflect hepatobiliary disease. Also discussed in this section are non-pregnancy-related liver disease in pregnancy and the effect of pregnancy on preexisting liver disease.

Hyperemesis Gravidarum

Hyperemesis gravidarum is characterized by nausea and vomiting and, in severe cases, dehydration and malnutrition. It typically occurs in the first trimester. When hyperemesis is severe enough to cause dehydration, abnormal liver enzyme values—usually less than four times the upper reference limit—are seen in approximately 50% of patients. Mild hyperbilirubinemia may occur. However, significant liver disease does not occur, and liver biopsy results are normal. Low birth weight babies are common, especially for women who develop malnutrition.

Cholestasis of Pregnancy

Pregnancy does not preclude the acquisition or aggravation of non-pregnancy-related liver disease. Thus cholestasis during pregnancy may reflect the presence of (1) hepatotoxicity from drugs, (2) primary biliary cholangitis (formerly primary biliary cirrhosis), (3) Dubin-Johnson syndrome, or (4) cholelithiasis. Abdominal ultrasound, endoscopic retrograde cholangiography, or liver biopsy may be necessary to exclude these conditions.

The onset of cholestasis during pregnancy usually occurs in the third trimester and is manifested clinically by diffuse pruritus and, in 10% of patients, jaundice. The typical features of cholestasis, including pale stools and dark urine, are present and last until delivery. Women who experience cholestasis while taking oral contraceptives usually develop cholestasis of pregnancy. Serum bilirubin rarely exceeds 5 mg/dL (85.5 μ mol/L). Alkaline phosphatase is typically two to four times the upper reference limit. Aminotransferase enzyme concentrations are mildly increased and may precede the increase of bile acids. Prothrombin time may be increased because of vitamin K malabsorption. The condition is associated with increased risk for preterm delivery and possibly fetal death, and has an increased risk for recurrence with subsequent pregnancies.

Fatty Liver of Pregnancy

Fatty liver of pregnancy occurs in approximately 1 in 10,000 pregnancies and is characterized by accumulation of microvesicular fat in the hepatocytes. Many of the cases of this maternal disorder are caused by an inherited mitochondrial fatty acid oxidation disorder in the fetus, long chain 3-hydroxyacyl-CoA dehydrogenase deficiency (LCHAD). Mothers carrying fetuses with this disorder are 50 times more likely to develop fatty liver of pregnancy. The disease typically

occurs at week 37 and is manifested clinically by the rapid onset of malaise, nausea, vomiting, and abdominal pain. Mild increases in aminotransferase enzyme concentrations occur, with the AST increase typically greater than that of ALT but both typically less than six times the upper reference limit. Serum bilirubin is usually greater than 6 mg/dL (102.6 μ mol/L). Life-threatening hypoglycemia may occur. Hyperuricemia, presumably from tissue destruction and renal failure, is characteristic. Liver histology shows acute fatty infiltration with little necrosis or inflammation. If untreated, fulminant hepatic failure with hepatic encephalopathy ensues (see Chapter 37). Treatment is immediate delivery, at which time rapid recovery usually occurs. Infant and maternal mortality is approximately 50% and 20%, respectively.

Effect of Pregnancy on Preexisting Liver Disease

Conception and full-term parturition do not usually occur in women who have cirrhosis. However, liver disease is not a reason for termination of a pregnancy. The hypervolemia associated with pregnancy may aggravate cirrhosis and predispose to bleeding from esophageal varices. Autoimmune chronic hepatitis is usually associated with amenorrhea, but pregnancy may occur after treatment to remission with corticosteroids.

Neonatal Thyroid Function

During the first trimester of pregnancy, the fetus is dependent on the mother for its supply of thyroid hormone. Low maternal thyroid hormone concentrations (overt or subclinical hypothyroidism) have been associated with adverse outcomes, such as preterm delivery, fetal death, and a reduced intelligence quotient (IQ) in children. Later in pregnancy, the fetal thyroid-pituitary axis functions independently from the mother's axis in most cases. However, if the mother has preexisting Graves disease, her IgG autoantibodies can cross the placenta and stimulate the fetal thyroid gland. Thus the fetus can develop hyperthyroidism. Measurement of TSH-receptor antibodies by thyrotropin-binding inhibitory immunoglobulin (TBII) or thyroid-stimulating immunoglobulin (TSI) assay is useful for assessing risk of fetal or neonatal Graves disease.

Hemolytic Disease of the Newborn

Hemolytic disease of the newborn (HDN) is a fetal hemolytic disorder caused by maternal antibodies directed against antigen on fetal erythrocytes. Commonly used synonyms for this disorder are *isoimmunization disease*, *Rh isoimmune disease*, *Rh disease*, or *D isoimmunization*. Any of a large number of erythrocyte surface antigens may be responsible for isoimmune hemolysis. When severe, the disorder is known as **erythroblastosis fetalis** and is life threatening to fetus and newborn. Disease severity is commonly assessed using non-invasive ultrasonographic determination of middle fetal cerebral artery velocity.

Etiology

Maternal sensitization may occur in response to blood transfusion or a pregnancy in which the mother is exposed

to fetal red blood cells carrying the antigen that the mother lacks. Antibodies against RhD are the most common cause of HDN, although antibodies against other erythrocyte antigens can also cause disease. The resulting maternal antibodies are actively transported across the placenta and into the fetus, where they cause destruction of the fetal erythrocytes. The severity of the resulting hemolysis is influenced by antibody specificity, titer, and transfer rate, as well as the functional maturity of the fetal spleen in which the sensitized erythrocytes are destroyed.

Destruction of the fetal erythrocytes leads to fetal anemia that imposes an extra burden on the fetal heart to provide an adequate oxygen supply to fetal tissues. Anemia stimulates the fetal marrow and extramedullary erythropoiesis in the liver and spleen to replace the destroyed erythrocytes. Extramedullary erythropoiesis destroys hepatocytes and leads to decreased production of serum albumin and decreased oncotic pressure in the intravascular space. When severe, the outcome is congestive heart failure and generalized fetal edema, a condition referred to as **hydrops fetalis**, which carries a very grave prognosis. Without therapeutic intervention via red blood cell transfusion into the umbilical cord, intrauterine demise soon follows.

Clinical Management of Rh-D Sensitized Mothers

To identify sensitized women, an alloantibody screen is performed at the first prenatal visit. If an antibody to an erythrocyte antigen is identified, the titer is determined. The critical anti-RhD titer, defined as the titer associated with risk for fetal hydrops, is usually 1:8 to 1:32. For all sensitized women, the paternal erythrocyte phenotype is determined. If the father is homozygous RhD-negative, then no follow-up studies are required. If he is D-positive, then zygosity is determined. Although this has historically been estimated from Rh antigen phenotypes (D, C/c, E/e) in conjunction with gene frequency tables based on race, DNA testing for RhD zygosity is more reliable. If the father is homozygous, then all of his offspring can be assumed to be RhD positive, negating the need for fetal RhD testing. Fetal RhD genotyping from cultured amniocytes is required if the father is heterozygous or is not available for testing. To guard against a false negative caused by a paternal RhD gene rearrangement (occurring in about 1.5% of Caucasians), the father can also be genotyped. A frequent occurrence in those of African ancestry is an RhD pseudogene; the patient is RhD-negative by serology, but RhD-positive on genotype. If the fetus is RhD-genotype-positive, the mother (who is RhD-negative serologically) should be tested for RhD genotype. In the United States, as well as other parts of the world, fetal Rh genotyping using cell-free fetal DNA that circulates in maternal blood is now available.

For sensitized mothers with an at-risk fetus, serial titers are performed on maternal serum every month until 24 weeks' gestation, and then every 2 weeks thereafter. If a critical titer anti-D is detected, ultrasound Doppler measurements are used to determine the peak velocity of blood flow in the fetal middle cerebral artery. Higher velocity is a strong indicator

of fetal anemia. Historically, amniocentesis was performed every 10 to 14 days to assess the bilirubin concentration in amniotic fluid. Therapy for fetal anemia involves intrauterine percutaneous umbilical cord red blood cell transfusion. If fetal hydrops develops later in gestation (weeks 35 or beyond) or multiple transfusions have been required over the course of pregnancy, delivery timing is decided to balance the risks of continued intrauterine development versus the risk for prematurity.

Trophoblastic Disease

Serum hCG determinations are very useful for monitoring patients with germ cell-derived neoplasms or other hCG-producing tumors, such as lung carcinoma. The use of hCG in these diseases is discussed in [Chapter 20](#).

Preterm Delivery

The leading cause of neonatal morbidity and mortality in the United States is **preterm delivery**, defined as delivery before 37 weeks' gestation. Rupture of the fetal membranes prior to the onset of uterine contractions is known as **premature rupture of membranes (PROM)**. When PROM occurs at less than 37 completed weeks' gestation, it is referred to as *preterm PROM* and is responsible for nearly one-third of preterm deliveries.

Infants born before 37 weeks' gestation are usually of low birth weight (<2500 g) and are vulnerable to numerous complications, including (1) infection, (2) necrotizing enterocolitis, and (3) intraventricular hemorrhage, and often develop (4) **respiratory distress syndrome (RDS)**. The cause of preterm labor is unknown, but it is likely that many factors are involved.

Premature Rupture of Membranes

Preterm PROM (PPROM) is a complication in 3% of pregnancies. Risk factors for PPROM include (1) a history of PPROM, (2) genital tract infection, (3) antepartum bleeding, and (4) smoking. Most women who experience PPROM will deliver their infants within 1 week. Management of PPROM varies according to the gestational age of the fetus and the presence or absence of maternal/fetal infection.

The diagnosis of PROM is often difficult, and the commonly used tests to detect it lack clinical sensitivity and specificity. These include (1) direct observation of fluid leaking from the cervix or pooling in the posterior fornix of the vagina, (2) ultrasound for the detection of oligohydramnios, (3) nitrazine (pH) and (4) fern tests, and (5) detection of placental alpha microglobulin-1 protein.

Respiratory Distress Syndrome

Respiratory distress syndrome (RDS), also called *hyaline membrane disease*, is the most common critical problem encountered in clinical management of preterm newborns. The worldwide incidence of RDS is 1% of live births and 10% to 15% of live preterm births (<37 weeks or <2500 g). The risk of RDS is affected strongly by the gestational age at the time of birth, with a likelihood of less than 5% at 37 weeks,

20% at 34 weeks, and 60% at 29 weeks. In 2010, RDS was the eighth leading cause of death in infants in the United States. Affected infants require supplemental oxygen and mechanical ventilation to remain properly oxygenated. The disorder is caused by a deficiency of pulmonary surfactant. In normal lungs, surfactant coats the alveolar epithelium and responds to alveolar volume changes by reducing the surface tension in the alveolar wall during expiration. When the quantity of surfactant is deficient, many of the alveoli collapse on expiration and thereby overinflate the remaining airways. The lungs become progressively noncompliant (stiff), and blood flowing through the capillary beds of collapsed alveoli fails to oxygenate. Infants at risk for developing RDS are treated with intratracheal administration of exogenous surfactant immediately at birth.

POINTS TO REMEMBER

Complications of Pregnancy

- When a fertilized egg implants in a location other than the body of the uterus, the condition is called an *ectopic pregnancy*.
- Preeclampsia is characterized by hypertension, proteinuria, and often edema. Eclampsia is characterized by the development of seizures in conjunction with preeclampsia.
- The diagnosis of PROM is often difficult, and the commonly used tests to detect it lack clinical sensitivity and specificity.
- Respiratory distress syndrome in a neonate is most commonly caused by a deficiency of pulmonary surfactant due to prematurity, which results in collapse of the alveoli.

Differential Diagnosis of Liver Disease

- **Acute fatty liver** is suggested in a patient with nausea and vomiting in the presence of jaundice, hypoglycemia and encephalopathy with a small or normal-sized liver.
- Preeclampsia and the HELLP syndrome are characterized by an enlarged liver, lower ALT concentrations than in liver disease, mildly increased or normal bilirubin, normal glucose, and hypertension.
- Liver biopsy may differentiate non-pregnancy-related causes of liver disease. Biopsy is not necessary to differentiate acute fatty liver from preeclampsia or HELLP syndrome because the treatment is the same for all of these conditions—delivery of the infant.

Hemolytic Disease of the Newborn

- HDN is a fetal hemolytic disorder caused by maternal antibodies directed against antigen on fetal erythrocytes.
- Maternal sensitization may occur in response to blood transfusion or exposure of the mother to fetal RBCs carrying antigen that the mother lacks.
- An alloantibody screen is performed to identify sensitized mothers. In positive women, a titer is determined to monitor risk for fetal hydrops.
- Fetal RhD genotyping using cultured amniocytes or circulating cell-free fetal DNA may be required in a sensitized mother if the father is heterozygous or is not available for testing.
- Noninvasive ultrasonographic determination of middle fetal cerebral artery velocity is useful to assess disease severity.

PRENATAL SCREENING FOR FETAL DEFECTS

Prenatal screening is the process of identifying pregnancies at sufficiently high risk of a serious birth defect such as an open NTD or **Down syndrome**. The risk for Down syndrome, calculated using screening tests, is more accurate than the use of maternal age alone, and women of all ages should be offered screening. In addition to prenatal screening tests for maternal serum analytes, detection of cell-free fetal DNA (cffDNA) in maternal blood holds promise for high quality noninvasive screening or diagnosis of some fetal aneuploidies. Prenatal screening of cffDNA is highly sensitive and specific for Down syndrome in both high-risk and routine pregnancies. (The reader is referred to chapter 53 of the *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics*, 6th edition, for a more detailed discussion of this technique and its applications.) However, cffDNA testing does not assess risk of NTDs and is not recommended for multiple gestations. Due to this and the lack of data on low-risk pregnancies, the American College of Obstetricians and Gynecologists (ACOG) recommends measurement of maternal serum analytes for routine prenatal screening.

Terminology and Method of Risk Calculation in Prenatal Screening

Multiple of the Median

Understanding prenatal screening requires an understanding of the **multiple of the median (MoM)**, the statistic used to normalize analyte values. The initial step in calculating a MoM is to develop a set of median values for each week (or day) of gestation, using the laboratory's own assay values measured on the population to be screened. [Fig. 44.2](#) graphically illustrates typical median values for the second-trimester markers used in prenatal screening. Individual test results are then expressed as a MoM by dividing each individual test result by the median for the relevant gestational age. The MoM is universally used as a common factor for converting analyte values into an interpretative unit and serves as the starting point for calculating screening results for NTDs, Down syndrome, and trisomy 18.

Calculating Individualized Patient-Specific Risks Using Multiple Biochemical Measurements

Measurements of each analyte are made on a serum sample, and the results in mass units are converted to MoM for the appropriate week of gestation. This MoM value is then adjusted for other variables, such as maternal weight and race. The individualized risk (patient-specific risk) for any given condition is determined by multiplying the a priori risk for that condition by a likelihood ratio that is calculated using the woman's MoM values, as shown in the following equation:

$$\text{Patient risk} = \text{A priori risk} \times \text{Likelihood ratio}$$

The a priori risk is obtained from large epidemiological studies that ascertain the prevalence for the condition under consideration. For example, a woman's age is used to define her a priori risk for having a fetus with Down syndrome. The

Fig. 44.2 Typical median values for maternal serum alpha-fetoprotein (AFP) (A), unconjugated estriol (uE_3) (B), human chorionic gonadotropin (hCG) (C), and inhibin A (inhA) (D) in the second trimester. The observed average gestational age is plotted on the horizontal axis, and the median of that week's marker measurements is plotted on the vertical axis. The thin vertical lines represent the 95% confidence interval of the medians.

likelihood ratio is determined by calculating the ratio of the heights of the affected and unaffected overlapping population distributions for any specified MoM value. When multiple tests are used, a single likelihood ratio is calculated using the overlapping distributions for each test but with the correlation between tests taken into account. This final calculated risk, rather than the analyte concentrations themselves, is the screening variable upon which clinical decisions are made.

PRENATAL SCREENING TESTS

Maternal serum screening for NTDs began in the 1970s using second trimester serum specimens. Since then, maternal serum screening has expanded to include partial detection of Down syndrome and trisomy 18, among others.

Neural Tube Defects

NTDs are serious abnormalities that occur early in embryonic development. By 19 days after fertilization, the area that is to form the central nervous system (brain and spinal cord) has differentiated into a plate of cells. The flat plate then rolls up, and its edges fuse into a hollow neural tube that drops into the embryo to develop just underneath what will become the skin of the back. Neural tube formation is normally complete

4 weeks after fertilization. Failure of neural tube fusion leads to permanent developmental defects of the brain, spinal cord, or both. These defects include *anencephaly*, *meningomyelocele* (which is commonly called **spina bifida**), and *encephalocele*. Although there are many heterogeneous causes, about 90% fall into the classification of multifactorial inheritance. Folic acid deficiency is clearly associated with increased frequency of neural tube closure defects.

The birth prevalence of open NTDs varies with factors such as geographic location (higher in the Eastern United States, lower in the West), race (lower in African Americans), ethnicity (higher in Scotch-Irish), family history (higher with prior births of affected individuals), and maternal weight (higher in obese women). An average figure for the United States is 1 open NTD per 1000 pregnancies. Almost all cases of anencephaly and about 95% of meningo-myeloceles are open, with no overlying skin, and therefore are in direct communication with the amniotic fluid. Thus the fetal serum proteins normally present in amniotic fluid at low concentrations gain access in large quantities to the amniotic fluid. The increased amniotic fluid AFP concentration leads to increased amounts in the maternal circulation. Thus only open NTDs are detected by maternal serum AFP screening.

Fig. 44.3 Distribution of maternal serum alpha-fetoprotein (AFP) measurements in unaffected pregnancies and in pregnancies affected with open spina bifida or anencephaly. *MoM*, Multiple of the median.

Prenatal Screening

AFP concentrations are increased in amniotic fluid and serum (in the second trimester) of mothers carrying fetuses affected with an open NTD (e.g., anencephaly, open spina bifida). Maternal serum AFP testing thus provides a screening method to identify pregnancies at high risk or to estimate the numerical risk of having a fetus with an open NTD. Because concentrations in serum in affected and unaffected pregnancies overlap considerably, maternal serum AFP is useful as an initial screening test to identify women at high risk for having an affected fetus (Fig. 44.3). These women are then referred for diagnostic procedures (e.g., high resolution ultrasound and, if indicated, amniocentesis for measurement of AFP and acetylcholinesterase in amniotic fluid) to determine if the fetus has an open NTD.

Down Syndrome

Down syndrome is the most common serious disorder of the autosomal chromosomes in liveborn infants, occurring in 1 in 700 live births. An extra copy of chromosome 21 results in a phenotype consisting of moderate to severe intellectual and developmental disabilities, hypotonia, congenital heart defects, and flat facial profile. Most often, an affected child has three copies of chromosome 21 (i.e., trisomy 21), but 5% of cases are caused by translocations and 1% of cases are mosaics. A woman's risk increases slowly up to age 30 and then steadily increases between ages 30 and 45 to a plateau.

Prenatal Screening

Maternal serum AFP concentrations are about 25% lower in Down syndrome than in unaffected pregnancies. The association of AFP and Down syndrome is independent of maternal age. The independence of maternal serum AFP measurements and maternal age established that it was possible to offer a screening method to younger women, in whom most cases of Down syndrome occur.

Unconjugated estriol (uE_3), a product of the fetoplacental unit, is also about 25% lower in pregnancies with Down syndrome. In contrast, concentrations of hCG and inhibin A are about twice as high. A screening method that combines

maternal age with measurements of these four analytes permits determination of a single Down syndrome risk estimate. This “quadruple test” provides approximately 80% detection at a 5% false positive rate. Table 44.3 illustrates general patterns of first- and second-trimester analytes associated with various disorders.

Trisomy 18

Trisomy 18 (Edwards syndrome) is caused by a nondisjunction event during meiosis that results in a fetus having an extra copy of chromosome 18. Although it occurs in only 1 in 8000 births, it is probably the most common chromosome defect at the time of conception. The dramatic change in prevalence is due to the very high fetal loss rate both before 8 weeks (>80%) and during the second and third trimesters (~70%). Following birth, half of the infants die within the first 5 days and 90% die within 100 days.

Prenatal Screening

Prenatal screening studies have found that fetal trisomy 18 has a distinctive triple-marker pattern that is different from the Down syndrome pattern (see Table 44.3). In trisomy 18 pregnancies, the AFP, uE_3 , and hCG concentrations are low. A method for trisomy 18 risk calculation is available and is often included in prenatal screening programs.

Other Aneuploidies

Although chromosome disorders other than trisomies 21 and 18 are not part of routine screening, the marker patterns exhibited in maternal serum for some aneuploidies are similar. In particular, hydropic Turner syndrome and triploidy of paternal origin have serum marker patterns resembling that of Down syndrome pregnancy and are sometimes identified as high risk using this algorithm. Similarly, Turner syndrome without hydrops and triploidy of maternal origin are sometimes identified by the trisomy 18 risk algorithm. The pattern for trisomy 13 is variable (see Table 44.3).

Newer Screening Algorithms

Following extensive use of screening tests in the second trimester, new tests have been introduced that use serum collected in the first trimester.

First Trimester Combined Test

For patients seeking early diagnosis, screening for Down syndrome in the first trimester (10 to 13 weeks' gestation) is available. First trimester screening involves measurement of maternal serum **pregnancy-associated plasma protein-A (PAPP-A)** concentration, which is relatively low in Down syndrome pregnancy, and hCG (free beta subunit or total) concentration, which is relatively high in Down syndrome. A third marker used to improve first trimester screening performance is ultrasound measurement of **nuchal translucency (NT)**, the subcutaneous space between the skin and cervical spine, which is increased in fetuses with Down syndrome. A combination of NT and serum tests (the combined test) was comparable or slightly better than the second-trimester quadruple test for Down syndrome screening, detecting 85% of cases at a 5% false-positive rate.

TABLE 44.3 Conditions Associated With Various Maternal Serum Screening Result Patterns

Condition	SECOND TRIMESTER				FIRST TRIMESTER		
	AFP	hCG	uE ₃	InhA	PAPP-A	hCG	NT
Amniocentesis	Normal to high	—	—	—	—	—	—
Anencephaly	Very high	—	Very low	—	—	—	—
Congenital nephrosis, duodenal atresia, encephalocele, esophageal atresia, gastroschisis, hydrocephalus, Meckel syndrome, omphalocele , sacrococcygeal teratoma	High	—	—	—	—	—	—
Cystic hygroma	High	—	—	—	—	—	Increased
Down syndrome	Low	High	Low	High	Low	High	Increased
Fetal blood contamination	High to very high	Unchanged	Unchanged	Unchanged	—	—	—

Turner syndrome with hydrops	Low	High	Very low	High	Variable	Variable	Increased
Twins and other multiple gestations	High	High	High	High	High	High	—
Underestimated gestational age	High	Low	High	Normal	—	—	—

AFP, α -Fetoprotein; hCG, human chorionic gonadotropin; inhA, inhibin A; NT, nuchal translucency; PAPP-A, pregnancy-associated plasma protein A; uE₃, unconjugated estriol.

The pattern of markers in trisomy 18 affected pregnancies consists of an increased NT measurement and reduced PAPP-A and hCG in the first trimester. Estimates for the performance of first trimester combined testing in the detection of trisomy 18 are varied, but detection rates have been suggested to be about 80% for a 0.3% false positive rate.

Adding First and Second Trimester Markers Into a Single Integrated Screening Test

The integrated test takes advantage of first- and second-trimester markers and avoids most of the limitations of

stand-alone first-trimester screening (Fig. 44.4). With this approach, measurements of NT and PAPP-A are made in the first trimester but are not interpreted or acted upon until testing in the second trimester is complete. In the second trimester, a quadruple test is performed on maternal serum. Results from all six tests (NT, PAPP-A, AFP, uE₃, hCG, and inhibin A) are then combined into a single risk estimate. This approach detects 85% of Down syndrome cases with only a 1% false-positive rate.

The integrated screening approach can be offered effectively and at a lower cost by using a modified test based only on the serum markers (serum integrated). Maternal serum

Fig. 44.4 Receiver operating characteristic curves for tests used to screen for Down syndrome. (Reprinted with permission from Wald, N. J., Rodeck, C., Hackshaw, A. K., Rudnicka, A. [2005]. *SURUSS in perspective. Semin Perinatol*, 29, 225–235.)

PAPP-A concentrations are measured at 10 to 13 weeks and combined with a second trimester quad test for a five-marker screening panel. The serum integrated test gives an 85% detection of Down syndrome cases with about a 3% false-positive rate. A summary of detection and false positive rates for second-trimester and integrated screening tests is illustrated in Fig. 44.4.

Adjustments for Factors That Influence Analyte Measurements

Prenatal screening for both open NTDs and Down syndrome is optimized when each woman's analyte concentration is compared with those of other women (the reference group) who are "similar" to her in many respects. In addition to gestational age, this "similarity" extends to other factors that have been shown to affect analyte concentrations, including (1) maternal weight, (2) race, (3) insulin-dependent diabetes (IDD), and (4) multiple pregnancy. Taking into account these factors increases the accuracy of the interpretation.

Pregnancies Achieved by Assisted Reproductive Technologies

The use of **assisted reproductive technologies (ART)**, such as **in vitro fertilization (IVF)**, for conception is increasing. Women who achieve pregnancy by IVF are about twice as likely to have a positive result after second-trimester Down syndrome screening as are women who achieve pregnancy spontaneously. Thus MoM values of certain analytes are adjusted to restore an appropriate screen positive rate. In particular, concentrations of uE_3 tend to be reduced, while hCG and inhibin A are increased in pregnancies achieved by IVF. Pregnancies achieved by

POINTS TO REMEMBER

Prenatal Screening

- Screening of maternal serum for AFP, hCG, uE_3 , and inhibin A together with nuchal translucency measurement is useful to identify women with increased risk for having a fetus with anomalies such as a neural tube defect, Down syndrome, and trisomy 18.
- Down syndrome is associated with increased nuchal thickness and decreased concentrations of AFP and uE_3 and increased concentrations hCG and inhibin-A in maternal serum.
- Increased risk for neural tube defects is associated with increased serum AFP.
- Trisomy 18 is associated with decreased concentrations of AFP, estriol, uE_3 , and hCG.

intrauterine insemination, with or without ovulation induction, show a similar trend in marker concentrations.

ANALYTICAL METHODOLOGY

In this section of the chapter, methods for measurement of (1) hCG, (2) AFP, (3) uE_3 , (4) inhibin A, (5) PAPP-A, and (6) tests for FLM are reviewed.

Human Chorionic Gonadotropin

Measurement of hCG is used to (1) detect pregnancy and its abnormalities (e.g., ectopic and molar pregnancies), (2) screen for Down syndrome and trisomy 18, and (3) monitor the course of a patient with a hCG-producing cancer. Because hCG has these diverse uses, many assays are used, including qualitative urine and serum devices and quantitative serum assays.

Biochemistry

hCG is a glycoprotein containing a protein core with branched carbohydrate side chains that usually terminate with sialic acid. The hormone is a heterodimer composed of two nonidentical, noncovalently bound glycoprotein subunits—alpha (α) and beta (β). When the hCG dimer is dissociated, the hormone activity is lost. However, a major part of the original activity is restored by equimolar recombination of the two subunits.

hCG is synthesized in the placenta. A single gene located on chromosome 6 encodes the α subunit of all four glycoprotein hormones (TSH, LH, FSH, and hCG). Chromosome 19 contains a family of seven genes that encode the hCG β subunit, though only three appear to be active. Separate messenger RNAs are transcribed from the respective genes, and the α and β subunits are translated from each. The subunits spontaneously combine in the rough endoplasmic reticulum and are then continuously secreted into the maternal circulation.

In the first weeks of pregnancy, hCG stimulates the corpus luteum in the ovary to make progesterone, a steroid that prevents menses and thus facilitates pregnancy. hCG binds weakly to TSH receptors in the maternal thyroid, and extremely increased hCG concentrations have the potential to be thyrotropic.

Methods

Qualitative human chorionic gonadotropin tests. Numerous tests for the qualitative detection of hCG in urine or serum are available as over-the-counter (home) or point-of-care (POC) devices, and their use for the rapid identification of pregnancy is well established. Qualitative detection of hCG in urine is a test granted waived status under the Clinical Laboratory Improvement Amendments of 1988. In contrast, the use of serum as a sample matrix is considered a moderately complex test, even when the test device itself is approved for use with urine or serum, due to the requirement that centrifugation of the specimen is necessary to obtain serum. POC devices are single-use tests that utilize immunochromatography for the rapid qualitative detection of hCG when its concentration exceeds a detection threshold, frequently 10 to 25 IU/L. First-morning specimens are preferred for qualitative urine pregnancy tests because they are concentrated and contain abundant hCG.

Quantitative human chorionic gonadotropin tests. Commonly used quantitative hCG tests are high-performance immunometric assays designed to measure hCG over a wide range of concentrations. Upper limits of detection vary from 400 to 15,000 IU/L. Thus specimen dilution is frequently required to obtain an absolute measurement. The lowest detectable concentration of these assays is from 1 to 2 IU/L.

The measurement of hCG is complicated by its molecular heterogeneity, and considerable variation in measured hCG concentrations is observed between the different assays. Because of variation between hCG assays, median hCG values calculated for maternal serum screening are not transferable and should be considered method specific. hCG

measurements in early pregnancy generally are expressed as international units per liter (IU/L). A typical hCG concentration at 16 weeks is approximately 30,000 IU/L.

Alpha Fetoprotein

Measurement of AFP in maternal serum and amniotic fluid is used extensively for prenatal detection of some serious fetal anomalies. Maternal serum AFP is increased in 85% to 95% of cases of fetal open NTD and is decreased in about 30% of cases of fetal Down syndrome. Additionally, AFP measurements are used in nonpregnant patients for monitoring certain cancers.

Chemistry

AFP is a glycoprotein encoded by a gene located within q11–22 on chromosome 4 that is part of a family of genes that also encodes for albumin and vitamin D-binding protein. The protein is composed of carbohydrate and a single polypeptide chain containing 591 amino acids. The carbohydrate composition varies depending on the organ of synthesis, the length of gestation, and source of the specimen (fetal serum vs. amniotic fluid).

Biochemistry

AFP is produced initially by the fetal yolk sac in small quantities and then by the fetal liver in larger quantities as the yolk sac degenerates. Trace amounts are also produced in the fetal gut and kidneys. Early in embryonic life, this protein has a high concentration in fetal serum, reaching about one-tenth the concentration of albumin. Maximal concentration in the fetal serum (~ 3 million $\mu\text{g/L}$) is reached at about 9 weeks' gestation. The concentration then declines steadily to about 20,000 $\mu\text{g/L}$ at term. The increase and decrease in concentration of AFP in the amniotic fluid roughly parallel those in the fetal serum but the concentration is two to three orders of magnitude lower ($\sim 15,000$ $\mu\text{g/L}$ at 16 weeks' gestation). Amniotic fluid AFP has been measured as early as 8 weeks. It rapidly decreases to a low point at 11 weeks and then increases to reach a second maximum at 13 weeks. The concentration then falls in a log-linear fashion until 25 weeks, when the decline steepens.

AFP is first detectable (~ 5 $\mu\text{g/L}$) in maternal serum at about the 10th week of gestation. The concentration increases about 15% per week to a peak of approximately 180 $\mu\text{g/L}$ around 25 weeks. The concentration in maternal serum then subsequently declines slowly until term. After birth, the maternal serum AFP rapidly decreases to less than 2 $\mu\text{g/L}$. In an infant, serum AFP declines exponentially to reach adult concentrations by the 10th month of life.

Methods

Although AFP was traditionally measured by radioimmunoassay (RIA), newer methods use immunoenzymometric assay (IEMA) or chemiluminescent immunoassay (CIA) because of their (1) lower detection limits, (2) increased precision, (3) speed, (4) avoidance of radioactivity, and (5) ease of automation.

Amniotic fluid AFP is measured using the same immunoassays as for maternal serum AFP after a suitable dilution (usually 1:50 to 1:200). AFP in amniotic fluid is less stable than in serum, and leaving samples at room temperature for prolonged periods results in degradation of amniotic fluid AFP. The presence of fetal blood in amniotic fluid samples has been known to increase AFP results, and laboratories should note the presence of blood on the report. In the event of an increased amniotic fluid AFP result (usually >2.0 or 2.5 MoM), the laboratory should test for the presence of fetal blood.

Measurement of acetylcholinesterase (AChE) is a confirmatory test for samples with increased amniotic fluid AFP. Cerebrospinal fluid contains high concentrations of the neural enzyme AChE, and in cases of fetal open NTDs, fluid leaks from the open lesion and allows AChE to enter the amniotic fluid.

Unconjugated Estriol

Any disruption in the biosynthetic pathway will lead to very low maternal serum uE_3 . Conditions that cause disruption include (1) fetal anencephaly, (2) placental sulfatase deficiency, (3) fetal death, (4) chromosome abnormalities, (5) molar pregnancy, and (6) Smith-Lemli-Opitz syndrome (SLOS). SLOS is a serious, rare birth defect that is the result of an inborn error in cholesterol metabolism, 7-dehydrosterol-7-reductase deficiency. Down syndrome leads to a modest decrease in uE_3 . This steroid, rather than total estriol (unconjugated plus conjugated estriol), is the most specific of the estrogens for identifying a fetus with Trisomy 21.

Chemistry

Estriol is an estrogen with hydroxyl groups at positions 3, 16, and 17. Although present in nonpregnant patients in very low concentrations, during late pregnancy this estrogen predominates. Only a minor amount (~10%) of the hormone circulates in plasma unconjugated, and this form is strongly bound to sex hormone binding globulin (SHBG) because of its low solubility. The majority exist as conjugates of glucuronate and sulfate. Conjugation, which occurs in the maternal liver, makes the hormone more soluble and permits renal clearance.

Biochemistry

Estriol is produced in very large amounts during the last trimester of pregnancy. The biosynthetic pathway requires three organs to be fully functioning: fetal adrenal, fetal liver, and placenta. The fetal adrenal avidly binds low-density lipoprotein to take in cholesterol, which is converted to two major steroid intermediates: pregnenolone sulfate and dehydroepiandrosterone sulfate (DHEA-S). These intermediates are secreted into the fetal circulation. The fetal liver, possessing 16α -hydroxylase, converts DHEA-S to 16α -hydroxy-DHEA-S, which is secreted back into the fetal circulation. Finally, the placenta synthesizes estriol from 16α -hydroxy-DHEA-S. Approximately 90% of maternal serum estriol is derived from this fetal-placental pathway.

A minor amount is made using precursors from the maternal ovary. Concentrations typical for the second trimester of pregnancy are 0.70 to 2.50 $\mu\text{g/L}$ (2.43 to 8.68 nmol/L), depending on the assay used.

Methods

The determination of uE_3 is made difficult by its low concentration. Values obtained with various uE_3 assays vary widely as judged using the CAP proficiency testing Survey FP. Conversion to MoM reduces the between-method differences, but uE_3 is still the most variable of the screening analytes.

Of the four analytes currently used for screening, uE_3 is the least stable, and consequently requirements for collection, storage, and shipment are dictated by this analyte. The uE_3 concentration increases in blood at room temperature and at 4°C because the conjugated forms are able to spontaneously deconjugate to form the parent hormone. Therefore collected blood should be allowed to clot, and serum should be removed promptly. uE_3 is stable in serum for up to 7 days at 2°C to 4°C . The concentration of uE_3 increases when sera has been stored for longer than 4 days at room temperature.

Inhibin A

Inhibins are members of the transforming growth factor- β (TGF β) superfamily of proteins. Inhibin is a negative feedback regulator of FSH secretion in both males and females. The placenta produces large quantities of inhibin A that completely suppress FSH. In addition to the usefulness of inhibin A as a predictor of Down syndrome risk, inhibin A and B measurements have found additional applications as tumor markers for ovarian cancer and in the evaluation of male infertility.

Chemistry

Inhibins are proteins consisting of dimers of dissimilar subunits (α and β) linked by disulfide bridges. The mature form of inhibin is produced by cleavage of larger precursor forms. In follicular fluid and serum, mature inhibins, precursors of inhibins, and intermediate molecules of varying molecular weight are present. Another group of related molecules, the activins, are dimers consisting of just the β -subunits. Inhibin A is the only form within the inhibin/activin family of proteins that provides sufficient discrimination to be useful for use in Down syndrome screening.

Biochemistry

In the reproductive system, inhibin and activin subunits are expressed in the placenta, as well as in the granulosa cells of the ovary and by the Sertoli cells of the testis. Inhibin A and inhibin B have distinctive serum profiles during the human menstrual cycle. Inhibin A rises in the follicular phase and peaks at ovulation, before decreasing to basal amounts in the luteal phase. In postmenopausal women, the concentrations of both forms of inhibin are nondetectable.

Inhibin A is produced by the fetoplacental unit beginning in early pregnancy. Inhibin A concentrations exhibit a

Fig. 44.5 Typical median values for maternal serum pregnancy-associated plasma protein-A (PAPP-A) and total human chorionic gonadotropin (hCG) in the first trimester. The observed average gestational age is plotted on the horizontal axis and the median of that week's PAPP-A (black solid line) or total hCG (blue dotted line) measurements on the vertical logarithmic axis.

complex pattern during the course of pregnancy, rising to a peak at 8 to 10 weeks' gestation, declining to a minimum at 17 weeks of pregnancy, and then resuming to slowly increase at term. Unlike the other screening tests, average inhibin concentrations change relatively little from 15 to 20 weeks' gestation. Values in the second trimester range from 50 to 400 ng/L, with typical levels at 17 weeks' gestation reaching a nadir of about 175 ng/L (175 pg/mL).

Methods

Inhibin assays used for Down syndrome screening must measure only dimeric inhibin A and not the free α subunits and the precursors of higher molecular weight, which also circulate in blood. Highly specific assays using monoclonal antibodies are available that measure only dimeric inhibin A. Specific inhibin A assays provide better screening performance than the nonspecific total inhibin assays.

Pregnancy-Associated Plasma Protein A

PAPP-A concentrations in the maternal serum during the first trimester of pregnancy are associated with fetal and placental health and development. Low PAPP-A concentrations early in pregnancy have been associated with (1) Down syndrome, (2) a high rate of fetal loss, (3) poor fetal growth (intrauterine growth restriction [IUGR]), (4) premature delivery, (5) hypertension, and (6) preeclampsia.

Biochemistry

PAPP-A is a zinc-containing metalloproteinase glycoprotein. It is expressed at low concentrations in all tissues, but high amounts of PAPP-A protein and mRNA are localized in placental tissues throughout gestation. Circulating PAPP-A is part of a larger molecular complex that includes two subunits of PAPP-A covalently bound to two subunits of pro major basic protein (pro MBP), forming a heterotetramer. PAPP-A immunoreactivity is found in syncytiotrophoblast cells.

Maternal serum PAPP-A concentrations increase as gestation proceeds to term (Fig. 44.5). Concentrations of PAPP-A are critical to normal fetal growth because of its role as an insulin-like growth factor binding protein (IGFBP) protease. PAPP-A regulates the action of insulin-like growth factor II (IGF-II) by cleaving its binding protein, primarily IGFBP-4, thereby increasing bioavailable forms.

Methods

PAPP-A immunoassays are available on routine clinical chemistry platforms. There are significant between-method differences, and efforts to achieve standardization are currently underway. A small increase in PAPP-A concentrations has been reported for collection in plastic versus glass tubes. First-trimester serum PAPP-A concentrations are stable in serum at 4°C for 1 week or longer, depending on the assay used for testing.

Fetal Fibronectin

Determining the risk of preterm labor would help clinicians manage those at high risk more aggressively, thereby lowering the incidence of preterm delivery. **Fetal fibronectin (fFN)** concentration in cervical and vaginal secretions was proposed as a test to aid in predicting preterm delivery. While patients with a negative test result have only a ~1% chance of delivering in 1 week, the positive predictive value of fFN is low. Thus fFN is of limited utility in predicting preterm birth within 7 days of sample collection. fFN may be measured by immunoassay of cervical or vaginal mucus collected with a Dacron polyester swab.

Placental Alpha Microglobulin-1

Placental alpha microglobulin-1 (PAMG-1) is a placental glycoprotein. During pregnancy, PAMG-1 is secreted into the amniotic fluid, where it is present at a high concentration (2000 to 25,000 ng/mL) relative to that of maternal blood (5 to 25 ng/mL) or cervicovaginal fluid with intact membranes (0.05 to 2 ng/mL). A test for PAMG-1 that exploits these large differences in concentrations has been developed for clinical use as an aid for the detection of PROM.

A rapid immunochromatographic method is commercially available for the rapid detection of PAMG-1 in cervicovaginal fluid. The specimen is collected using a polyester swab, and the fluid is eluted off the swab by rinsing it in a vial containing a buffer solution. A test strip is then placed into the buffer for 10 minutes. The test result is determined by visual inspection of a test and a control line on the lateral flow device. The analytical limit of detection of the test is 5 ng/mL.

This test is more sensitive and specific for the detection of PROM than clinical assessment or the nitrazine or ferning tests. Contamination with large amounts of blood will cause a false-positive result. False-negative results may occur if the specimen is collected 12 or more hours after a rupture that is subsequently obstructed by the fetus or is resealed.

Fetal Lung Maturity

FLM tests help assess the risk of a fetus to develop RDS. Numerous tests of amniotic fluid for FLM have been developed that exhibit high sensitivity for immaturity and an excellent predictive value of a mature result. Despite performing well, the number of FLM tests performed each year in the United States has declined, and several studies have demonstrated that FLM testing does not improve fetal morbidity or mortality.

In 2008, the ACOG issued a revised practice bulletin concerning FLM. This bulletin discourages FLM testing before 32 weeks of gestation or when delivery is mandated due to fetal or maternal indications and specifies that assessment of FLM is indicated prior to a scheduled delivery at less than 39 weeks of gestation if it cannot be inferred from clinical history. However, the practice of scheduled deliveries at less than

39 weeks of gestation is now strongly discouraged by ACOG, unless delivery is justified by medical or obstetric complications. Thus testing for FLM is becoming infrequent.

Fetal Lung Maturity Assessment

Fetal lung liquids contribute to amniotic fluid, resulting in an exchange of surfactants from the developing lungs to the amniotic fluid. Therefore amniotic fluid is the required specimen for FLM testing, and it is obtained by transabdominal amniocentesis, usually during real-time sonographic visualization. Currently available methods for FLM testing include (1) **lamellar body count (LBC)**, (2) phosphatidylglycerol measurement, and the (3) lecithin/sphingomyelin ratio. Readers are referred to previous editions of this textbook for a detailed discussion of FLM testing methodology.

REVIEW QUESTIONS

- The most severe form of hemolytic disease of the newborn (HDN) is referred to as:
 - respiratory distress syndrome (RDS).
 - ectopic pregnancy.
 - jaundice.
 - erythroblastosis fetalis.
- In a developing fetus, the major blood-forming organ until 24 weeks' gestation is the:
 - bone marrow.
 - liver.
 - lung.
 - kidney.
- Preeclampsia is diagnosed by the presence of which findings?
 - Hypertension and proteinuria ≥ 300 mg of protein in 24-hour urine
 - Hypertension and proteinuria ≥ 100 mg of protein in 24-hour urine
 - Hypertension and new onset of platelet count $> 100,000/\mu\text{L}$
 - Hypertension and decreased liver transaminases
- The composition of amniotic fluid is most typically like that of which one of the following?
 - Extracellular fluid
 - Intracellular fluid
 - Cerebrospinal fluid
 - Blood
- Hemolytic disease of the newborn (HDN) is caused by:
 - lack of folic acid in the maternal diet.
 - increased formation of fetal hemoglobin (Hb F).
 - maternal antibodies against fetal erythrocytes.
 - blockage of placental transfer of immunoglobulin A (IgA) antibodies.
- What is the function of the hormone hCG (human chorionic gonadotropin) in pregnancy?
 - It signals the corpus luteum to produce progesterone to maintain pregnancy.
 - It inhibits the production of estrogen and progesterone by the ovary.
 - It stimulates the production of estrogen to promote uterine growth.
 - Its concentration peaks near birth, which helps initiate the birth process.
- Which of the following best describes changes in concentrations of placental hormones during pregnancy?
 - Estrogen peaks in the first trimester, and then remains stable throughout gestation.
 - Estrogen concentration increases throughout gestation.
 - hCG concentration is stable throughout gestation.
 - Progesterone concentration declines throughout gestation.
- The integrated screen for prediction of Down syndrome risk includes testing for:
 - PAPP-A in the first trimester and hCG, AFP, and uE₃ in the second trimester.
 - AFP, hCG, uE₃, and inhibin A in the second trimester.
 - PAPP-A and nuchal translucency in the first trimester and AFP, hCG, uE₃, and inhibin A in the second trimester.
 - hCG in the first trimester and nuchal translucency, AFP, and PAPP-A in the second trimester.
- The majority of waste produced by a fetus is in the amniotic fluid. Which one of the following structures is responsible for removal of this waste from the amniotic fluid?
 - Fetal kidneys
 - Fetal liver
 - Fetal lungs
 - Placenta
- When a fertilized egg implants in a location other than the body of the uterus, the condition is called:
 - Down syndrome.
 - spina bifida.
 - ectopic pregnancy.
 - hyperemesis gravidarum.

Newborn Screening and Inborn Errors of Metabolism

Marzia Pasquali, Nicola Longo

OBJECTIVES

1. Define the following:
 - Aminoacidopathy
 - Fatty acid oxidation disorder
 - Inborn error of metabolism (IEM)
 - Multiplex analysis
 - Newborn screening
 - Organic acidemia
 - Second-tier testing
 - Tandem mass spectrometry (MS/MS)
 - Urea cycle disorder
 - Lysosomal storage disorder
2. Describe autosomal recessive inheritance patterns, including their significance in inborn errors of metabolism (IEMs) and percent risk of having an affected child in each pregnancy; diagram an autosomal recessive inheritance pattern pedigree.
3. List the six components of a newborn screening program; state the criteria required of any newborn screening program.
4. State the classes of metabolic disorders identifiable by newborn screening and list an example of each class.
5. For the following disorders, list causes and symptoms, treatments, available screening, and second-tier laboratory analyses and results:
 - Galactosemia
 - Glutaric acidemia type I
 - Homocystinuria
 - Maple syrup urine disease (MSUD)
 - Medium-chain acyl-coenzyme A (CoA) dehydrogenase (MCAD) deficiency
 - Phenylketonuria (PKU)
 - Tyrosinemia type I
 - Urea cycle disorders
6. Outline how the results of tandem mass spectrometry are interpreted with regard to inborn errors of metabolism (IEMs); state an advantage of using this type of analysis.
7. Discuss the issue of false positive results in newborn screening, including tests most commonly misinterpreted and the use and principle of second-tier tests.
8. List four types of confirmatory laboratory tests used to verify out of range newborn screening test results.

KEYWORDS AND DEFINITIONS

Aminoacidopathy A disorder of amino acid metabolism caused by defective activity of an enzyme leading to elevated amino acids in blood (and urine).

Argininosuccinate lyase (ASL) deficiency A genetic disorder that affects the body's ability to clear the nitrogen already incorporated into the urea cycle as argininosuccinate. This disorder often presents with rapid-onset hyperammonemia in the newborn period. Also known as *argininosuccinic aciduria*.

Argininosuccinate synthetase (ASS) deficiency A genetic disorder characterized by a deficiency of argininosuccinate synthetase and an increase in the ammonia concentration in the blood. Also known as *citrullinemia type I*.

Autosomal recessive disorder A disorder characterized by the requirement that both copies of a gene (called alleles) are abnormal (see following definition for *autosomal recessive inheritance*).

Autosomal recessive inheritance A mendelian inheritance pattern in which (1) nonsex chromosomes (autosomes)

carry a DNA sequence (gene) for the inherited trait and (2) two abnormalities (one from each parent) in the DNA sequence must be present for the trait to appear in an individual; heterozygous parents have a 25% chance of having an affected offspring.

Citrullinemia type II An autosomal recessive disease characterized by increased concentrations of citrulline in serum and urine. Ammonia intoxication is another manifestation. This disorder is characterized by jaundice and liver failure early in life; neuropsychiatric symptoms, including abnormal behaviors, loss of memory, seizures, and coma in older individuals.

Dihydropteridine reductase (DHPR) An enzyme that catalyzes the reversible formation of tetrahydrobiopterin (BH4) from dihydrobiopterin; deficiency of BH4 results in malignant hyperphenylalaninemia.

Disorders of amino acid metabolism A group of disorders of amino acid metabolism caused by defective activity of an enzyme leading to increased concentration of amino acids in blood (and urine).

Disorders of carbohydrate metabolism A group of disorders caused by loss of an enzyme in the metabolic pathway of a carbohydrate, leading to increased accumulation of that carbohydrate within organs and tissues.

Disorders of fatty acid oxidation A group of disorders caused by deficiency of an enzyme in the oxidation pathway of fatty acids, leading to inability to use fat as an energy source.

Dried blood spot (DBS) A form of biosampling where blood samples are blotted and dried on filter paper.

Galactosemia An inherited disease in which the transformation of galactose to glucose is blocked, allowing galactose to increase to toxic concentrations in the body.

Glucose-6-phosphate dehydrogenase (G-6-PD) deficiency An X-linked recessive hereditary disease characterized by abnormally low quantities of the enzyme G-6-PD involved in the pentose phosphate pathway, especially important in red blood cell metabolism.

Glutaric acidemia type 1 (GA1) An inherited disorder in the metabolism of lysine and tryptophan causing accumulation of excessive quantities of glutaric acid (GA) and related compounds that can damage the brain.

Glycogen storage diseases Genetic diseases, also known as *glycogenoses* that involve the enzymes regulating glycogen accumulation and breakdown.

Homocystinuria A condition characterized by accumulation of excess homocysteine in blood. This biochemical abnormality has a variety of genetic causes.

Inborn error of metabolism (IEM) Inherited disorder due to deficiency of an enzyme or transporter impairing the transformation of body chemicals.

Long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency A metabolic disease characterized by defective fatty acid oxidation due to a defect in an enzyme in the β -oxidation pathway.

Lysosomal storage disorder A disorder characterized by impaired degradation of complex macromolecules in the lysosomes leading to accumulation of these substrates in organs and tissues.

Maple syrup urine disease (MSUD) An autosomal recessive metabolic disorder affecting branched-chain

amino acids (leucine, isoleucine, and valine). The urine of affected individuals smells like maple syrup.

Medium-chain acyl-CoA dehydrogenase (MCAD)

deficiency A disorder of fatty acid oxidation that impairs the body's ability to break down medium-chain fatty acids into acetyl-CoA.

Methylmalonic acidemia An autosomal recessive metabolic disorder resulting from defects in the metabolic pathway in which methylmalonyl-coenzyme A (CoA) is converted into succinyl-CoA by the enzyme methylmalonyl-CoA mutase.

Microcephaly A condition characterized by an abnormally small head due to failure of brain growth.

Multiplex analysis Simultaneous assessment of multiple analytes in a single sample.

Organic acidemia A disorder of intermediary metabolism in which lack of an enzyme leads to buildup of an organic acid (from deamination of the amino acid) as opposed to the buildup of the parent amino acid.

Peroxisomal disorders A group of conditions caused by impaired function of peroxisomes resulting from either impaired peroxisomes biogenesis or impaired activity of one of the peroxisomal enzymes.

Phenylketonuria (PKU) A disorder characterized by the accumulation of phenylalanine in blood caused by deficiency of phenylalanine hydroxylase activity leading to production of phenylketones that are excreted in urine.

Propionic acidemia An organic acid disorder due to deficiency of an enzyme involved in amino acid and fatty acid catabolism. It is characterized by excess of propionic acid in blood and urine.

Tandem mass spectrometry (MS/MS) An analytical technique where two mass spectrometers are connected in series. It involves separation and identification of substances and chemicals based on their mass to charge (m/z) ratio.

Tyrosinemia A genetic disorder involving the metabolism of the tyrosine. Affected individuals have high concentrations of tyrosine in blood (hypertyrosinemia).

Urea cycle disorder Any disorder in which the body is unable to excrete waste nitrogen—ammonia, resulting in mental and behavioral dysfunction, coma, and death.

Inborn errors of metabolism (IEM) are genetically determined disorders affecting an individual's ability to convert nutrients or to use them for energy production. They are caused by the impaired function of (1) enzymes, (2) transporters, or (3) cofactors, and result in accumulation of abnormal metabolites (substrates) proximal to the metabolic block or by lack of necessary products (path A to D, Fig. 45.1). Abnormal by-products can also be generated when alternative pathways are used to dispose of the excess metabolites (path A to F, see Fig. 45.1).

Typically IEMs present in the newborn period or in infancy. Some diseases, however, such as fatty acid oxidation defects or milder variants of classic metabolic disorders, may not be detected until adulthood. Despite the long asymptomatic period, their consequences are still devastating and may result in death. Therefore it is critical to identify and treat these diseases before irreversible damage occurs. The frequency of individual diseases is rare, varying from 1:10,000 to 1:200,000 or even rarer. Their cumulative frequency, however, is substantial and approaches a frequency of 1:2,000.

Fig. 45.1 General schematic of a metabolic pathway. The substrate *A* is converted by a series of reactions into product *D*. If one of the enzymes (arrows) is defective (metabolic block), the substrate of the reaction will accumulate (*A* in this case) and can enter alternative pathways of metabolism, leading to the formation of byproducts (*E* and *F* in this case). At the same time, the concentration of the product of the reaction (*D*) will decrease.

POINTS TO REMEMBER

- IEMs are disorders affecting the conversion of nutrients into energy.
- IEMs usually present in the newborn period or in early infancy, although there are cases that can become symptomatic in adulthood.
- The majority of IEMs are inherited as autosomal recessive traits.
- Symptoms vary and include vomiting, lethargy, delays in development, seizures, and coma leading to death.
- For some IEMs symptoms are triggered by environmental stress, such as fasting, infections, exercise.
- The diagnosis requires analysis of specific metabolites (amino acids, carnitine, acylcarnitines, organic acids), measurement of enzyme activity, and DNA testing.
- Treatment is available for many IEMs, and it is effective if it is initiated early.
- Newborn screening can identify many of these disorders pre-symptomatically.

INHERITANCE PATTERN OF METABOLIC DISORDERS

Metabolic disorders are caused by mutations in genes that code for specific enzymes or transporters involved in metabolic pathways. The majority of metabolic disorders have **autosomal recessive inheritance**, in which affected individuals have a mutation in both alleles encoding for a specific enzyme or transporter (Fig. 45.2) and girls are affected as often as boys. In the vast majority of cases, the parents of children with one of these metabolic conditions are carriers of the condition—that is, they carry one normal allele and one mutant allele, and they do not show clinical signs of the condition. In each singleton pregnancy when both parents are carriers, there is (1) a 25% chance that the child is affected, (2) a 50% chance that the child is a carrier like the parents, and (3) a 25% chance that the child has two normal alleles (see Fig. 45.2).

Clinical Presentation of Metabolic Disorders

The medical consequences of IEMs vary from failure to thrive to acute illness leading in some cases to (1) brain damage, (2) coma, and (3) death. In many cases, the acute presentation is

Fig. 45.2 Autosomal recessive inheritance pattern.

preceded by a symptom-free period that is variable in length depending on the specific disease. In many cases, there is a treatment available for these disorders consisting of special diets (formulas) that do not contain the specific nutrients that the patients are unable to metabolize. The treatment is effective if begun early before symptoms occur, but damage that has already occurred is usually irreversible. Thus the ideal time for identifying patients with metabolic disorders is at birth or earlier.

Biochemical Diagnosis

The biochemical diagnosis of IEMs and treatment monitoring involve analysis of (1) metabolites, (2) enzymatic activity, and/or (3) DNA sequence. Because of technological advances, such as **tandem mass spectrometry (MS/MS)**, which allows for the simultaneous detection of multiple analytes, many IEMs are now included in newborn screening programs.

NEWBORN SCREENING

Newborn screening is a public health activity aimed at early identification of conditions for which timely intervention is expected to result in elimination or reduction of (1) morbidity, (2) mortality, and (3) disabilities.

Background

Newborn screening was originally instituted in the 1960s as a result of the pioneering efforts of Robert Guthrie and his colleagues, who developed a screening assay for measuring the phenylalanine content of a **dried blood spot (DBS)** collected from the blood of newborn babies on filter paper.

Criteria of Newborn Screening Programs

The disease to be screened must be serious, must be fairly common, must have a natural history that is understood, and must have helpful treatment and genetic counseling (in

the case of genetic disease) available. In addition, the screening test must be acceptable to the public, reliable, valid, and affordable. The newborn screening program requires the availability of expedient diagnosis and treatment of the disease and effective communication of results. Newborn screening programs must be effectual public health approaches to the diagnosis of treatable disorders early in life. Because newborn screening is a program, its efficacy depends on the integration and collaboration among its different components, involving (1) public health, (2) screening and diagnostic laboratories, (3) physicians, and (4) families of affected children.

After the efforts of the American College of Medical Genetics and Genomics to uniform newborn screening practices in the United States, the newborn screening panel is periodically updated by the Advisory Committee on Heritable Disorders in Newborns and Children, and it is known as the recommended uniform screening panel (RUSP). States then decide if, when, and how they will implement the recommendations of the committee. Current recommendations for the uniform screening panel of core conditions (<https://www.hrsa.gov/advisorycommittees/mchbadvisory/heritabledisorders/recommendedpanel/>) include at least (1) five fatty acid oxidation disorders, (2) nine organic acidemias, (3) six aminoacidopathies, (4) two endocrinopathies (congenital hypothyroidism and congenital adrenal hyperplasia), (5) three hemoglobinopathies/thalassemias, (6) two lysosomal storage disorders (Pompe disease and Hurler syndrome), and (6) seven other disorders (Table 45.1), two of which (hearing loss and critical congenital heart disease) are tested directly at the birth facility. In addition, many secondary conditions can be identified using MS/MS and are routinely reported by most newborn screening programs (Table 45.2).

Advances in therapeutic interventions for IEMs are continuously expanding the role of newborn screening. Of note, newborn screening does not identify all metabolic disorders, and some patients with these disorders can be missed. Therefore a symptomatic patient at any age should be investigated despite normal newborn screening results.

Newborn screening is accomplished using MS/MS, which as a multiplex methodology allowing the measurement of multiple metabolites, which identifies the largest number of diseases, and other screening methods, such as (1) enzyme assays, (2) immunoassays, (3) electrophoresis, and (4) DNA tests.

Steps to be Followed in a Newborn Screening Program

The different steps that need to be coordinated and tracked in a newborn screening program are:

1. Screening (sample collection and delivery, laboratory testing)
2. Follow-up (complete demographic information, satisfactory specimens, abnormal screening results, access to testing and clinical care)
3. Diagnosis (confirmatory tests, clinical consultation)
4. Clinical management (primary care physician, specialist physician, genetic counselor, dietitian)
5. Education (healthcare professionals, parents)

6. Quality assurance: analytical (proficiency testing, quality controls, standards), efficiency of follow-up system, efficacy of treatment, long-term outcome

Each of these components should have specifically-written protocols that deal directly with the performance of the tasks involved. To assist laboratories in writing such protocols and procedures, the Clinical and Laboratory Standards Institute has published guidelines for newborn Screening, including guidelines on (1) blood collection on filter paper (NBS01-A6), (2) laboratory testing by tandem mass spectrometry (NBS04), (3) follow-up activities (NBS02-A2), and (4) document preparation (QMS02-A6). These documents describe the basic principles, scope, and range of activities within a newborn screening program and how to prepare the prerequisite documents. They are available at <https://clsi.org/standards/products/newborn-screening/documents/>.

Second-Tier Testing

One of the major pitfalls in newborn screening is the number of false-positive results associated with certain screening tests. To reduce the number of infants requiring additional and unnecessary confirmatory testing, second-tier tests have been developed. These second-tier tests involve further analysis of the same blood spot with an abnormal result targeting different, more specific analytes and, often, using a methodology different from the one used in the primary screening test. They include (1) DNA analysis for cystic fibrosis (see Chapter 49) (2) MS/MS steroid profiling for congenital adrenal hyperplasia (see Chapter 41), and (3) metabolic disorders. Second-tier testing has become a crucial component of newborn screening programs to increase the sensitivity and the specificity of the screening test.

INBORN ERRORS OF METABOLISM

In this section, disorders of metabolism included in the RUSP are discussed in general, with selected individual disorders of each class reviewed in more detail as examples. An online database containing a catalog of human genetic disorders is found at www.ncbi.nlm.nih.gov/omim/. This database is entitled “Online Mendelian Inheritance in Man” (OMIM) and is a comprehensive and authoritative compendium of human genes and genetic phenotypes. In this database, individual disorders are assigned a specific OMIM number.

Disorders of Amino Acid Metabolism

Disorders of amino acid metabolism collectively affect approximately 1 in 8000 newborns. Almost all are transmitted as autosomal recessive traits and result from a lack of a specific enzyme in the metabolic pathway of an amino acid, leading either to the accumulation of (1) the parent amino acid, (2) its by-products, or (3) the catabolic products (organic acids), depending on the location of the enzyme block. Disorders of amino acid metabolism are divided into two groups: (1) **aminoacidopathies**, in which the parent amino acid accumulates in excess in blood and spills over into urine; and (2) **organic acidemias**, in which

TABLE 45.1 Uniform Screening Panel Recommended by the Secretary of the Department of Health and Human Services for States to Screen as Part of Their State Universal Newborn Screening Programs: Core Conditions^a

ACMG Code	Core Condition	METABOLIC DISORDER					
		Organic Acid Condition	Fatty Acid Oxidation Disorders	Amino Acid Disorders	Endocrine Disorder	Hemoglobin Disorder	Other Disorder

TABLE 45.2 Uniform Screening Panel: Secondary Conditions as Recommended by the Advisory Committee on Heritable Disorders in Newborns and Children^a

ACMG Code	Secondary Condition	METABOLIC DISORDER				
		Organic Acid Condition	Fatty Acid Oxidation Disorders	Amino Acid Disorders	Hemoglobin Disorder	Other Disorder
Cbl C,D	Methylmalonic acidemia with homocystinuria	X				
MAL	Malonic acidemia	X				
IBG	Isobutyrylglycinuria	X				
2MBG	2-Methylbutyrylglycinuria	X				
3MGA	3-Methylglutaconic aciduria	X				
2M3HBA	2-Methyl-3-hydroxybutyric aciduria	X				
SCAD	Short-chain acyl-CoA dehydrogenase deficiency		X			
M/SCHAD	Medium/short-chain L-3-hydroxyacyl-CoA dehydrogenase deficiency		X			
GA2	Glutaric acidemia type II		X			
MCAT	Medium-chain ketoacyl-CoA thiolase deficiency		X			
DE RED	2,4-Dienoyl-CoA reductase deficiency		X			
CPT IA	Carnitine palmitoyltransferase type I deficiency		X			
CPT II	Carnitine palmitoyltransferase type II deficiency		X			
CACT	Carnitine acylcarnitine translocase deficiency		X			
ARG	Argininemia			X		
CIT II	Citrullinemia, type II			X		
MET	Hypermethioninemia			X		
H-PHE	Benign hyperphenylalaninemia			X		
BIOPT (BS)	Biopterin defect in cofactor biosynthesis			X		
BIOPT (REG)	Biopterin defect in cofactor regeneration			X		
TYR II	Tyrosinemia, type II			X		
TYR III	Tyrosinemia, type III			X		
Var Hb	Various other hemoglobinopathies				X	
GALE	Galactosepimerase deficiency					X
GALK	Galactokinase deficiency					X
	T-cell-related lymphocyte deficiencies					X

^aThese secondary conditions are detected in the differential diagnosis of the core disorders listed in Table 45.1. Selection of conditions based upon American College of Medical Genetics. (2006). Newborn screening: towards a uniform screening panel and system. *Genetic Med*, 8(5, Suppl), S12–S252 as authored by the ACMG and commissioned by the Health Resources and Services Administration. Nomenclature for Conditions based upon Sweetman, L., et al. (2006). Naming and counting disorders (conditions) included in newborn screening panels. *Pediatrics*, 117(5, Suppl): S308–S314. <<https://www.hrsa.gov/advisorycommittees/mchbadvisory/heritabledisorders/recommendedpanel/>>.

intermediary products (organic acids) in the catabolic pathway of certain amino acids accumulate.

An example of an aminoacidopathy is **phenylketonuria (PKU)**, a disorder of phenylalanine metabolism caused in the majority of cases by deficiency of phenylalanine hydroxylase, the enzyme responsible for the conversion of phenylalanine to tyrosine. Other examples include (1) **maple syrup urine disease (MSUD)**, (2) **homocystinuria**, and (3) **tyrosinemia type I**.

Glutaric acidemia type 1 (GA1), a disorder of lysine and tryptophan metabolism, is an example of an **organic**

acidemia. Other organic acidemias include (1) isovaleric acidemia, (2) **methylmalonic acidemia**, and (3) **propionic acidemia** (see Table 45.1). The clinical manifestations of the organic acidemias vary from no observable clinical consequences to neonatal mortality. Conditions, such as (1) developmental retardation, (2) seizures, (3) alterations in sensorium, (4) failure to thrive or (5) behavioral disturbances, occur in more than half the disorders. Metabolic ketoacidosis, often accompanied by hyperammonemia, is a frequent finding in organic acidemias. The compound(s) accumulated

depend on the (1) site of the enzymatic block, (2) reversibility of the reactions proximal to the lesion, and (3) availability of alternative pathways of metabolic “runoff.”

Phenylketonuria

PKU (OMIM #261600) is a disorder of phenylalanine metabolism that results from impaired phenylalanine hydroxylase activity leading to the accumulation of phenylalanine, lack of tyrosine, and production of phenylketones that are excreted in urine.

Phenylalanine is an essential amino acid, constituting 4% to 6% of all dietary protein. Phenylalanine not used for protein synthesis is converted to tyrosine by the enzyme phenylalanine hydroxylase and further degraded via a ketogenic pathway (Fig. 45.3). The frequency of hyperphenylalaninemia/PKU is 1:16,500 live births. The majority (98%) of cases of PKU are caused by mutations in the phenylalanine hydroxylase gene, with the remaining 2% being caused by defects in biosynthesis or recycling of tetrahydrobiopterin (BH₄), the cofactor for phenylalanine hydroxylase, or by a defect in chaperone protein.

Primary or secondary (due to a deficiency of the cofactor/chaperone) impairment of phenylalanine hydroxylase causes (1) increased phenylalanine, (2) increased phenylketones, and (3) deficiency of tyrosine (see Fig. 45.3). The greatly increased concentration of phenylalanine impairs brain development and function, affecting other organs minimally. Patients with classic PKU are clinically asymptomatic at birth, with developmental delays and neurological manifestations typically becoming evident at several months of life when brain damage has already occurred. Untreated PKU patients develop (1) **microcephaly**, (2) eczematous skin rash, (3) “mousy” odor (due to accumulation of phenylacetate), and (4) severe mental retardation. The treatment of PKU includes a diet (1) low in protein and phenylalanine and (2) supplemented with tyrosine, minerals, vitamins, and other nutrients to sustain healthy growth. Some patients respond to treatment with pharmacological amounts of a synthetic form of tetrahydrobiopterin. Treatment should be continued for life.

Newborn screening leads to early detection and therapy of patients with PKU with prevention of mental retardation. Ideally treatment should start before 2 weeks of age. Pregnant women with PKU should adhere to a strictly controlled diet that is low in phenylalanine and proteins, because phenylalanine is teratogenic and results in an increased risk of spontaneous abortions or of having a child with (1) growth retardation, (2) microcephaly, (3) significant developmental delays, and (4) birth defects.

The diagnosis of PKU is confirmed biochemically by demonstration of increased plasma phenylalanine and an increased phenylalanine: tyrosine ratio. Urine specimens from affected individuals contain increased concentrations of phenylketones (hence the name *phenylketonuria*). Enzymatic confirmation of phenylalanine hydroxylase deficiency is not usually performed (the enzyme is expressed only in the liver), but mutational analysis of the gene is increasingly used because there is a correlation between severity of the mutation and phenylalanine

Fig. 45.3 Inborn errors of metabolism (IEMs) resulting from deficiency of key enzymes required in the catabolism of phenylalanine. Specific disorders caused by enzyme deficiency are shown on the left side of the figure. Phenylalanine is an essential amino acid obtained from the hydrolysis of almost all protein part of a normal diet. It is transformed to tyrosine by phenylalanine hydroxylase, the enzyme defective in phenylketonuria. The amino group of tyrosine is then removed by tyrosine hydroxylase, the enzyme defective in tyrosinemia type 2, to become *p*-hydroxyphenylpyruvate. *p*-Hydroxyphenylpyruvate dioxygenase (the enzyme defective in tyrosinemia type 3) adds oxygen to generate homogentisic acid. Homogentisic acid oxidase generates maleylacetoacetate, and a deficiency of this enzyme causes alkaptonuria, a condition in which urine turns black after standing at room temperature or with the addition of alkali. Maleylacetoacetate isomerase generates fumarylacetoacetate; a deficiency of this enzyme has not been reported in humans. Fumarylacetoacetate is very unstable and becomes succinylacetone, a very toxic compound capable of causing cancer and cell death. Succinylacetone also inhibits delta-aminolevulinic acid synthase, the enzyme that converts delta-aminolevulinic acid (ALA) into porphobilinogen (PBG). Accumulation of delta-aminolevulinic acid causes severe pain and neurological symptoms. Succinylacetone accumulates in tyrosinemia type 1 caused by deficiency of fumarylacetoacetate hydrolase. This enzyme normally generates fumarate and acetate that can enter the citric acid cycle for the production of energy, water, and carbonic anhydride.

tolerance, and it can exclude deficiency of the chaperone. All children with hyperphenylalaninemia should be screened for defects in BH₄ synthesis or recycling. This is performed by measuring the urinary pterin profile and by measuring the enzyme activity of **dihydropteridine reductase (DHPR)** in blood spotted on filter paper. Deficiency of BH₄ affects the synthesis of several neurotransmitters, including dopamine and serotonin because it is a cofactor of (1) phenylalanine hydroxylase, (2) tyrosine hydroxylase, (3) tryptophan hydroxylase, and (4) nitric oxide synthase. Patients with a defect in BH₄ synthesis or recycling have neurological symptoms and developmental regression in the first few months of life, despite adequate control of phenylalanine intake and plasma concentrations. They can develop seizures and have a characteristic hypotonia

of the trunk with hypertonia of the extremities. These patients require therapy with BH_4 and appropriate neurotransmitters. They may or may not require a low phenylalanine diet once BH_4 therapy is initiated.

Tyrosinemia

Tyrosinemia is characterized by increased blood concentrations of tyrosine. There are three types of tyrosinemia (I–III); each is caused by the deficiency of a different enzyme (Fig. 45.3). Tyrosinemia type I (TYR-I) is the most severe form and is caused by a deficiency of fumarylacetoacetate hydrolase. Tyrosinemia type II is caused by a deficiency of tyrosine aminotransferase, and tyrosinemia type III is caused by a deficiency of 4-hydroxyphenylpyruvate dioxygenase.

The incidence of TYR-I is approximately 1 in 100,000 with a clustering of cases in the Lac-St. Jean region of Quebec (Canada). Patients with TYR-I present, usually before 6 months of age, with severe liver involvement, or with (1) failure to thrive, (2) liver dysfunction, and (3) rickets due to renal Fanconi syndrome. They have extreme irritability caused by peripheral neuropathy mimicking acute intermittent porphyria. Untreated patients develop liver cirrhosis and are at very high risk for liver cancer.

Patients with TYR-I have increased concentrations of tyrosine in the plasma, but this increase usually is not as marked as in patients with other forms of tyrosinemia. Increased tyrosine can also be seen in (1) other types of tyrosinemia (type II and III), (2) transient tyrosinemia of the newborn, (3) prematurity, (4) liver disease from any cause, (5) mitochondrial DNA depletion syndrome, and (6) diets very rich in proteins. The biochemical diagnosis of TYR-I is based on the detection in urine of succinylacetone, derived from fumarylacetoacetic acid, the intermediate immediately upstream of the enzyme defect. TYR-I is identified by newborn screening only when succinylacetone is used as the primary marker, because tyrosine might not be elevated in the newborn period in these patients. Therapy consists of (1) low dietary tyrosine, (2) low dietary phenylalanine, and (3) drug therapy with 2-(2-nitro-4-trifluoro-methylbenzoyl)-1,3-cyclohexanedione (NTBC), an inhibitor of 4-hydroxyphenylpyruvate dioxygenase (see Fig. 45.3). NTBC prevents the synthesis of succinylacetone, which is rapidly reduced within the normal range after initiation of treatment. Measurement of alpha fetoprotein is also used to monitor these patients, because liver cancer is a complication of this condition. Liver transplantation is indicated in patients who progress to liver failure and in those acquiring liver cancer.

Homocystinuria

Homocystinuria is characterized by increased concentrations of the sulfur-containing amino acid, homocysteine, in blood and urine (see Fig. 45.4). It can be caused by defects of methionine metabolism (classic homocystinuria) or defects in homocysteine remethylation. Classic homocystinuria is caused by reduced activity of cystathionine β -synthase. The incidence is approximately 1:450,000 live births in the United States with a very high incidence in the country of

Qatar (1:1800). Clinical manifestations are nonspecific at first and may include failure to thrive and developmental delay. Patients usually develop lens dislocation (often requiring surgery) and a body habitus like that seen in Marfan syndrome. (Homocysteine interferes with disulfide formation in fibrillin, the protein defective in Marfan syndrome.) Patients whose blood homocysteine concentration remains increased are at risk of blood clots, which are a life-threatening complication of the condition.

The biochemical diagnosis of homocystinuria is obtained by plasma amino acid analysis showing increased plasma concentrations of methionine (especially in children) and the presence of the disulfide homocystine. Classic homocystinuria is detected in newborn screening by increased concentrations of methionine in whole blood spots, although often the concentration of methionine is not high in the newborn screening period and this condition could be missed. Therapy for classic homocystinuria requires (1) high doses of pyridoxine (the cofactor of cystathionine β -synthase), (2) a special diet low in methionine, and (3) administration of betaine that donates a methyl group to homocysteine to generate methionine.

Maple Syrup Urine Disease

Maple syrup urine disease (MSUD) is an **autosomal recessive disorder** with an incidence of approximately 1:200,000 live births. It is caused by a deficiency of the branched-chain alpha-keto acid dehydrogenase complex (BCKDC), leading to a buildup of the branched-chain amino acids leucine, isoleucine, and valine and their toxic ketoacids in the blood and urine. The disease is named for the presence of sweet-smelling urine with an odor similar to that of maple syrup. Several forms of this disease may occur, depending on the gene affected and the severity of the mutations. The enzyme complex consists of four subunits designated $\text{E}_1\alpha$, $\text{E}_1\beta$, E_2 , and E_3 . MSUD results from mutations in any of the genes that code for the enzyme subunits.

Individuals with classic MSUD present with poor feeding and vomiting during the first week of life followed by lethargy and coma within a few days. This usually follows a normal birth and an uneventful first few days of life. Routine laboratory work is mostly unremarkable except for the presence of ketones in urine. Diagnosis is established by measuring plasma amino acids and finding increased branched chain amino acids and the presence of alloisoleucine, which is characteristic of this disease.

Cornerstones of treatment include diets that have a restricted content of branched-chain amino acids and include supplementation with (1) high-dose thiamine and, in many patients, (2) valine and (3) isoleucine.

Urea Cycle Disorders

A **urea cycle disorder**, or urea cycle defect, is caused by a deficiency of one of the enzymes or a transporter in the urea cycle, which is responsible for removing ammonia from the blood stream. The urea cycle involves a series of biochemical steps in which nitrogen derived from protein metabolism is

Fig. 45.4 Sulfur amino acid metabolism. Defects in methionine metabolism (classic homocystinuria caused by cystathionine beta synthase deficiency) or defects in homocysteine remethylation (defects in vitamin B₁₂ or folic acid metabolism) cause homocystinuria. Methionine transfers a methyl group during its conversion to homocysteine. Defects in methyl transfer or in the subsequent metabolism of homocysteine by the pyridoxal phosphate (vitamin B₆)-dependent cystathionine β-synthase increase plasma methionine concentrations. Excess homocysteine is transformed back to methionine via remethylation. This reaction is catalyzed by methionine synthase and requires methylcobalamin and folic acid. Deficiencies in these enzymes or lack of vitamin B₁₂ (cobalamin) or folic acid or defects in their metabolism (defects in vitamin B₁₂ metabolism are named cblC, cblD, cblF; methylenetetrahydrofolate reductase [MTHFR] deficiency is the most common defect of folic acid metabolism) are associated with decreased or normal methionine concentrations and with elevated homocysteine. In an alternative pathway, homocysteine is remethylated by betaine:homocysteine methyltransferase.

removed from the blood and converted to urea, which is then excreted in urine. In urea cycle disorders, the nitrogen accumulates in the form of ammonia, a toxic substance, and is not removed from the body.

Urea cycle disorders can result in (1) mental and behavioral dysfunction, (2) coma, and (3) death. The urea cycle disposes of the nitrogen groups of amino acids before their carbon skeleton is metabolized to gluconeogenic (most amino acids) or ketogenic precursors (leucine and lysine), or both (isoleucine, phenylalanine, tyrosine, and tryptophan). This cycle requires the combined action of different enzymes and mitochondrial transporters (Fig. 45.5). Deficiency of any of these enzymes or transporters impairs the function of the urea cycle, causing hyperammonemia.

Newborn screening can effectively identify **argininosuccinate synthetase (ASS) deficiency** (or citrullinemia type I), **citrullinemia type II** (mitochondrial aspartate transporter/citrin deficiency), **argininosuccinate lyase (ASL) deficiency**,

and arginase deficiency. OTC (ornithine transcarbamylase) deficiency, an X-linked disorder that is also the most common of the urea cycle defects, CPS-1 (carbamylphosphate synthase 1) and NAGS (N-acetylglutamate synthase) deficiencies are not effectively detected by NBS. Patients with urea cycle defects may have symptoms at any age. In the neonatal period, there is usually a brief interval between birth and clinical manifestations, with the most severe cases having symptoms before the results of newborn screening are available. Hyperammonemia and the accumulation of glutamine in the brain lead to (1) poor feeding, (2) vomiting, (3) lethargy, or (4) irritability progressing to coma and death.

Diagnosis is accomplished by measuring plasma amino acids and identifying the compound present in excess. Patients are treated with a diet low in proteins and administration of nitrogen scavengers, such as sodium benzoate and phenylacetate or its precursor phenylbutyrate, which bind and remove glycine and glutamine, respectively.

Fig. 45.5 The urea cycle. In this cycle, urea is formed starting from ammonia (NH_3). It requires several enzymes (in *italics*) and mitochondrial transporters (*blue*), any of which can be defective and may impair the function of the urea cycle. Within the mitochondrial matrix, ammonia, derived from amino acid catabolism, is combined with carbonic anhydride and phosphorus to generate carbamoylphosphate by carbamoyl phosphate synthase 1 (*CPS-1*). This enzyme is active only in the presence of *N*-acetylglutamate, an allosteric activator synthesized by *N*-acetylglutamate synthase (*NAGS*). Carbamoylphosphate is then attached to ornithine by ornithine transcarbamylase (*OTC*) to generate citrulline. Citrulline then exits the mitochondrial matrix using the ornithine/citrulline mitochondrial transporter (*ORC1*). This transporter is an exchanger and couples the exit of citrulline from mitochondria to the entry of ornithine. Citrulline in the cytoplasm combines with aspartate (transported from the mitochondrial matrix by the citrin transporter) to generate argininosuccinic acid by the action of a synthase (*ASS*). Argininosuccinic acid is then split to arginine and fumarate by a lyase (*ASL*). Fumarate enters the citric acid cycle, and arginine is converted to urea (excreted in urine) and ornithine by arginase (*ARG*). Ornithine can then enter the mitochondrial matrix again to restart another cycle. The two nitrogens in urea excreted in urine derive from ammonia and the amino group of aspartate. Carbamoylphosphate not utilized in the urea cycle (usually because of deficiency in ornithine transcarbamylase or any of the downstream enzymes) exits to the cytoplasm to generate nucleotides (UTP and CTP). The concentration of orotic acid (an intermediate in nucleotide synthesis) can be measured in the urine of patients with *OTC*, *ASS*, *ASL* or *ARG* deficiency. *citrin*, Aspartate/glutamate exchanger; *CP*, carbamoylphosphate; *CPS-1*, carbamoyl phosphate synthase 1; *CTP*, cytidine triphosphate; *UTP*, uridine triphosphate.

Glutaric Acidemia Type I

Glutaric acidemia type 1 (GA1; OMIM #231670) is an autosomal recessive disorder of the metabolism of (1) lysine, (2) hydroxylysine, and (3) tryptophan; it is caused by deficiency of glutaryl-coenzyme A (CoA) dehydrogenase. In this condition, glutaric acid (GA) and 3-hydroxyglutaric acid (3-OH-GA), formed in the catabolic pathway of the above mentioned amino acids, accumulate, especially in urine. Affected patients have brain atrophy and macrocephaly (head circumference often increases dramatically following birth), and they can develop acute dystonia secondary to degeneration of the corpus striatum (a component of the motor system in the brain). In most cases this is triggered by an infection with fever between 6 and 18 months of age.

GA1 is identified by an increased concentration of glutarylcarnitine (C5DC) on newborn screening. The diagnosis is biochemically confirmed by urine organic acid analysis that indicates the presence of excess 3-OH-GA, with plasma and

urine acylcarnitine profiles showing glutarylcarnitine as the major peak. Therapy consists of (1) carnitine supplementation to remove GA, (2) a diet restricted in amino acid precursors of GA, and (3) prompt administration of intravenous calories in the patient who is unable to eat for any reason such as (1) infections, (2) fever, and (3) gastroenteritis. Early diagnosis and therapy reduce the risk of acute dystonia in patients with GA1.

Treatment of Organic Acidemias and Aminoacidopathies

As with the treatment regimens for aminoacidopathies, therapy for organic acidemias consists of (1) special diets restricting the compounds (usually amino acids) that result in the formation of the abnormal organic acid, (2) supplementation with vitamins specific for each disorder, (3) carnitine supplements, and (4) sometimes avoidance of fasting. For some of these conditions, aggressive therapy of illnesses with intravenous fluids containing glucose is essential to avoid catabolism that aggravates clinical symptoms.

POINTS TO REMEMBER

Disorders of Amino Acid Metabolism

- They result from impaired activity of an enzyme involved in the metabolic pathway of an amino acid.
- The impaired enzyme activity leads to the accumulation of the parent amino acid, its by-products, or its catabolic products (organic acids).
- In aminoacidopathies the parent amino acid accumulates in blood; in organic acidemias the intermediary products in the catabolic pathway of amino acids accumulate and are excreted in the urine.
- Phenylketonuria, tyrosinemia type I, maple syrup urine disease, and homocystinuria are examples of aminoacidopathies.
- Glutaric acidemia type 1 is an example of organic acidemia.
- The treatment consists of a special diet that restricts the offending amino acid(s) and includes supplements of cofactors and vitamins, including carnitine for organic acidemias. Fasting should also be avoided.

Disorders of Fatty Acid Oxidation

Fatty acids are metabolized within mitochondria to produce energy. Carnitine and the carnitine cycle are required to transfer long-chain fatty acids into mitochondria for subsequent beta-oxidation (Fig. 45.6). Within the mitochondrial matrix, long-chain fatty acids are progressively shortened by two carbon units at each cycle to generate acetyl-CoA, which is used by the Krebs cycle to produce energy (Fig. 45.7).

Disorders of fatty acid oxidation, such as **medium-chain acyl-CoA dehydrogenase (MCAD) deficiency**, occur when an enzyme is missing in the metabolic pathway and fatty acids fail to undergo oxidation to supply energy. These disorders are usually silent and become evident only when the body needs energy from fat during times of increased energy demand, such as (1) fasting, (2) infections/fever, or (3) strenuous exercise. In these cases, apparently healthy children with these disorders (1) become acutely sick, (2) lose consciousness, (3) become comatose, and (4) may die. When symptomatic, patients with fatty acid oxidation disorders develop hypoglycemia and might show increased serum transaminases indicating liver damage. Some fatty acid oxidation disorders (such as **long-chain 3-hydroxyacyl-CoA dehydrogenase [LCHAD] deficiency**) also (1) affect skeletal muscle, (2) affect cardiac muscle, and (3) affect the mother during pregnancy. Other disorders include carnitine transporter defects and very long-chain acyl-CoA dehydrogenase deficiency (see Table 45.1).

Medium-Chain Acyl-CoA Dehydrogenase Deficiency

MCAD (OMIM #201450) deficiency is the most common disorder of fatty acid oxidation with a frequency of about 1:18,000 in the United States. The clinical presentations of this disease are (1) asymptomatic, (2) hypoglycemia, (3) lethargy, (4) coma, and (5) sudden death, which is usually triggered by prolonged fasting, acute illness, or both. The majority of patients have symptoms in the first year of life, but clinical

symptoms can occur at any time during life, and often the first episode is fatal. The treatment consists of (1) avoidance of fasting, (2) consumption of low-fat foods after 1 year of age, (3) carnitine supplementation, and (4) institution of an emergency plan in case of illness or other metabolic stress. Early diagnosis through newborn screening and early initiation of treatment leads to a favorable prognosis. Patients with MCAD deficiency are identified by MS/MS newborn screening because of the characteristic acylcarnitine profile with increased concentrations of (1) C6- (hexanoyl), (2) C8- (octanoyl), and (3) C10:1- (decenoyl) carnitine (with C8-carnitine being the highest) and increased C8/C2 and C8/C10 ratios.

The diagnosis of MCAD is confirmed biochemically by urine organic acid and acylglycine analyses showing (1) excess hexanoylglycine and suberylglycine, (2) plasma acylcarnitine profile (confirming increased C6-, C8-, and C10:1 carnitine), and (3) DNA analysis. A common pathogenic variant (c.985A>G, p.Lys329Glu) is prevalent in symptomatic patients (80% of symptomatic patients are homozygous for this mutation; 98% carry at least one copy).

Treatment of Fatty Acid Oxidation Disorders

Treatment of fatty acid oxidation disorders consists of (1) avoidance of fasting, (2) adherence to a low-fat diet, and (3) carnitine supplementation. For some disorders of fatty acid oxidation, therapy includes administration of medium chain triglycerides (oil) that enter mitochondria independently from carnitine and bypass the metabolic block. In addition, conditions that increase catabolism such as (1) fever, (2) vomiting, and (3) infections need to be aggressively treated with antibiotics (if necessary), antipyretics, and intravenous glucose.

POINTS TO REMEMBER

Disorders of Fatty Acid Oxidation

- Fatty acids are metabolized in mitochondria via beta-oxidation to produce energy.
- Most disorders of fatty acid oxidation are triggered by environmental stress (fasting, infections, exercise) when energy demands increase.
- The clinical presentation includes hypoketotic hypoglycemia, cardiomyopathy, sudden death.
- The diagnosis relies on plasma acylcarnitines and urine organic acids analyses, in addition to DNA testing.
- The treatment consists of avoidance of fasting, low-fat diet, in addition to special types of fat and carnitine supplementation for some of these disorders.

Lysosomal Storage Disorders

Lysosomal storage disorders are a group of diseases caused by deficiency of one or more lysosomal enzymes responsible for the degradation of complex macromolecules, such as mucopolysaccharides. The impaired degradation of these macromolecules results in their accumulation in organs and tissues. The disease phenotype depends on the substrate accumulated and its sites of turnover—for example, muscle and heart in Pompe disease and connective tissue in

Fig. 45.6 The carnitine cycle in fatty acid (FA) oxidation. The carnitine cycle is responsible for delivering long-chain fatty acid to the mitochondrial matrix for subsequent beta oxidation. FAs bound to albumin are transferred across the plasma membrane by the action of fatty acid transport proteins (FATP). Inside the cell, fatty acids undergo vectorial acylation, a process catalyzed by acyl-coenzyme A (CoA) synthases, that traps them in the cytoplasm as acyl-CoA thioesters (acyl-S-CoA). The acyl-CoA thioesters are then conveyed through different metabolic pathways in mitochondria, peroxisomes, and microsomes based on the cell energy status. Metabolism of fatty acid by peroxisomes and microsomes is usually minimal, except in disorders of fatty acid oxidation. The mitochondrial membrane is impermeable to acyl-CoAs and fatty acids must be conjugated to carnitine to enter mitochondria. Carnitine is accumulated inside the cell by the high-affinity organic cation transporter novel 2 (OCTN2) carnitine transporter. Carnitine forms a high-energy ester bond with long-chain fatty acids by the action of carnitine palmitoyl transferase 1 (CPT-1), located in the inner aspect of the outer mitochondrial membrane, with the formation of acylcarnitines. Acylcarnitines are then translocated across the inner mitochondrial membrane by the carnitine acylcarnitine translocase (CACT). Once inside mitochondria, carnitine palmitoyl transferase 2 (CPT-2), located in the inner mitochondrial membrane, removes carnitine from acylcarnitines and re-generates acyl-CoAs. Carnitine then returns to the cytoplasm for another cycle (using CACT), while the acyl-CoAs can enter (in aerobic conditions and in the presence of low levels of ATP) β -oxidation with final production of acetyl-CoA for oxidative phosphorylation or production of ketone bodies in the liver.

mucopolysaccharidoses. In addition to symptomatic therapy to alleviate the most severe clinical symptoms, specific therapies for lysosomal storage disorders are available or in development: (1) enzyme replacement therapy; (2) substrate reduction therapy; (3) chaperone therapy; (4) bone marrow and hematopoietic stem cell transplantation; (5) gene therapy. Currently newborn screening for two lysosomal storage disorders, Pompe disease and mucopolysaccharidosis type I (Hurler, Hurler-Scheie, and Scheie syndrome), have been approved for inclusion in the RUSP.

Pompe Disease

Pompe disease is an autosomal recessive lysosomal storage disorder caused by deficiency of the enzyme, acid alpha-glucosidase (GAA), with an estimated incidence of approximately 1:40,000 births. In this condition, glycogen accumulates within the lysosomes in the skeletal muscle and heart. There are two main forms of Pompe disease: infantile and

late-onset. In infantile Pompe disease, hypertrophic cardiomyopathy, muscle weakness, and hypotonia are usually evident by 2 months of age and most patients die within the first year of life. Late-onset Pompe disease is characterized by variable age of onset and presentation, with symptoms including progressive muscle weakness and respiratory insufficiency. The neonatal screening for Pompe disease is based on the measurement of enzyme activity in blood spots by (1) LC-MS/MS, which measures the enzymatic conversion of a substrate to a product, or (2) fluorimetric methods, which detect the release of a fluorescent compound from the substrate mediated by the enzyme. The diagnosis of Pompe disease is confirmed by measurement of enzyme activity in leukocytes or in fibroblasts and by DNA testing. DNA testing is important to identify patients with pseudodeficiency of enzymatic activity: a condition in which the enzyme functions normally against the natural substrate, but not against the synthetic substrate used to measure activity in the laboratory.

Fig. 45.7 Beta oxidation of fatty acids. In the mitochondrial matrix, long-chain fatty acids undergo a series of steps to progressively shorten the fatty acids of two carbon units (acetyl-coenzyme A [CoA]) through a series of enzymatic reactions. Chemical structures are shown on the left, enzymes (blue) and reactions are in the middle, and the carbon chain lengths for various disorders are on the right. Dehydrogenases introduce a double bond between C2 and C3 and are specific for fatty acids with different chain lengths: *LCAD*, Long-chain acyl CoA dehydrogenase; *MCAD*, medium-chain acyl-CoA dehydrogenase; *MKAT*, medium-chain acyl-CoA thiolase; *SCAD*, short-chain acyl-CoA dehydrogenase; *SCHAD*, short-chain 3-hydroxyacyl-CoA dehydrogenase; *VLCAD*, very long-chain acyl-CoA dehydrogenase. A trifunctional protein (TFP) adds water and cleaves two carbon atoms from the long-chain fatty acid. This is done through sequential action of a hydratase (enoyl-CoA hydratase), a L-3-hydroxyacyl-CoA dehydrogenase (*LCHAD*, long-chain 3-hydroxyacyl-CoA dehydrogenase), and a thiolase (acyl-CoA acetyltransferase). The two carbon units generated can be completely oxidized in the muscle to CO₂ or can generate ketone bodies in the liver that may be exported to other organs to provide energy.

Enzyme replacement therapy with human recombinant acid alpha-glucosidase improves the manifestations of the disease, including survival in affected children.

Mucopolysaccharidosis Type I

Mucopolysaccharidosis type I (MPS I) is an autosomal recessive lysosomal storage disorder caused by deficiency of the lysosomal hydrolase alpha-iduronidase. The incidence is estimated at 0.7 to 4:100,000. Alpha-iduronidase is involved in the degradation of the glycosaminoglycans heparan sulfate and dermatan sulfate, and its impaired activity leads to their accumulation in organs and tissues. MPS I is a progressive, debilitating, and often life-threatening disease. Typical features of MPS I are coarse facial features, hepatosplenomegaly, cardiac involvement, joint stiffness, skeletal deformities, and corneal clouding. There is a wide spectrum of phenotypes, with the most severe, MPS-IH or Hurler syndrome, presenting in the first 6 months of life with a rapid disease progression involving the central nervous system (CNS) and death by 10 years of age. In patients with the attenuated presentation, Hurler-Scheie (MPS-IHS) and Scheie (MPS-IS), the disease progression is slower, does not involve the CNS,

and life expectancy is close to normal in the milder affected individuals. Newborn screening methods for MPS I are based on measurement of alpha-iduronidase activity. As for Pompe disease, there are two methods available for high throughput screening: (1) LC-MS/MS based and (2) fluorimetric. The diagnosis is confirmed by measuring enzyme activity in freshly isolated leukocytes and by sequencing of the *IDUA* gene. As for Pompe disease, DNA can identify individuals with enzyme pseudodeficiency. Enzyme replacement therapy with human recombinant alpha-iduronidase improves organ and skeletal involvement in MPS I patients, but is not effective in the neuropathic form (Hurler syndrome). In this case, hematopoietic stem cell transplantation early in life remains the only option to prevent CNS involvement, often in conjunction with enzyme replacement therapy to prevent peripheral complications.

Peroxisomal Disorders

Peroxisomes are single membrane organelles containing enzymes responsible for the alpha- and beta-oxidation of very long-chain fatty acids, the synthesis of the membrane glycerophospholipids plasmalogens, and the oxidation of bile acids

and cholesterol. Defects in the biogenesis of peroxisomes or defects in one or more peroxisomal function lead to severe clinical manifestations.

X-Linked Adrenoleukodystrophy

X-linked adrenoleukodystrophy (X-ALD) is an X-linked **peroxisomal disorder** resulting in defective oxidation of very long-chain fatty acids. Its incidence is approximately 1:20,000. X-ALD is caused by mutations in the *ABCD1* gene located on Xq28 that encodes for the adrenoleukodystrophy protein (ALDP) in the peroxisomal membrane, which transfers very long-chain fatty acids inside the peroxisomes for degradation. X-ALD can present in males before 5 years of age with progressive cognitive and neurological deterioration leading to a vegetative state and death. A milder variant, adrenomyeloneuropathy (AMN) presents usually in the 2nd to 3rd decade of life with progressive spastic paraplegia. Adrenal dysfunction occurs in about 2/3 of males with AMN. A total of 50 % to 65% of female carriers develop symptoms similar to AMN; however, the onset is usually in the 4th or 5th decade of life. X-ALD can be diagnosed by newborn screening measuring C26:0 lysophosphatidylcholine (C26:0 LPC) by LC-MS/MS. C26:0 LPC is elevated in DBS of patients with X-ALD, with peroxisomal biogenesis defects, and in approximately 80% of female carriers for X-ALD. The diagnosis is confirmed by measurement of very long-chain fatty acids (VLCFA) in plasma and by DNA sequencing of the *ABCD1* gene. VLCFAs in plasma are elevated and diagnostic in all males. However, they are elevated and informative only in 80% to 85% of heterozygous females for whom DNA testing should be considered. The only effective treatment for X-ALD is hematopoietic stem cell transplantation, to be performed before the appearance of neurological symptoms.

Disorders of Carbohydrate Metabolism

Enzyme deficiency in the metabolic pathways for carbohydrates results in accumulation of sugars within organs or tissues impairing their function, inability to obtain energy from them, or toxicity from the excess of monosaccharides or their derivatives (phosphorylated sugars). **Disorders of carbohydrate metabolism** include the (1) glycogen storage diseases, (2) **glucose-6-phosphate dehydrogenase (G-6-PD) deficiency**, and (3) classic **galactosemia**.

Glycogen storage disorders affect primarily the liver or the skeletal muscle. The accumulation of glycogen impairs organ function and, if the liver is affected, prevents release of glucose with resulting hypoglycemia. They are usually treated with avoidance of fasting and a special diet rich in protein, devoid of simple sugars and supplements with uncooked cornstarch.

G-6-PD deficiency affects red blood cells, causing them to break down (hemolysis). It can cause mild to severe jaundice in newborns and in some cases hemolytic anemia. Symptoms can be triggered by (1) infections, (2) certain drugs (some antibiotics and medications used to treat malaria), or (3) exposure to fava beans (a reaction called favism). The gene for this condition is on the X chromosome, and the condition affects mostly males. Avoidance of stressors can mitigate or avoid symptoms.

Classic galactosemia results from absence of galactose-1-phosphate uridyl transferase. Galactose is derived from the disaccharide lactose found in milk. In galactosemia, galactose is phosphorylated to galactose-1-phosphate, but it is not further metabolized. Increased concentrations of galactose-1-phosphate in cells are toxic. Infants have (1) failure to thrive, (2) jaundice, (3) liver failure, and (4) predisposition to life-threatening infections with *E. coli* and other Gram-negative bacteria. The treatment of galactosemia involves removal of lactose (contained in human or animal-derived milk, but not in soy milk) and avoidance of all foods containing galactose. In galactosemia, intervention early in life provides the best prognosis, although some long-term complications (speech apraxia, learning disorders, and ovarian insufficiency in females) can still occur in treated individuals.

DIAGNOSTIC TESTS FOR INHERITED DISORDERS OF METABOLISM

A newborn screening result highly suggestive of a metabolic disorder typically leads to an immediate evaluation using confirmatory tests and a referral of the newborn to a metabolic center.

In asymptomatic patients, the confirmation of diagnosis relies on specific tests, such as (1) ion-exchange chromatography and (2) liquid chromatography-tandem mass spectrometry (LC-MS/MS) for amino acids analysis, (3) gas chromatography-mass spectrometry (GC-MS) for organic acids analysis, and (4) MS/MS without or with liquid chromatographic separation for acylcarnitines and acylglycines analyses, respectively. A combination of tests is often key in the confirmation of abnormal newborn screening results, especially for those with borderline values. DNA testing and enzyme assays are available for further confirmation of most of these conditions.

These techniques are described in [Chapters 12, 13, 18, and 48](#). MS/MS is a technique of choice in newborn screening programs.

Tandem Mass Spectrometry

The introduction of MS/MS as a routine laboratory technique has dramatically increased the number of disorders amenable to newborn screening, since multiple metabolites are detected simultaneously in the same blood spot (**multiplex analysis**). This allows the identification of several disorders at once, whereas traditional screening techniques were based on one test for one disorder.

Methodological Details

MS/MS measures the ratio of the mass (m) of a chemical to its charge z (see [Chapter 13](#)). For newborn screening, a tandem mass spectrometer is configured to measure only acylcarnitines and amino acids using the information about their mass and fragmentation pattern. Labeled internal standards are added to the extraction mixtures to quantify the different species.

Interpretation

With MS/MS screening, several analytes are detected at the same time and the interpretation of the results is based heavily on pattern recognition, whereas the measurement of the concentration of the different metabolites supports the interpretation. The ability to detect multiple metabolites by MS/MS allows the use of ratios of metabolites to define whether an increased value is due to a metabolic derangement or to the clinical and nutritional status of the newborn.

Assessment of congenital disorders at the appropriate time after birth is crucial. For example, although amino acid concentrations do not change significantly with newborn age, acylcarnitine concentrations vary significantly. For most acylcarnitines, the concentrations are highest in the first week of life and decrease rapidly afterward. Typically the first screen sample should be collected within 24 to 48 hours of life, while the second screen sample, in states mandating two screens, is collected between 7 and 28 days of age. Age-appropriate cutoff values for all screening tests should be used for the interpretation of newborn screening results.

REVIEW QUESTIONS

1. An inherited disorder that affects the conversion of nutrients into energy is referred to as a(n):
 - a. aminoacidopathy.
 - b. autosomal recessive disorder.
 - c. inborn error of metabolism (IEM).
 - d. hemolytic disease of a newborn.
2. Tandem mass spectrometry (MS/MS) involves:
 - a. an ultraviolet laser to ionize small amounts of matrix and analyte that are directed into the mass analyzer.
 - b. screening a large number of infants for disorders of amino acid metabolism using different growth antagonists.
 - c. an ion trap designed to trap ions in three dimensions instead of two dimensions.
 - d. assessment of the mass-to-charge ratio of a chemical.
3. An inborn disorder of metabolism that is triggered by prolonged fasting and/or acute illness and that is confirmed by abnormal acylcarnitine concentrations is:
 - a. galactosemia.
 - b. medium-chain acyl-CoA dehydrogenase (MCAD) deficiency.
 - c. phenylketonuria (PKU).
 - d. homocystinuria.
4. Deficiency of an enzyme that results in excess of monosaccharides in the blood of a newborn leads to a specific disorder of metabolism. An example of this type of disorder would be:
 - a. galactosemia.
 - b. medium-chain acyl-CoA dehydrogenase (MCAD) deficiency.
 - c. phenylketonuria (PKU).
 - d. glutaric acidemia type I (GAI).
5. The disorder that is identified by increased blood glutaryl carnitine on newborn screening is characterized by dysfunctional metabolism of:
 - a. hydroxylysine and phenylalanine.
 - b. tyrosine and tryptophan.
 - c. tryptophan, hydroxylysine, and lysine.
 - d. cystine and hydroxylysine.
6. In a disorder that has an autosomal recessive inheritance pattern, what is the risk of two carrier parents having an affected child with that disorder?
 - a. 0%
 - b. 25%
 - c. 50%
 - d. 100%
7. In relation to newborn screening for inborn errors of metabolism (IEMs), second-tier testing is done to:
 - a. assess the parents of the newborn for possible carrier status.
 - b. assess the siblings of the newborn for similar symptoms or disorders.
 - c. determine the number of false negatives that might have occurred with initial screening.
 - d. further assess a positive screening test result by targeting more specific analytes.
8. The disorder of amino acid metabolism in which the parent amino acid accumulates in blood and spills over into urine is classified as:
 - a. an organic acidemia.
 - b. an aminoacidopathy.
 - c. a carbohydrate disorder.
 - d. a disorder of fatty acid oxidation.
9. The simultaneous analysis of multiple analytes using a single sample, such as a blood spot from a newborn, is referred to as:
 - a. multiplex analysis.
 - b. newborn screening.
 - c. tandem mass spectrometry (MS/MS).
 - d. multiple of means.
10. The enzyme that is absent in the aminoacidopathy phenylketonuria (PKU) is:
 - a. phenylalanine decarboxylase.
 - b. ornithine translocase.
 - c. phenylalanine hydroxylase.
 - d. succinyl-coenzyme A (CoA) mutase.

Pharmacogenetics

Gwendolyn A. McMillin, Mia Wadelius, Victoria M. Pratt

OBJECTIVES

1. Define the following:
 - Adverse drug reaction (ADR)
 - Prodrug
 - Haplotype
 - Pharmacogenetics
 - Pharmacokinetics
 - Pharmacodynamics
2. Describe the difference between type A and type B ADRs and provide an example of each.
3. Provide examples of pharmacogene-drug pairs that are associated with each of these three drug response processes: pharmacokinetics, pharmacodynamics, and immune response.
4. Explain how the CYP2D6 phenotype could predict a poor response to codeine and other prodrugs that are substrates of CYP2D6.
5. Explain how multiple pharmacogenes affect the therapeutic dose of warfarin.
6. Explain how genetic testing is used to evaluate whether or not a patient is a good candidate for ivacaftor.

KEY WORDS AND DEFINITIONS

Adverse drug reaction (ADR) Any undesirable side effect or toxic reaction that is caused by the administration of a drug.

Allele One of the alternative versions of a gene at a given location (locus) along a chromosome. An individual typically inherits two alleles for each gene, one from each parent. If the two alleles are the same, the individual is homozygous for that locus. If the alleles are different, the individual is heterozygous. The term now also refers to variation among noncoding DNA sequences in addition to genes.

Cytochrome P450 (CYP) A large family of metabolic enzymes that catalyze the oxidation of organic substrates. They are important in the metabolism of drugs, steroid hormones, fatty acids, and other substances.

Drug metabolism The process by which drugs are chemically modified in the body, typically by drug-metabolizing enzymes. Most but not all drugs are metabolized.

Gene duplication A process by which a chromosome or a portion of DNA is duplicated, resulting in an additional copy of a gene.

Genotype The genetic makeup of an individual or a group of individuals. An individual's genotype codes for that individual's phenotype. The genotype for a specific gene requires knowledge of both *alleles* of the gene.

Genotyping Laboratory testing designed to detect specific genetic variants that are used to identify and

classify variant alleles. The alleles are reported together as a genotype that may or may not be predictive of a phenotype.

Haplotype A combination of alleles on the same chromosome that are usually located close together and tend to be inherited together.

International normalized ratio (INR) A method of reporting prothrombin time results for patients receiving oral anticoagulant therapy.

Metabolite A chemically modified form of a compound. Drug metabolites may or may not exhibit pharmacological activity. There are often many metabolites of a single drug, some of which may be identical to independently administered drugs.

Metabolizer classification A classification of four drug-metabolism phenotypes as they relate to an individual's metabolic efficiency for processing a specific therapeutic drug. The four types are (1) poor metabolizers (PMs), (2) ultrarapid metabolizers (UMs), (3) extensive/normal metabolizers (EMs), and (4) intermediate metabolizers (IMs).

Pharmacodynamics A process in pharmacology that defines how a drug acts on its target and its mechanisms of action.

Pharmacogene A gene that is known to influence the pharmacokinetics and/or pharmacodynamics of a drug.

Pharmacogenetics Study of the variations in single genes or small groups of related genes that affect the response to a drug, including its metabolism.

Pharmacogenomics The study of how combinations of variations in several genes, potentially extended to the complete genome, influence the pharmacology of a drug or drugs.

Pharmacokinetics A process in pharmacology that describes how a drug is (1) absorbed, (2) distributed, (3) metabolized, and (4) eliminated.

Phenotype The observable physical or biochemical characteristics of an individual as determined by his

or her genetic makeup and environmental influences, including drug-drug or food-drug interactions.

Prodrug A drug that is administered in an inactive or poorly active form and converted to an active drug by metabolism.

Pseudogene A defective segment of DNA that resembles a gene but cannot be transcribed.

Star (*)-allele nomenclature A nomenclature developed to standardize genetic polymorphism annotation for many pharmacogenes, such as cytochrome P450.

PRINCIPLES OF PHARMACOGENETICS

The term **pharmacogenetics** comes from merging the terms pharmacology and genetics. Pharmacogenetics can predict and/or explain how individuals respond to drugs and is a prominent component of personalized precision medicine. Initiatives exist around the globe to improve patient care with pharmacogenetics. For example, former US President Barack Obama announced his “Precision Medicine Initiative” at his January 2015 State of the Union Address. This initiative was intended to promote “patient-powered research” and “provide clinicians with new tools, knowledge, and therapies to select which treatments will work best for which patients,” including pharmacogenetics. Related work associating drug response with **pharmacogenes**, and ultimately the whole genome, is known as **pharmacogenomics**, although the terms are commonly used interchangeably. Pharmacogenetics and pharmacogenomics can apply to the human germline genome, tumor genomes (e.g., somatic mutations), and pathogen genomes (e.g., viral genomes). The goal of this chapter is to explain concepts and provide examples of human pharmacogenetics, with an emphasis on germline variants. Targeted variants of some pharmacogenes and specific applications to drugs are described.

Drug Response

For simplicity, the term drug(s) is used throughout this chapter to reflect any xenobiotic (foreign compound absorbed by the human body) that is capable of evoking a physiologic or behavioral response. Responses to drugs depend on many variables such as drug formulation, route of administration, age, gender, clinical status (e.g., kidney function, liver function, protein status), comedications, and genetics. Most drugs are selected and initially dosed according to drug labeling, clinical experience, and institutional protocols that stem from population-based dosage and dose frequency recommendations. However, dose optimization still largely relies on trial and error. Minimizing this process of trial and error with pharmacogenetics can improve efficacy of drugs and prevent **adverse drug reactions**.

Pharmacogenetic testing is designed to predict specific aspects of the two major processes upon which drug response is based: pharmacokinetics and pharmacodynamics. **Pharmacokinetics** describes how the body acts on a drug, often called ADME, referring to absorption,

distribution, metabolism, and elimination. Pharmacogenes that encode drug-metabolizing enzymes and transport proteins are involved in pharmacokinetics. Parent drugs that are administered as inactive compounds and require metabolism to convert the compound to an active drug are called **prodrugs**. Drug **metabolites** can be pharmacologically active or inactive. Therefore it is important to consider whether pharmacogenetic variation influences the concentrations or kinetics of pharmacologically active or inactive compounds. **Fig. 46.1** illustrates the common metabolic relationship for prodrugs, active drugs, and metabolites (active and/or inactive). **Pharmacodynamics** describes how the body responds to drugs, both desirable (e.g., therapeutic) and undesirable (e.g., therapeutic failure and/or toxicity). Pharmacogenes that encode for mechanistic proteins such as enzymes, receptors, and ion channels are involved in pharmacodynamics. Sometimes drugs cause adverse effects due to mechanisms that are unrelated to the intended use of the drug. For example, carbamazepine, a drug used to treat seizures and neuropathic pain largely by inhibiting voltage-gated sodium channels, can stimulate the immune system, leading to a severe cutaneous adverse reaction that can be life-threatening. The risk of this adverse reaction is increased in the presence of the **HLA-B*15:02 allele**, representing variation in the genes that code for the human leukocyte antigen (HLA) system, and is unrelated to the mechanisms responsible for managing seizures and pain. The adverse reaction is also unrelated to the pharmacokinetics of carbamazepine. Pretherapeutic testing to detect this allele in people being considered for carbamazepine therapy is recommended for vulnerable populations, particularly people of Asian descent.

Many different pharmacogenes are often associated with the pharmacokinetics and pharmacodynamics of a single drug. In selecting drugs and drug dosing for an individual, one should consider the clinically significant pharmacogenes in combination with relevant clinical, demographic and nongenetic factors. After drug and dose are selected, response to the drug should be monitored. If the response is desirable (therapeutic), the pharmacokinetics and pharmacodynamics are appropriate. Therapeutic failure may occur if the concentrations of active drug are insufficient (e.g., pharmacokinetic variability) or if the physiology required to elicit the response to the drug is absent or impaired (e.g., pharmacodynamic variability). If the response is not optimal or is undesirable, therapy may have to

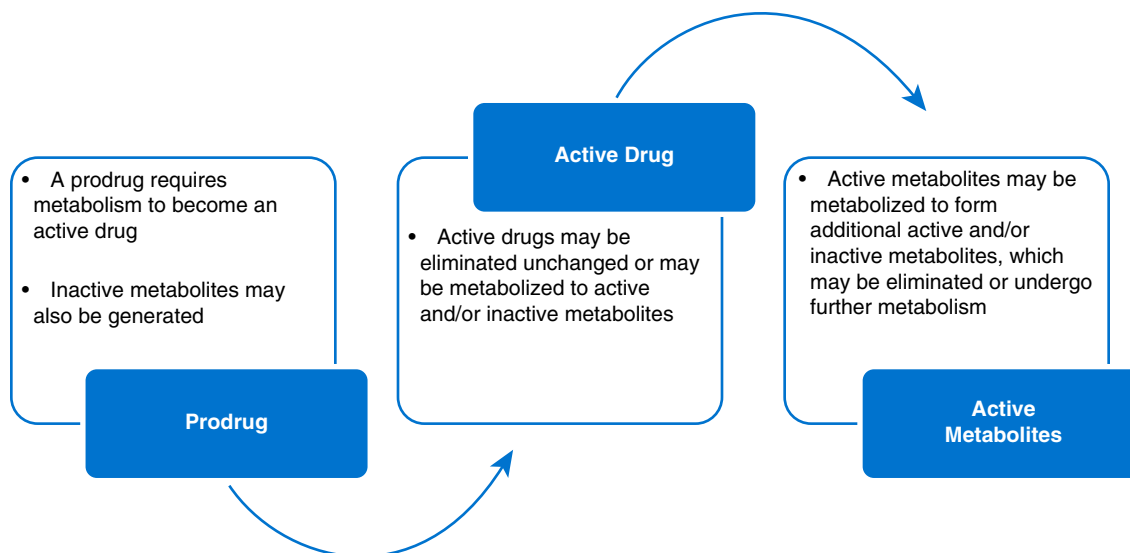

Fig. 46.1 Schematic relationships between prodrugs, active drugs, and metabolites.

be adjusted. The dose of a drug is adjusted based on results of clinical measurements (e.g., blood pressure for antihypertensive drugs), therapeutic drug monitoring (TDM), or monitoring of biochemical markers indicating response.

The goal of TDM is to adjust the dose to achieve blood concentrations of active drug that fall within an established therapeutic range at particular times after dose administration. This practice of dose adjustment is common to immunosuppressant drugs such as tacrolimus or anticonvulsant drugs such as carbamazepine. Thus blood specimens are collected at specific times after the drug is administered. The dose is adjusted to achieve concentrations that consistently fall within the therapeutic range selected for the patient population and clinical indication, noting that pharmacokinetic variation can contribute to differences in time to achieve stable drug concentrations, called achieving steady state. Pretherapeutic pharmacogenetic testing can guide drug selection, determine the initial drug dose, and predict the time required to achieve steady state.

An example of a biochemical marker of response is the **international normalized ratio (INR)**, which is calculated from the prothrombin time (PT) test (Box 46.1); it is used

to guide and adjust doses of the common anticoagulant drug warfarin. As with TDM, blood samples are collected at specific times after the administration of warfarin. The dose is adjusted until the INR consistently falls within a target range, selected for the patient population and clinical indication. The target INR range is set to 2.0 to 3.0 for most indications. Pretherapeutic pharmacogenetic testing can guide the initial dose of warfarin and predict the time required to achieve steady state.

Adverse drug reactions that are dose-dependent are classified as type A. Such scenarios can be managed by adjusting the dose of a drug based on clinical or laboratory monitoring of drug concentrations and/or biomarkers. Inappropriate dosing of tacrolimus, carbamazepine, or warfarin can lead to type A reactions. Adverse drug reactions that occur independently of dose are classified as type B. As such, monitoring and the adjusting dose will be unsuccessful. In this case, an alternate drug is required. The carbamazepine-induced hypersensitivity example illustrates a type B reaction. Carbamazepine is an example of a drug that can produce both type A and type B adverse reactions. Pretherapeutic pharmacogenetic testing may predict vulnerability to type A and type B adverse reactions should these drugs be administered.

BOX 46.1 International Normalized Ratio (INR)

$INR = [(PT \text{ result for the patient}) / (PT \text{ result for a normal control})]^{ISI}$

- Established by the World Health Organization and the International Committee on Thrombosis and Hemostasis.
- Standardizes reporting of the prothrombin time (PT) test, a common method of evaluating how many seconds it takes for a person's blood to clot.
- Includes an international sensitivity index (ISI) that compensates for variability in laboratory methods (usually 1.0–2.0).
- A typical therapeutic range of the INR for a patient treated with warfarin is 2.0–3.0.

POINTS TO REMEMBER

Phenotypes described for drug metabolizing enzymes are as follows:

- Ultrarapid or rapid metabolizer: more than normal enzyme activity and/or gene expression is expected/observed.
- Extensive/normal metabolizer: normal enzyme activity and/or gene expression is expected/observed.
- Intermediate metabolizer: less than normal enzyme activity and/or gene expression is expected/observed.
- Poor metabolizer: little or no enzyme activity is expected/observed.

Implementation and Logistics of Pharmacogenetics

Pharmacogenetic testing is intended to predict and/or explain discrete aspects of pharmacokinetics and pharmacodynamics to guide drug and dose selection. Once a drug is initiated, the response is monitored and dosing optimized with clinical and/or laboratory tools. It is not practical, medically indicated, or cost-effective to apply pharmacogenetics to every drug therapy situation. The pharmacogenetic tests that have proven to be most successful are those that produce actionable results. Many resources for labeling information, gene-drug associations, and clinical consensus guidelines are maintained and updated electronically. Some specific gene-drug relationships for which US Food and Drug Administration (FDA) labeling includes pharmacogenetic information are shown in Table 46.1. These gene-drug examples apply to medical disciplines including oncology, psychiatry, neurology, infectious disease, pain management, and cardiology. Other areas of medicine can also benefit from pharmacogenetic testing, and the number of clinically useful targets will only increase as comprehensive pharmacogenetic testing becomes more widely available with analytic techniques such as massively parallel sequencing.

Specimens

Most pharmacogenetic testing revolves around DNA extracted from blood, saliva, buccal cells, or other specimens from which DNA can be obtained. Specimens for DNA testing do not require special timing or patient preparation in most situations. Saliva or buccal cells may be preferred due to the noninvasive nature of collection, but this may not produce a sufficient quantity or quality of DNA for all applications.

Analytic Strategies

The analytic strategy used in pharmacogenetic testing depends on a variety of factors, such as the complexity of the gene; the extent, frequency, and type of genetic variation; and the time needed for return of the results. Most **genotyping** assays cannot detect all variants that have been identified in a gene. If the need for a rapid time to result is clinically indicated, an assay may be designed to limit complexity, as through targeted detection of the most common and clinically relevant variants. Commercially available in vitro diagnostics (IVDs) are available for some pharmacogenetic applications and may reduce the complexity of testing and data analysis in order to reduce the time to result. However, most pharmacogenetic testing is based on laboratory-developed approaches designed to target specific gene variants, and performed at a central or reference laboratory. Clinical laboratories that offer pharmacogenetic testing can be found through the voluntary National Institutes of Health Genetic Testing Registry.

Laboratory services may include a single-gene or multiple-gene panels where known variants are interrogated. Targeted genotyping will not detect any variant or alleles that are not directly interrogated, so a negative genotyping result does not rule out the possibility that a patient is carrying another variant not detected by the assay. Multiple gene panels may be achieved through exome or whole-genome sequencing. Exome sequencing is able to identify only those variants near to and including the coding regions of genes. This approach cannot identify intergenic differences, including structural and noncoding variants, which can be found by whole-genome sequencing. Massively parallel sequencing platforms available today have additional limitations

TABLE 46.1 Drug-Gene Examples With Published Guidelines, FDA Labeling Comments, and Graded Level of Evidence

Gene or Allele	Generic Drug Name	GRADES, GUIDELINES ^a			COMMENT IN FDA LABELING ^a			
		PharmGKB	CPIC	DPWG	Testing Required	Testing Advised	Actionable	Not Available
HLA-B*57:01	Abacavir	1A	Yes	Yes		X		
CYP2D6	Amitriptyline	1A	Yes	Yes			X	
CYP2C19								
HLA-B*15:02	Carbamazepine	1A	Yes	No	X ^b			
CYP2C19	Clopidogrel	1A	Yes	Yes		X		
CYP2D6	Codeine	1A	Yes	Yes			X	
CFTR	Ivacaftor	1A	Yes	No	X			
TPMT	Mercaptopurine	1A	Yes	Yes		X		
G6PD	Rasburicase	1A	Yes	No	X			
SLCO1B1	Simvastatin	1A	Yes	No				X
CYP3A4	Tacrolimus	1A	Yes	Yes				X
CYP2C9	Warfarin	1A	Yes	No			X	
VKORC1								

^aLevels of evidence (grades), status of guidelines, and comments in FDA labeling are provided as examples but are time-sensitive and therefore may change. The PharmGKB grade of 1A indicates that the highest level of evidence to support the gene-drug association, for which CPIC guidelines are available and/or widespread clinical implementation is known. The PharmGKB grade of 2A indicates moderate evidence and lack of a CPIC guideline or widespread clinical implementation.

^bIn patients with ancestry in genetically at-risk populations, mainly Asians.

CPIC, Clinical Pharmacogenetics Implementation Consortium; DPWG, Dutch Pharmacogenomics Working Group; PharmGKB, pharmacogenomics knowledge base.

including the following: (1) decreased coverage in regions with high GC content (e.g., the 5' ends of genes), limited detection of copy number variants, limited detection of insertions/deletions, and interference from **pseudogenes**. These technical limitations are expected to improve if not resolve over time. However, rare and novel variants will likely be of uncertain clinical significance, causing difficulty in interpretation. Novel combinations of variants may also be identified by sequencing, which will necessitate the evolution of nomenclature and may affect **phenotype** predictions. Currently whole-genome sequencing is not practical for routine pharmacogenetics applications owing to the high costs and time associated with sequencing and interpretation.

Gene Dose (Copy Number)

Human DNA is normally associated with two copies of each gene, one copy inherited from each parent for autosomal regions on each chromosome. However, many genetic regions display a variation in the number of copies and are termed copy number variants (CNVs). CNVs can range in size from one kilobase to several megabases due to deletion, insertion, **duplication**, or complex recombination. CNVs in some pharmacogenes play a clear role in producing drug efficacy and toxicity. One example is the human CYP2D locus, which contains two pseudogenes, *CYP2D7* and *CYP2D8*, closely located and evolutionarily related to *CYP2D6*, and thus facilitates homologous crossovers and the formation of large gene conversions, deletions, duplications, and multiplications of *CYP2D6*. CNVs are not always included in analytic methods designed for genotyping.

Haplotyping

Many of the pharmacogenes exhibit combinations of variants—for example, single-nucleotide variants (SNVs) and insertion-deletions (indels) within a gene that are inherited together on the same chromosome and are referred to as **haplotypes**. Many nomenclature systems have been developed to describe pharmacogenetic haplotypes. In the most commonly used nomenclature system, combinations of pharmacogenetic sequence variants are designated **by star (*) alleles**, where *1 is designated as normal (commonly referred to as wild-type or fully functional), and numbered star alleles are assigned as new variants are identified. Pragmatically the *1 allele is assigned by default when none of the targeted variant alleles are detected. Therefore the true accuracy of a *1 allele designation depends on whether the assay detects all possible functional variants.

Reporting

The results of clinical pharmacogenetic testing should be reported using current recommended standard nomenclature. Pharmacogenetic nomenclature is constantly evolving, and laboratories or users of laboratory services might not be familiar with most current nomenclature. Therefore test results should be provided in current recommended standard nomenclature, which should include clarifications of commonly used terms and should indicate the **genotypes** detected.

In general, which variants/alleles should be interrogated and reported for the pharmacogenes is not standardized. In addition, some assays use different combinations of variants to define or infer the haplotypes that the assay detects, which ultimately can lead to discrepancies in star allele genotypes between platforms. Laboratories are required by the Clinical Laboratory Improvement Amendment (CLIA) to include interpretation of the test results on the test report. Clinical pharmacogenetic laboratories often provide an interpreted phenotype (e.g., poor **metabolizer**) based on the genotype results. Laboratories that are accredited by the College of American Pathologists (CAP) are required to include a summary of methods and the variants that can be detected on the report, but overall the lack of consensus for pharmacogenetic nomenclature (e.g., *alleles, rs#, or HGVS, diplotype vs. haplotype, etc.) and variable assay designs add to the complexity of analyzing and reporting results from pharmacogenetic assays.

Clinical Interpretation

Pharmacogenetic testing is clinically useful only when information is sufficient to allow clinical interpretation of the results. This information must be derived from human studies. Many examples of this type of information can be found in the peer-reviewed literature. One limitation of the existing literature, however, is that most data are based on retrospective studies, and there is no single printed source in which all of this information has been collated. The Pharmacogenetics and Pharmacogenomics Knowledge Base (PharmGKB) is a publicly available Internet research tool developed at Stanford University through a nationwide collaborative research consortium. Its aim is to aid researchers in understanding how genetic variation among individuals contributes to differences in reactions to drugs. This regularly updated database is a source of genetic and clinical information. In addition, the Pharmacogene Variation (PharmVar) Consortium was introduced in September 2017 as a central electronic repository and resource.

Many ongoing clinical trials designed to study the efficacy and toxicity of new pharmaceutical products or new indications for previously developed pharmaceuticals have employed pharmacogenetic testing. Thus it is anticipated that pharmacogenetic guidelines and new diagnostic products will be available in the coming years. In addition, drugs that were previously removed from development because of adverse drug reactions or poor therapeutic response may be reconsidered if a genetic test can be demonstrated to identify individuals who are likely to respond favorably to the drug. For each of the major pharmacogenes discussed in this chapter, [Table 46.1](#) provides a list of common drugs with pharmacogenetic associations that have resulted in several FDA-revised drug labels. Because many other drug-gene combinations are recognized that may lead to additional drug label revisions, the discussion provided here is in no way comprehensive. In addition, many of the specific genes discussed later have applications to other areas of medicine, some of which are mentioned briefly. The European Medicines Agency has

TABLE 46.2 Recommendations for Pharmacogenetics in the Summary of Product Characteristics Sections of the European Union Drug Labeling for Germline Variation, by Gene

Section	Section Title	Recommendation	Gene Examples
4.1	Therapeutic indications	State when a product indication depends on a particular genotype, phenotype, or expression of a gene	<i>HLA-B*57:01, CFTR</i>
4.2	Posology and method of administration	State dose adjustment recommendations linked to a particular genotype	<i>TPMT, CFTR</i>
4.3	Contraindications	State contraindications linked to a particular genotype	<i>DPYD, G6PD</i>
4.4	Special warnings and precautions for use	State when adverse drug reactions including therapeutic failure are linked to a specific genotype or phenotype	<i>HLA-B*57:01, TPMT, CFTR, CYP2C19, UGT1A1</i>
4.5	Interaction with other medicinal products	State when interactions with other medicinal products depend on specific genotype or phenotype	<i>CYP2D6, CYP2C19, UGT1A1</i>
4.8	Undesirable effects	State any clinically relevant differences in adverse drug reactions including therapeutic failure that are linked to a specific genotype	<i>HLA-B*57:01, CFTR, G6PD</i>
5.1	Pharmacodynamic properties	State relevant clinical studies that show a difference in benefit or risk depending on a specific genotype or phenotype	<i>HLA-B*57:01, CFTR, G6PD</i>
5.2	Pharmacokinetic properties	State variations in metabolism and associated quantitative terms if clinically relevant	<i>CYP2D6, TPMT, DPYD, CYP2C19, UGT1A1</i>

Data from Ehmann, F., Caneva, L., Prasad, K., et al. (2015). Pharmacogenomic information in drug labels: European Medicines Agency perspective. *Pharmacogenomics J*, 15, 201–210.

included pharmacogenetic information in drug labeling as well. Although not all European countries participate, the European Union has promoted standardization in the labeling of pharmaceuticals and included pharmacogenetic information in the summary of product characteristics. Table 46.2 provides examples of the sections in a European drug label that may include pharmacogenetic information and examples of genes that are targeted in drug labels. The specific examples discussed further on can be used as a guide for translating the principles of pharmacogenetics to additional gene-drug pairs in this continually evolving field of laboratory medicine.

SPECIFIC EXAMPLES OF PHARMACOGENE ASSOCIATIONS

Associations With Pharmacokinetics

Drug-Metabolizing Enzymes

Most drugs are metabolized by at least one reaction mediated by **cytochrome P450 (CYPs)** enzymes. CYPs are classified into families and further into subfamilies based on amino acid homology. Using *CYP2D6* as an example, the naming convention for CYPs is shown in Fig. 46.2, illustrating that the core name of the gene and protein is shared, identifying the family, subfamily and polypeptide, also referred to as the isozyme. The variant allele designations follow the name of the protein. When referring to a gene, the name should be italicized, whereas the name of the associated the protein should not be.

Genetic variants of CYPs have been associated with changes in enzyme activity, stability, and/or substrate (e.g., drug or drug metabolite) affinity that can lead to clinically significant phenotypes. Alleles for all CYP genes are

Fig. 46.2 Description of the nomenclature for the *CYP2D6*4C* allele.

described according to international consensus, based on the star (*) nomenclature described earlier, often followed by a letter to describe an allele subtype. Subtypes do not usually influence the clinical phenotype but could be important for haplotype assignment or to support research studies.

Cytochrome P450 CYP2D6 (CYP2D6). CYP2D6 is one of the most important drug-metabolizing enzymes as it is responsible for metabolizing approximately 25% of all drugs and is commonly involved in drug-drug interactions. Common alleles for the *CYP2D6* gene are shown in Table 46.3 with the predicted functional consequences. Although the definition of an allele may involve detection of many variants, a common SNV is frequently chosen as the primary analytic target used to detect each allele (bolded). In many cases, however, detection of other variants is required to accurately classify an allele. For

TABLE 46.3 Examples of Common Star (*) Allele Definitions for *CYP2D6*

Allele	Nucleotide Changes (cDNA) ^a	Effect	Enzyme Function
CYP2D6*1	None		Normal
CYP2D6xN	Gene amplifiers (multiple copies)	Depends on allele	Increased for functional alleles; no effect for nonfunctional alleles
CYP2D6*2A	–1584C>G; –1235A>G; –740C>T; –678G>A; CYP2D7 gene conversion in intron 1; 1661G>C; 2850C>T; 4180G>C	R296C; S486T	Normal
CYP2D6*3A	2549delA	Frame shift	Nonfunctional
CYP2D6*4A	100C>T; 974C>A; 984A>G; 997C>G; 1661G>C; 1846G>A ; 4180G>C	P34S; L91M; H94R; splicing defect; S486T	Nonfunctional
CYP2D6*5	Gene deletion		Nonfunctional
CYP2D6*10A	100C>T ; 1661G>C; 4180G>C	P34S; S486T	Decreased function
CYP2D6*17	1023C>T ; 1661G>C; 2850C>T ; 4180G>C	T1071; R296C; S486T	Decreased function
CYP2D6*36 (single)	–1426C>T; –1235A>G; –1000G>A; 100C>T ; 310G>T; 843T>G; 1039C>T; 1661G>C; 2097A>G; 3384A>C; 3582A>G; gene conversion to CYP2D7 in exon 9; 4180G>C	P34S ; P469A; T470A; H478S; G479R; F481V; A482S; S486T	Nonfunctional
CYP2D6*41	–1235A>G; –740C>T; –678G>A; CYP2D7 gene conversion in intron 1; 1661G>C; 2850C>T; 2988G>A ; 4180G>C	R296C; splicing defect; S486T	Decreased function

^aWhen known, *bold* nucleotide variants represent the major alterations responsible for the effect.

TABLE 46.4 Summarized Assignment of *CYP2D6* Phenotype

Predicted Function of Star (*) Allele	Star Allele (Determined from Genotype)	Diplotype	Predicted Phenotype Based on Diplotype	Predicted Activity Score Based on Diplotype
Increased function		More than two copies of normal functional alleles	Ultrarapid metabolizer (~2% of people ^a)	>2.0
Normal function	*1, *2, *33, *35	Two copies of functional or decreased-function alleles One functional allele and one decreased-function or nonfunctional allele	Extensive/normal metabolizer (~80% of people ^a)	1.0–2.0
Decreased function	*9, *10, *17, *29, *36, *41	One decreased-function allele and one nonfunctional allele	Intermediate metabolizer (~10% of people ^a)	0.5
Nonfunctional	*3, *4, *5, *6, *7, *8, *11, *12, *13, *14, *15, *16, *18, *19, *20, *21, *36, *38, *40, *42, *44, *68, *92, *100, *101	Two or more copies of nonfunctional alleles	Poor metabolizer (~8% of people ^a)	0

^aActual prevalence is population-dependent; percentages shown here represent published estimates for the general population.

Data from Kroetz, D. L., Yee, S. W., & Giacomini, K. M. (2010). The pharmacogenomics of membrane transporters project: research at the interface of genomics and transporter pharmacology. *Clin Pharmacol Ther*, 87, 109–116.

example, the *CYP2D6* c.100C>T variant (rs1065852) is present in three of the alleles shown in Table 46.3. Misclassification of *CYP2D6*4* or *CYP2D6*36* as *CYP2D6*10* would incorrectly predict the phenotype. Allele frequencies vary among populations. The most common variant allele in Caucasians is *CYP2D6*4*, whereas the most common variant alleles in African American, Middle Eastern, and East Asian populations are *CYP2D6*17*, *CYP2D6*41*, and *CYP2D6*10*, respectively.

The assignment of phenotype predictions from the *CYP2D6* genotype is described in Table 46.4. An alternate approach to *CYP2D6* phenotype characterization is the assignment of *activity scores*. Drug-specific dosing guidelines have been published by the Clinical Pharmacogenetics Implementation Consortium (CPIC) and other organizations such as the Dutch Pharmacogenomics Working Group (DPWG) for *CYP2D6*, and many other pharmacogenes (see Table 46.1 for examples).

BOX 46.2 Definition of Drug Inhibitors as per the US Food and Drug Administration

Strong Inhibitors

≥5-fold increase in the area under the curve (AUC), wherein the AUC refers to a plot of drug concentration in blood versus time after drug administration *or* >80% decrease in clearance (CL) of a drug from the blood expressed in terms of volume cleared per unit of time.

Moderate Inhibitors

≥2 but <5-fold increase in AUC *or* 50%–80% decrease in CL.

Weak Inhibitors

≥1.25 but <2-fold increase in AUC *or* 20%–50% decrease in CL.

Drug-drug or food-drug interactions often occur at the level of **drug metabolism** and are of particular concern under circumstances when multiple medications are prescribed and used by a single patient at one time. Drugs can be classified as inducers as well as strong, moderate, or weak inhibitors (Box 46.2). Some drugs may be both substrates and inducers or inhibitors for the same enzyme. A well-recognized food-drug interaction is the inhibition of CYP3A4 by grapefruit juice. For a person who is genetically an intermediate, extensive/normal, or ultrarapid metabolizer, the metabolic phenotype may be modified by drug-drug interactions. For a person who is genetically a poor metabolizer, drug-drug and/or food-drug interactions are not expected to affect drug and dose selections.

Codeine application. Codeine is a widely used medication, prescribed for pain management and to suppress coughing. Codeine must be activated by metabolism to morphine. This occurs through a demethylation reaction mediated primarily by CYP2D6 (Fig. 46.3). Therefore a CYP2D6 poor metabolizer would not activate codeine and should avoid this drug owing to the lack of predicted efficacy. An intermediate metabolizer may require higher doses of codeine than an extensive/normal metabolizer. The guidelines published by the CPIC suggest that alternative analgesia be sought should a CYP2D6 intermediate metabolizer fail to respond to codeine. An ultrarapid metabolizer should avoid codeine owing to the potential for toxicity. In a typical extensive/normal metabolizer, approximately 10% of a codeine dose is converted to morphine. Administration of codeine to a person with the ultrarapid metabolizer phenotype is a significant safety concern because higher than expected concentrations of morphine can be produced, leading to the risk of unintentional overdose and opioid toxicity. For example, when nursing women with an ultrarapid metabolizer phenotype for CYP2D6 are prescribed codeine, their babies can be exposed to higher than expected morphine concentrations in the breast milk. Children who receive codeine for pain control after tonsillectomy and adenoidectomy are also vulnerable to potentially deadly opioid-induced respiratory depression. A similar pharmacogenetic vulnerability to opioid-induced toxicity exists for other opioids that utilize CYP2D6 for activation, such as tramadol.

Antidepressant application. Antidepressant dosing is challenging because several weeks are typically required to assess efficacy, and optimizing dose may require several months of trial and error. Many antidepressant medications available today are substrates of CYP2D6, and many are also inhibitors. For example, fluoxetine is a selective serotonin reuptake inhibitor (SSRI) that is demethylated to form an active metabolite, norfluoxetine. Although several CYP enzymes are involved in the metabolism of fluoxetine, metabolism by CYP2D6 is considered the major route. CYP2D6 is also inhibited by fluoxetine and norfluoxetine, which are classified as strong inhibitors that lead to prolongation in the half-life of the drug and the metabolite within the first weeks of therapy. The CPIC has published guidelines based on CYP2D6 phenotype for SSRIs. Poor and ultrarapid metabolizers should avoid these drugs due to risk of toxicity and lack of efficacy, respectively.

Tricyclic antidepressants (TCAs) such as nortriptyline are also metabolized by CYP2D6. The relationship between drug concentrations and toxicity for CYP2D6 phenotypes and genotypes has been extensively characterized for nortriptyline. As shown in Table 46.5, lower doses of nortriptyline are recommended for a CYP2D6 poor metabolizer than for an extensive/normal metabolizer in order to produce similar serum concentrations of active drug. Nortriptyline, which is also an active metabolite of amitriptyline, is hydroxylated by CYP2D6 to form an inactive metabolite (10-hydroxy-nortriptyline). Clearance of amitriptyline, nortriptyline, and other TCAs is reduced by at least 50% in poor metabolizers of CYP2D6. TCAs have a narrow therapeutic index and are associated with severe adverse drug reactions that may be life-threatening. The CPIC has published dosing guidelines based on CYP2D6 phenotype for TCAs.

Cytochrome P450 2C family. The CYP2C family includes four genes that code for enzymes with the same name: CYP2C8, CYP2C9, CYP2C18, and CYP2C19. CYP2C9 and CYP2C19 are commonly involved in drug metabolism. CYP2C9 is involved in the metabolism of vitamin K–dependent anticoagulants (e.g., warfarin), anticonvulsants, nonsteroidal anti-inflammatory drugs, antidiabetic agents, cholesterol-lowering drugs, angiotensin receptor blockers, and drugs used to treat infection. Genotype-based dosing guidelines have been proposed for some CYP2C9 substrates, sometimes in combination with other pharmacogenes. The most common variant in Caucasians, CYP2C9*2 (c.430C>T, rs1799853), decreases enzyme activity to approximately 12% in homozygotes. CYP2C9*2 has a lower allele frequency in individuals of African and Native American ancestry and is not detected in Asians. The second most common variant in Caucasians, CYP2C9*3 (c.1075A>C, rs1057910), decreases enzyme activity to approximately 5% in homozygotes. The allele frequency of CYP2C9*3 is lower in people of Asian, African, and Native American ancestry. A low activity variant mainly present in African populations is CYP2C9*8 (c.449G>A, rs7900194).

The CYP2C19 enzyme is involved in the metabolism of a number of therapeutic drugs, such as citalopram, diazepam,

Fig. 46.3 Schematic illustration of codeine pharmacokinetics. Purple boxes indicate codeine and metabolites and the blue ovals are genes that code for drug metabolizing enzymes. Codeine is the prodrug, Morphine is the primary active metabolite, formed through a reaction mediated by CYP2D6. The orange stars indicate the importance of this metabolic activation. All other metabolites are thought to have little to no pharmacological activity. (From Thorn, C. F., Klein, T. E., & Altman, R. B. [2009]. Codeine and morphine pathway. *Pharmacogenet Genomics*, 19, 556–558. Reproduced with permission from the copyright holder, PharmGKB and Stanford University.)

TABLE 46.5 Examples of Dose Adjustments for Antidepressants Based on CYP2D6 or CYP2C19 Metabolizer Phenotype						
Antidepressant	CYP2C19	CYP2D6	METABOLIZER PHENOTYPE			
			Ultrarapid (%)	Extensive/Normal (%)	Intermediate (%)	Poor (%)
Amitriptyline	X		141	105	87	70
		X	138	114	90	67
Citalopram	X		130	107	87	59

Paroxetine		X	169	125	81	51
Trimipramine	X		154	107	76	45
		X	147	118	88	59
Venlafaxine	X		124	107	89	44
		X	172	109	92	77

Data from Stingl, J., & Viviani, R. (2015). Polymorphism in CYP2D6 and CYP2C19, members of the cytochrome P450 mixed-function oxidase system, in the metabolism of psychotropic drugs. *J Intern Med*, 277, 167–177.

omeprazole, and clopidogrel. Approximately 90% of CYP2C19 poor metabolizers are explained by *CYP2C19**2 (c.681G>A, rs4244285) and *CYP2C19**3 (c.636G>A, rs4986893). *CYP2C19**17 is responsible for rapid (one copy) and ultrarapid (two copies) phenotypes and is common in Caucasians and African Americans but less frequent in Hispanics and Asians. This allele arises from a promoter variant in the gene (c.-806C>T, rs12248560) that is associated with increased expression of the allele. However, the phenotype prediction is altered when multiple variants are detected. For example, the presence of both *CYP2C19**2 and *CYP2C19**17 is associated with an intermediate metabolizer phenotype.

Clopidogrel application. Clopidogrel inhibits platelet aggregation and is widely used in combination with aspirin to reduce the incidence of thrombotic and ischemic events in patients with coronary artery disease or acute coronary syndrome and/or after percutaneous coronary intervention with stenting. Yet many patients do not achieve adequate platelet inhibition; rates of drug resistance are estimated at 30% and are partly due to the fact that clopidogrel is a prodrug. Intermediate and poor CYP2C19 metabolism is associated with reduced formation of the active metabolite of clopidogrel, poor clopidogrel-induced platelet inhibition, and a higher incidence of major thrombotic events. The CPIC guidelines recommend drugs that do not require bioactivation by CYP2C19, such as prasugrel or ticagrelor, for CYP2C19 intermediate and poor metabolizers. No dose adjustment for clopidogrel is recommended for CYP2C19 ultrarapid or extensive/normal metabolizers.

Cytochrome P450 3A family and tacrolimus. The CYP3A family includes four genes that code for enzymes with the same name: *CYP3A4*, *CYP3A5*, *CYP3A7* and *CYP3A43*. *CYP3A7* is expressed primarily during the fetal period and the *CYP3A43* is not significantly involved in drug metabolism. In contrast, *CYP3A4* and *CYP3A5* enzymes are responsible for the metabolism of approximately half of all currently used drugs. *CYP3A4**22 (g.15389C>T, rs35599367) is the most common loss-of-function allele for this gene; other variants are rare. However, the *CYP3A5**3 allele (c.6986A>G, rs776746), is a very common loss-of-function allele in many populations. Thus 70% to 90% of Caucasians and Asians are poor metabolizers for CYP3A5. The nonfunctional *CYP3A5**6 (c.14690G>A, rs10264272) and *CYP3A5**7 (c.27131_27132insT, rs41303343) alleles are relatively common in African populations but rare in Caucasians, Asians, and Middle Eastern populations. Approximately 50% of African Americans are predicted to be poor metabolizers.

The immunosuppressant drug tacrolimus is widely used to prevent rejection in solid organ transplantation. This drug has a narrow therapeutic index and doses are adjusted based on the results of routine TDM. Acute rejection may result if blood concentrations are insufficient, and life-threatening toxicity can ensue with excess dosing. Predicting a target dose for a patient pretherapeutically could reduce dosing errors, particularly in the critical early posttransplant period. Tacrolimus is the active drug that is inactivated by reactions mediated primarily by CYP3A4 and CYP3A5. CYP3A5 poor

metabolizer genotypes predict lower dose requirements than the extensive/normal metabolizer (e.g. *CYP3A5* *1/*1) or intermediate metabolizer phenotypes (e.g., *CYP3A5* *1/*3). The CPIC guideline suggests standard doses for poor metabolizers and 1.5 to 2 times higher doses for extensive/normal and intermediate metabolizers followed by TDM to optimize dose.

N-Acetyltransferases (*NAT1* and *NAT2*). The N-acetyltransferase (NAT) polymorphism is one of the earliest pharmacogenetic targets recognized and characterized. NATs catalyze the transfer of an acetyl moiety from acetyl-CoA to homocyclic and heterocyclic arylamines and hydrazines. Substrates include drugs, carcinogens, toxicants, and possibly endogenous compounds. There are two forms of NAT, with 81% amino acid sequence identity, coded by genes of the same names (*NAT1* and *NAT2*), and both enzymes have affinity for most substrates. NAT2 slow acetylators are common in many populations, particularly Egyptians, Europeans, and African Americans.

Genotyping can predict NAT2 phenotype, but testing has limited clinical utility. For many NAT drug substrates, the acetylator status is managed through nongenetic approaches. For example, the antiarrhythmic drug procainamide is routinely monitored along with the active metabolite N-acetylprocainamide in timed blood samples. The dose of procainamide is adjusted based on the parent/metabolite ratio. For isoniazid, the neuropathic adverse drug reactions are linked to pyridoxine deficiency and can be avoided by the coadministration of pyridoxine to all patients. Also, isoniazid dosing intervals can be changed from once a week to twice a week to compensate for the fact that rapid acetylators are less likely to respond to the conventionally administered dose.

Glucose-6-phosphate dehydrogenase and rasburicase application. Glucose-6-phosphate dehydrogenase (G6PD) is one of the most common human enzymatic defects that, triggered by oxidative stress, can lead to neonatal jaundice and hemolytic anemia. G6PD catalyzes the first step of the pentose phosphate pathway, resulting in the production of nicotinamide adenine dinucleotide phosphate (NADPH). NADPH is essential to cope with oxidative stress in red blood cells. Factors such as infections, certain drugs, and ingesting fava beans can increase the levels of reactive oxygen species, thus causing red blood cells to undergo hemolysis faster than the body can replace them. The loss of red blood cells causes the signs and symptoms of hemolytic anemia, such as dark urine, enlarged spleen, fatigue, rapid heart rate, shortness of breath and jaundice, which are the characteristic features of G6PD deficiency.

More than 400 mutations in the *G6PD* gene have been identified; most are missense mutations that affect protein stability. The nomenclature for *G6PD* variants is based on the location where the variant was first described. All *G6PD* variants are broadly divided into five classes according to the resulting level of enzyme activity, with class I being the most severely dysfunctional and class V having the highest enzyme activity (Table 46.6). Targeted *G6PD* genotyping can establish

TABLE 46.6 Dosing for Rasburicase and *G6PD* as Recommended by the Clinical Pharmacogenetics Implementation Consortium

Phenotype/Genotype	Examples of Diplotypes	Implications for Outcome	Dosing Recommendations
Normal. A male carrying a nondeficient (class IV) allele or a female carrying two nondeficient (class IV) alleles.	Male: B, Sao Boria. Female: B/B, B/Sao Boria.	Low or reduced risk of hemolytic anemia.	Use label-recommended dosage and administration.
Deficient or deficient with CNSHA. A male carrying a class I, II, or III allele or a female carrying two deficient class I–III alleles.	Male: A–, Orissa, Kalyan-Kerala, Mediterranean, Canton, Chatham, Bangkok, Villeurbanne. Female: A–/A–, A–/Orissa, Orissa/Kalyan-Kerala, Mediterranean/Mediterranean, Chatham/Mediterranean, Canton/Viangchan, Bangkok/Bangkok, Bangkok/Villeurbanne.	At risk of acute hemolytic anemia.	Select alternate drug; avoid use of rasburicase.
Variable. A female carrying one nondeficient (class IV) and one deficient (class I–III variants) allele.	B/A–, B/Mediterranean, B/Bangkok.	Unknown risk of hemolytic anemia.	<i>G6PD</i> enzyme activity must be measured to determine phenotype or rasburicase use should be avoided; consider allopurinol.

Rasburicase and *G6PD* data from Relling, M. V., McDonagh, E. M., Chang, T., et al. (2014). Clinical Pharmacogenetics Implementation Consortium (CPIC) guidelines for rasburicase therapy in the context of *G6PD* deficiency genotype. *Clin Pharmacol Ther*, 96, 169–174.

a molecular diagnosis of *G6PD* deficiency; however, prediction of drug response can be difficult without testing *G6PD* enzyme activity levels.

Rasburicase is a drug approved by the FDA for the prophylaxis and treatment of hyperuricemia during chemotherapy in adults and children with lymphoma, leukemia, and solid tumors. When chemotherapy is administered, cancer cells are destroyed, releasing large amounts of uric acid into the blood. Rasburicase is a recombinant urate oxidase enzyme that works by breaking down uric acid to allantoin and hydrogen peroxide, which are eliminated from the body by the kidneys. The pegylated form of urate oxidase, pegloticase, is also FDA-approved for the treatment of refractory gout. Notably, both rasburicase and pegloticase carry an FDA boxed warning and are contraindicated for use in patients with known *G6PD* deficiency due to mutations in the *G6PD* gene. Additionally, the CPIC guidelines (see Table 46.6) recommend an alternative therapy (e.g., allopurinol) for *G6PD*-deficient patients.

Thiopurine S-methyltransferase and thiopurines application. Thiopurine S-methyltransferase (TPMT) is a metabolic enzyme that catalyzes the inactivation of thiopurine drugs (i.e., azathioprine, mercaptopurine, and thioguanine) by S-methylation, thus preventing the formation of thioguanine nucleotides (TGNs). These drugs are analogs of the nucleic acid guanine and are incorporated into RNA and DNA by phosphodiester linkages, ultimately inhibiting several metabolic pathways and inducing apoptosis. In addition, mercaptopurines are metabolized to methyl-thioinosine monophosphate, which inhibits de novo purine synthesis and cell proliferation, thus adding another mechanism of cytotoxicity. However, approximately 10% of many populations have intermediate levels of TPMT activity and approximately 0.3%

have low or undetectable enzyme activity, which results in significantly increased risks for thioguanine nucleotides toxicity and life-threatening myelosuppression.

Over 30 variant alleles of the *TPMT* gene have been identified, many of which are missense mutations associated with decreased in vitro activity. The star (*) nomenclature is used to describe *TPMT* haplotypes. The first variant allele described, *TPMT**2 (c. 238G>C; rs1800462), is rare in all populations studied. *TPMT**3A contains two missense variants *in cis*, c.460G>A (rs1800460) and c.719A>G (rs1142345), while *TPMT**3B and *TPMT**3C contain only one, c.460G>A (rs1800460) and c.719A>G (rs1142345), respectively. *TPMT**3A is the most common variant allele associated with low TPMT activity in Caucasians. The assumed diplotype is *1/*3A when both variants are present in an individual of Caucasian descent, although *3B/*3C cannot be ruled out. If *3B/*3C is suspected, phenotypic testing should be used to distinguish between *1/*3A and *3B/*3C. *TPMT**3C is the most common variant allele in East Asian and African American populations.

Thiopurines are used for the treatment of childhood acute lymphoblastic leukemia, autoimmune diseases, inflammatory bowel diseases, lupus, and transplantation. With conventional doses of thiopurines, individuals who inherit two loss-of-function *TPMT* alleles universally experience severe myelosuppression; a high proportion of heterozygous individuals show moderate to severe myelosuppression, whereas individuals in whom no variant is detected have a low risk of myelosuppression. The CPIC guidelines suggest dose reductions for both intermediate and poor metabolizers (Table 46.7).

Testing TPMT enzyme activity directly (phenotyping) is an alternative to *TPMT* genotyping that is challenged by storage and stability concerns. TPMT enzyme activity depends

TABLE 46.7 Dosing for Thiopurines and *TPMT* as Recommended by the Clinical Pharmacogenetics Implementation Consortium

Phenotype/Genotype	Examples of Diplotypes	Implications for Outcome	Dosing Recommendations
Homozygous wild-type or normal, high activity (two functional *1 alleles)	*1/*1	“Normal” (low) concentrations of thioguanine nucleotide metabolites. Note that thioguanine nucleotide metabolite concentrations with thioguanine are 5–10x higher than after mercaptopurine or azathioprine.	Use label-recommended dosage and administration. Adjust based on degree of myelosuppression and disease-specific guidelines. Allow 2–4 weeks to reach steady state after each dose adjustment.
Heterozygote or intermediate activity (one functional allele—*1, plus one nonfunctional allele)	*1/*2, *1/*3A, *1/*3B, *1/*3C, *1/*4	Moderate to high concentrations of thioguanine nucleotide metabolites.	Reduce dose by 30%–50% and adjust based on degree of myelosuppression and disease-specific guidelines. Allow 2–4 weeks to reach steady state after each dose adjustment.
Homozygous or compound heterozygous variant, mutant, low, or deficient activity (two nonfunctional alleles)	*3A/*3A, *2/*3A, *3C/*3A, *3C/*4, *3C/*2, *3A/*4	Extremely high concentrations of thioguanine nucleotide metabolites; fatal toxicity possible without dose decrease.	Reduce daily dose by 10-fold and dose thrice weekly instead of daily; adjust based on degree of myelosuppression and disease-specific guidelines. Allow 4–6 weeks to reach steady state after each dose adjustment. For nonmalignant conditions, consider nonthiopurine alternative.

Thiopurines and *TPMT* data from Relling, M. V., Gardner, E. E., Sandborn, W. J., et al. (2011). Clinical Pharmacogenetics Implementation Consortium guidelines for thiopurine methyltransferase genotype and thiopurine dosing. *Clin Pharmacol Ther*, 89, 387–391.

on stable enzyme activity between the times of blood collection and analytic testing. In addition, because the *TPMT* enzyme is expressed in red blood cells, testing is limited to patients who have not received a blood transfusion over the previous weeks and who have healthy red blood cells, which is often not the case when acute lymphoid leukemia is diagnosed. Coadministered drugs such as ibuprofen and thiazide diuretics may inhibit enzyme activity such that an inaccurate phenotype prediction may be assigned. Nonetheless, as with other pharmacogenetics applications designed to predict metabolic phenotype, dose optimization requires clinical and/or therapeutic drug monitoring.

Solute Carrier Organic Anion Transporter Family Member 1B1 and Simvastatin Application

Drug transporters are membrane proteins that mediate the influx and efflux of chemicals using active and passive mechanisms. They can be divided into two major families: the adenosine triphosphate (ATP) binding cassette subfamily B member 1 (e.g., ABCB1) and the solute carrier family (e.g., *SLCO1B1*). The solute carrier organic anion-transporting polypeptide 1B1 (OATP1B1) is one of the main influx transporters expressed in hepatocytes. OATP1B1 substrates include several drugs as well as endogenous compounds such as bile acids, thyroid hormones, and estrogens. OATP1B1 is encoded by the solute carrier organic anion transporter gene *SLCO1B1*. Of more than 40 known *SLCO1B1* variants, two have been well characterized: 388A>G (c.492A>G,

rs2306283) and 521T>C (c.625T>C, rs4149056). These two variants are in partial linkage disequilibrium and lead to important haplotypes that contain neither, either, or both polymorphisms. The star (*) nomenclature has been applied. Clinical relevance of haplotypes that contain 521C (*5, *15, and *17) has been shown especially for simvastatin and high-dose methotrexate. In addition, OATP1B1 transport activity is inhibited by several drugs including atorvastatin, rifampicin, immunosuppressants (cyclosporine and tacrolimus), and the HIV drugs (ritonavir, lopinavir, and nelfinavir).

Statins, such as simvastatin, are safe and effective in the majority of patients but are associated with muscle toxicity in approximately 10%. The clinical spectrum of muscle toxicity ranges from mild forms to pain with evidence of muscle degradation (myopathy) and finally to severe muscle damage with acute kidney injury (rhabdomyolysis). Homozygous carriers of *SLCO1B1* 521C are exposed to higher levels of the active simvastatin acid due to decreased hepatic uptake and have an increased risk of myopathy during treatment with simvastatin. The *SLCO1B1* 521C variant does not explain all simvastatin myopathy; other genetic contribution is currently sought.

Associations With Pharmacodynamics

Vitamin K Epoxide Reductase Complex Subunit 1 and Warfarin Application

Vitamin K epoxide reductase (VKOR) performs the rate-limiting step in the vitamin K cycle. Impairment of VKOR

Fig. 46.4 Schematic illustration of warfarin pharmacodynamics. Purple boxes show the two enantiomers of warfarin. Green rounded boxes are cofactors important for reductive metabolism. Blue ovals are genes that code for enzymes or coagulation factors. Warfarin is administered as a racemic mixture of R- and S-enantiomers with S-warfarin being the more potent inhibitor of vitamin K epoxide reductase (VKORC1) in the vitamin K cycle. Other enzymes involved in the vitamin K cycle are epoxide hydrolase 1 (EPHX) and gamma-glutamyl carboxylase (GGCX). The vitamin K cycle is further regulated by calumenin (CALU) that inhibits GGFX and by oxidation of reduced vitamin K by cytochrome P450 4F2. The vitamin K cycle activates the coagulation factors FII, FVII, FIX and FX, and proteins C, S and Z into their functional forms. Other vitamin K-dependent proteins activated are the apoptotic growth arrest specific 6 (Gas-6); the bone gamma-carboxyglutamate (Gla) protein (BGLAP), which regulates bone remodelling; and the matrix Gla protein (MGP), which inhibits osteogenic factors. (From Whirl-Carrillo, M., McDonagh, E. M., Hebert, J. M., et al. [2012]. Pharmacogenomics knowledge for personalized medicine. *Clin Pharmacol Ther*, 92[4], 414–417, PMID: 22992668. Reproduced with permission from the copyright holder, PharmGKB and Stanford University.)

limits activation of coagulation factors II, VII, IX, and X and explains the anticoagulant effect of warfarin (Fig. 46.4). Warfarin is a widely used oral anticoagulant used to treat deep venous thrombosis and to prevent thromboembolic disease. Common *VKORC1* variants are associated with warfarin sensitivity. The allele frequency of the warfarin-sensitive *VKORC1* haplotype is low in African Americans, moderate in whites, and high in Asians. It is not known which polymorphism on

the haplotype mediates the effect. Most clinical tests detect the upstream *VKORC1* variant c.-1639G>A (rs9923231), typically along with *CYP2C9**2 and *CYP2C9**3. Additional variants in these and other genes, such as *CYP4F2*, appear to have little importance for warfarin dosing in Caucasians but may be important in other populations.

Individual response to warfarin is highly variable and is monitored by the INR (see Box 46.1). It is influenced by

clinical factors such as age, body size, diet, comorbidities, and interacting medications as well as by genetic variation. Carriers of variant alleles *CYP2C9* and *VKORC1* are more sensitive to warfarin and risk being overdosed by standard doses. Patients who are sensitive to warfarin spend a higher proportion of time above target range in the first 90 days of treatment and have an increased risk of bleeding compared with normal responders.

Several algorithms that predict individual warfarin dose requirements have been developed. These algorithms usually include *CYP2C9* *2 and *3, a *VKORC1* genetic variant, and clinical factors such as age, body size, and interacting drugs. Dose revision algorithms also include previous warfarin doses and existing INR data. The performance of these algorithms varies between populations partly due to different frequencies of the included variables.

It has been predicted that dosing guided by *CYP2C9* and *VKORC1* would improve the management of warfarin, particularly for warfarin-sensitive patients. In 2013, two large randomized clinical trials on genotype-guided warfarin dosing, EU-PACT and COAG, evaluated the primary outcome time in the therapeutic INR range. In EU-PACT, time in range improved with genotype-guided dosing, whereas no difference was seen in COAG. Different dosing strategies and allele frequencies due to continental ancestry explain part of the divergent results. In 2017, a third large randomized controlled trial, the Genetics-InFormatics Trial (GIFT), showed a 27% relative reduction in the composite outcome for the genotype-guided arm, including venous thromboembolism, major hemorrhage, and INR equal to or greater than 4. CPIC has also published an update on genotype-guided warfarin dosing that takes continental ancestry into account.

Cystic Fibrosis Transmembrane Conductance Regulator and Ivacaftor Application

Cystic fibrosis (CF) is one of the most common lethal autosomal recessive diseases in Caucasians, with an estimated incidence of 1 in 2500 to 3300 live births. Worldwide, approximately 70,000 individuals have CF, the majority of whom are diagnosed before the age of 1 year. The gene mutated in CF is the cystic fibrosis transmembrane conductance regulator (*CFTR*). More than 1800 *CFTR* mutations have been identified. The Human Genome Variation Society (HGVS) nomenclature is used to describe these mutations leading to a complex multisystem disease that affects the respiratory tract, pancreas, intestine, male genital tract, hepatobiliary system, and exocrine system. There is, however, wide variability in clinical presentation, severity, and the rate of disease progression between patients, which can be influenced by the underlying *CFTR* genotype as well as other genetic modifiers and environmental factors.

Traditionally the treatment of CF has focused on ameliorating symptoms (e.g., fighting infection, thinning mucus, and reducing inflammation) rather than directly targeting the genetic cause. Ivacaftor is the first FDA-approved therapeutic developed to target a specific *CFTR* defect by

improving the transport of sodium through the *CFTR* ion channel. It was originally indicated in CF patients 6 years of age and older who have a specific variant (c.1652G>A), but the indication now includes additional *CFTR* gating defect variants. In all these variants, *CFTR* is trafficked correctly to the epithelial cell surface, but once there, the protein cannot transport chloride through the channel. Coadministration of *CYP3A* inducers (e.g., rifampin, St. John's wort) that substantially decrease exposure to ivacaftor is not recommended.

Human Leukocyte Antigen Complex and Applications

The HLA complex is a cornerstone of the immune system because of its involvement in the identification of foreign proteins. The HLA proteins produced from the associated genes are expressed on the surface of nearly all cells, where they bind to peptides that are displayed to the circulating cells of the immune system. If the immune system recognizes the peptides as foreign (e.g., viral or bacterial peptides), it responds by triggering the infected cell to self-destruct. The HLA complex is highly variable and its classification is very complicated. The *HLA-B* gene is best characterized from the perspective of pharmacogenetics, based on the association of variants with drug hypersensitivity, specifically severe and life-threatening cutaneous reaction syndromes, such as Stevens-Johnson syndrome and toxic epidermal necrolysis. Because these hypersensitivity reactions are not dose-dependent, they are classified as type B adverse drug reactions. Pretherapeutic testing has been recommended for select applications.

Published clinical consensus guidelines exist for *HLA-B*15:02* and the anticonvulsants carbamazepine and phenytoin and for *HLA-B*57:01* and the HIV drug abacavir. Typing of *HLA-B*15:02* in patients of East Asian origin, where this allele is common, and of *HLA-B*57:01* in all patients, substantially reduces risk of the associated adverse drug reaction. A summary of CPIC guidelines for carbamazepine or abacavir based on HLA alleles is shown in [Table 46.8](#).

FUTURE DIRECTIONS

The future success of pharmacogenetics depends on understanding the following: (1) the interrelationship of the various proteins involved in pharmacokinetics and pharmacodynamics, (2) the balance between major versus minor pathways, and (3) the mechanisms of action of specific drugs. Standardization of test content and interpretation is needed. Although massively parallel sequencing will increase the complexity of pharmacogenetics, it will also improve our understanding and the utility of genotype-phenotype relationships. Additional clinical studies, particularly prospective and outcome-related studies, are needed to guide implementation of pharmacogenetic findings in the clinic. Finally, closer integration of pharmacy professionals with clinical laboratories and clinicians and increased availability of cost-effective commercial testing will improve the success of pharmacogenetic applications.

TABLE 46.8 Dosing for Carbamazepine and Phenytoin with HLA-B*15:02 and Abacavir with HLA-B*57:01 as Recommended by the Clinical Pharmacogenetics Implementation Consortium

Phenotype/Genotype	Implications for Outcome	Dosing Recommendations
HLA-B*15:02		
Absence of *15:02 alleles (may be reported as “negative” on a genotyping test)	Low or reduced risk of carbamazepine and phenytoin associated hypersensitivity	Use label-recommended dosage and administration.
Presence of at least one *15:02 allele (may be reported as “positive” on a genotyping test)	Increased risk of carbamazepine or and phenytoin hypersensitivity	Select alternative drug; avoid use of carbamazepine and phenytoin.
HLA-B*57:01		
Absence of *57:01 alleles (may be reported as “negative” on a genotyping test)	Low or reduced risk abacavir hypersensitivity	Use label-recommended dosage and administration.
Presence of at least one *57:01 allele (may be reported as “positive” on a genotyping test)	Increased risk of abacavir hypersensitivity	Select alternate drug; avoid use of abacavir.

REREVIEW QUESTIONS

- How a drug elicits responses, whether the responses are desirable or undesirable, is described by which one of the following?
 - Pharmacodynamics
 - Phenocopying
 - Pharmacokinetics
 - Pharmacogenetics
 - Pharmacogenomics
- A drug that is administered in an inactive form that must be metabolized to an active form is referred to as a(n)
 - Cytochrome P450 (CYP450) enzyme
 - Antimetabolite
 - Prodrug
 - Poor metabolizer
 - Drug metabolite
- Which of the following is an active drug that gets inactivated by metabolism?
 - Clopidogrel
 - Codeine
 - Tamoxifen
 - Warfarin
 - Irinotecan
- What is the drug-metabolizing phenotype when an individual has two nonfunctional alleles?
 - Extensive/normal metabolizer
 - Intermediate metabolizer
 - Rapid metabolizer
 - Poor metabolizer
 - Ultrarapid metabolizer
- What characterizes a type A adverse drug reaction?
 - It is caused by the drug's pharmacological effects
 - It is independent of dose
 - It is an unexpected effect
 - The drug class can never be given again
 - It can be caused by the immune system
- A pathologic disorder linked to the ingestion of fava beans, commonly described as favism, is caused by an enzyme deficiency that also has pharmacogenetic implications. Which gene is involved?
 - CFTR*
 - TPMT*
 - G6PD*
 - NAT2*
 - CYP2C19*

Molecular Principles

John Greg Howe, Elaine R. Mardis, Jason Y. Park, Carl T. Wittwer

OBJECTIVES

1. Compare and contrast the structure and function of DNA and RNA.
2. Identify five different types of RNA in the cell and describe their functions.
3. Detail how the information in DNA is used to make protein through transcription and translation.
4. Describe the genetic code and why it is important.
5. Compare and contrast the human genome with bacterial, viral, and fungal genomes.
6. Identify different kinds of sequence variants and discuss how they can cause disease.
7. Compare and contrast the different types of single nucleotide variants.
8. Describe three reversible reactions on histones that can increase accessibility for transcription, repair, or replication.
9. Learn how to name single nucleotide variants.
10. Describe the spectrum of genomic variations found in cancer.

KEYWORDS AND DEFINITIONS

Alleles Different variants of a gene.

Annotation Biologic information attached to a genomic sequence.

Assembly Reconstruction of short-sequence reads on a scaffold of reference DNA.

Autosome A non-sex chromosome.

Base pair Complementary base pairing of guanine and cytosine and adenine and thymine through hydrogen bonding.

Centromere The region of a chromosome between the small and long arms that is used during mitosis to attach the spindle fibers.

Chromatin A structure in the eukaryotic nucleus composed of DNA and histone proteins.

Chromosome A nucleic acid structure bound by protein containing all or a portion of an organism's genetic information.

Codon A three-base code found in messenger RNA, used in translation to specify the amino acid to be incorporated in the growing polypeptide chain.

Copy number variant (CNV) A structural variant of a large region of the genome that has been deleted or duplicated.

Deletion A DNA sequence that is missing in one sample compared with another. Deletions may be as small as one nucleotide or as large as an entire chromosome.

Deoxyribonucleic acid (DNA) Repository of the genetic material in an organism.

DNA methylation Addition of a methyl group to a cytosine, used to regulate gene expression.

Epigenetics Modifications that affect DNA packaging and accessibility without changing the DNA sequence.

Eukaryote An organism that contains a nucleus and whose DNA is in chromosomes.

Exon Portion of a gene that codes for protein.

Exonuclease An enzyme that cuts in the middle of a stretch of DNA at a specific sequence of bases.

FASTQ file A text output file of sequencing reads in a run, along with the quality scores of each position.

Fusion A translocation, inversion, large deletion, or large duplication resulting in a hybrid gene formed from originally separate genes.

Gene DNA structure that codes for the production of a protein.

Gene expression Synthesis of a gene product in the form of an RNA or protein from a gene.

Genetic code Collection of three base sequences called codons used to translate the nucleic acid information into amino acids during protein synthesis.

Genome The complete genetic content of an organism.

Genotype The unique genetic information of an organism or cell.

Heteroplasmic A mixture of more than one type of mitochondrial sequence in one cell.

Histones Basic proteins that bind to DNA to form nucleosomes, basic units of chromatin.

Indels Originally, designating a unique class of sequence variants including both insertions and deletions, resulting in an overall change in the number of base pairs. Today the term more commonly refers to either insertions or deletions or a combination thereof.

Insertion An extra DNA sequence that is present in one sample compared with a reference sequence.

Intergenic DNA sequence between genes.

Intron DNA between exons that do not code for protein and are removed by RNA splicing.

Micro RNA (miRNA) Small RNAs that are not translated and function to regulate translation.

Missense variant A nucleotide substitution that changes a codon to the code for a different amino acid. Although these sequence changes are commonly referred to as missense “mutations,” this is strictly a misnomer because missense variants may be benign and cause no disease. The preferred nomenclature for nucleotide changes in clinical testing is now “variants” rather than mutations.

Mitochondrial DNA Genetic information found uniquely in mitochondria that codes for proteins involved with energy production.

Mutation A disease-causing sequence variation. Historically the term has been interchangeable with *variant* to describe any change in a DNA sequence regardless of its relation to disease causation. For current clinical descriptions or reporting, the use of *mutation* is reserved for the scenario when disease causation is known. The preferred nomenclature for a disease-causing variation is now “pathogenic” or “likely pathogenic” variant. There is also an evolving tendency to describe whether a DNA variant causes disease within a specific clinical context.

Nonsense variant A nucleotide substitution that results in a stop codon, prematurely terminating the protein. The preferred nomenclature for nucleotide changes in clinical testing is now “variants” rather than mutations.

Nucleases Enzymes that cleave DNA to smaller fragments.

Nucleic Acid A polymer made of nucleotides consisting of a sugar, a phosphate group, and a nitrogenous base.

Nucleosome A unit of DNA that contains 146 bases and is wound around 8 histone proteins.

Nucleotide A basic unit of DNA and RNA consisting of a sugar, a phosphate group, and a nitrogenous base.

Phenotype The physical and biologic characteristics of a genotype.

Phred score Estimate of the error probability for a base called in DNA sequencing. It is represented as a Q score; the higher the number, the higher the probability of a correct call.

Plasmid An extrachromosomal ring of double-stranded closed DNA found in bacteria.

Polymerase A protein that is able to connect individual molecules into a single strand.

Promoter A DNA sequence usually upstream from the start of transcription of the gene that regulates its expression.

Pseudogene A genetic element that does not code for a functional gene product, usually because of accumulated sequence variations.

Purine A double-ring structure that constitutes the foundation for adenine and guanine, two of the bases in DNA.

Pyrimidine A single ring structure that constitutes the foundation for thymine and cytosine, two of the bases in DNA and uracil and one of the bases of RNA.

Recombination The rearrangement of DNA through the breaking and rejoining of DNA strands to create a different sequence.

Replication The process that synthesizes a copy of an organism’s DNA.

Ribonucleic acid (RNA) A polymer made of ribonucleotides consisting of ribose, a phosphate group, and four bases—guanine, adenine, cytosine, and uracil.

Ribosome A large structure that functions to convert messenger RNA to protein.

Short tandem repeat (STR) A simple sequence repeat that is 1 to 13 bases long.

Simple sequence repeat (SSR) A sequence from 1 to 500 bases that is repeated end to end. If the repeat unit is 1 to 13 bases, it is a microsatellite or STR. If the repeat is 14 to 500 bases, it is a minisatellite.

Single nucleotide polymorphism (SNP) A benign single nucleotide variant (substitution, deletion, or insertion) that occurs in a population at a frequency of at least 1%.

Single nucleotide variation (SNV) A single nucleotide variant (substitution, deletion, or insertion). SNVs may be benign or may cause disease.

Spliceosome A large structure that functions to remove introns from a heterogeneous RNA and splice the remaining exons together to form a messenger RNA.

Structural variation A region of DNA greater than 1000 bases in size that is inverted, translocated, inserted, or deleted.

Synonymous variant A nucleotide change that results in no change to the predicted amino acid sequence. Although synonymous variants are typically considered to be benign, since there is no protein coding change, there is the possibility of pathogenicity by changes in splicing, gene expression, or mRNA stability.

Telomere A repetitive DNA sequence at the end of a chromosome.

Transcription The biologic process that copies the information in DNA into RNA.

Translation The biologic process that uses ribosomes to convert RNA to protein.

Variant A disease-causing sequence variation. Historically the term has been interchangeable with *mutation* to describe any change in a DNA sequence regardless of its relation to disease causation.

Variant call format (VCF) After aligning all reads onto a reference sequence, variants that are different from the reference genome at a given nucleotide position are stored in a text file in a specific format.

Molecular diagnostics and its parent field, molecular pathology, examine the origins of disease at the molecular level, primarily by studying **nucleic acids**. **Deoxy-ribonucleic acid (DNA)**, which contains the blueprint for constructing a living organism, is the centerpiece for research and clinical analysis. Molecular pathology is an outgrowth of the enormous amount of successful research in the field of molecular biology that has discovered the basic biologic and chemical processes of how a living cell functions. Molecular biology is now used for clinical diagnosis and the development and use of therapeutics. In this chapter the fundamentals of molecular biology are reviewed, followed by a focus on **genomes** and their variants as well as an introduction to solid tumor genomics.

MOLECULAR BIOLOGY ESSENTIALS

Whether it is a bacterium, virus, or eukaryotic cell, the genetic material located in these organisms dictates their form and function. For the most part the genetic material is DNA, which is composed of two strands of a sugar-phosphate backbone that are bound together by hydrogen bonds between **purines** and **pyrimidines** attached to the sugar molecule, deoxyribose, in a double helix (Figs. 47.1 and 47.2). DNA in human cells is wrapped around histone proteins and packaged into **nucleosome** units, which are compacted further to form **chromosomes** (Fig. 47.3). Each chromosome is a single length of DNA with a stretch of short repeats at the ends called **telomeres** and additional repeats in the **centromere** region. In humans, there are two sets of 23 chromosomes that are a mixture of DNA from the mother's egg and father's sperm. Each egg and sperm is therefore a single or haploid set of 23 chromosomes and

the combination of the two creates a diploid set of human DNA, allowing each individual to possess two different sequences, genes, and **alleles** on each chromosome, one from each parent. Each child has a unique combination of alleles because of **recombination** between homologous chromosomes during meiosis in the development of gametes (egg and sperm cells). This creates genetic diversity within the human population. If a child has a random DNA sequence change, the child's **genotype** will be different from that inherited from either of the parents (de novo variant).

DNA is composed of **genes** that code for proteins and **ribonucleic acid (RNA)**. For DNA to convert its store of vital information into functional RNA and protein, the DNA strands must separate so that RNA **polymerase** can bind to the gene. With the help of transcription factors that bind upstream to **promoters**, an RNA polymerase produces single strands of RNA that are further processed to remove the **introns** and retain the protein-encoding **exons**. The mature, processed RNA molecule, the messenger RNA (mRNA), migrates to the cytoplasm, where it is used in the production of protein.

To start the process of protein synthesis or translation, the mRNA is bound by various protein factors and a **ribosome** containing ribosomal RNA (rRNA) and additional protein. The mRNA-bound ribosome begins to produce a polypeptide chain by binding a methionine-bound transfer RNA (tRNA) to the mRNA's initiating AUG **codon** or triplet code. The conversion of the nucleic acid triplet code to a polypeptide is accomplished by additional specific tRNAs, which contain nucleic acid triplet codes (anticodons) and specific amino acids that are transferred to the growing polypeptide chain. After synthesis is complete, the protein migrates to its functional location and eventually is removed and degraded.

Fig. 47.1 (A) Purine and pyrimidine bases and the formation of complementary base pairs. Dashed lines indicate the formation of hydrogen bonds. (^aIn RNA, thymine is replaced by uracil, which differs from thymine only in its lack of a methyl group.) (B) A single-stranded DNA chain. Repeating nucleotide units are linked by phosphodiester bonds that join the 5' carbon of one sugar to the 3' carbon of the next. Each nucleotide monomer consists of a sugar moiety, a phosphate residue, and a base. (^bIn RNA, the sugar is ribose, which adds a 2'-hydroxyl to deoxyribose.)

Fig. 47.2 The DNA double helix, with a sugar-phosphate backbone and pairing of the bases in the core-forming planar structures. (From Jorde, L. B., Carey, J. C., & Bamshad, M. J. [Eds.]. [2010]. *Medical genetics* [4th ed.]. Philadelphia: Mosby.)

NUCLEIC ACID STRUCTURE AND FUNCTION

DNA is a rather simple molecule with a limited number of components compared with those of proteins. DNA is composed of a deoxyribose sugar, phosphate linkages, and four nitrogen-containing bases. Deoxyribose contains five carbon atoms that are numbered from 1' to 5', starting with the carbon that will be attached to the base in DNA and progressing around the ring until the last carbon, which is attached to a phosphate. The bases consist of the purines, adenine and guanine and the pyrimidines, cytosine, and thymine; an additional base, uracil, replaces thymine in RNA. The basic building block is the **nucleotide**, which consists of a deoxyribose sugar with an attached base at the 1' carbon and a triphosphate group at the 5' carbon. The triphosphate nucleotide is the building block for making newly synthesized DNA, which then forms a polynucleotide chain that connects the individual nucleotides through the 5' and 3' carbons of each deoxyribose sugar via phosphodiester bonds.

Structure of Deoxyribonucleic Acid

DNA is double-stranded, and the two strands bind to one another through hydrogen bonds between the bases on each strand. Hydrogen bonding is augmented by hydrophobic attraction (stacking) between bases on adjacent rungs of the DNA ladder. Both hydrogen bonds and base stacking are not covalent but are weak bonds that can be broken and reestablished. This important property is exploited by many of the methods that are used in molecular diagnostics. There are two hydrogen bonds between adenine (A) and thymine (T) and three hydrogen bonds between cytosine (C) and guanine (G); because of this difference in the number of hydrogen bonds, separating a guanine-cytosine (G-C) pair takes more energy than an adenine-thymine (A-T) pair (see Fig. 47.1).

Each of the two DNA strands is formed by a phosphate sugar backbone that starts at the 5' phosphate and ends at a 3' hydroxyl group, with the complementary bases binding to one another between the two phosphate sugar backbones (see Fig. 47.2). When the two strands are bound to one another, they run in opposite 5' to 3' directions called an *antiparallel configuration*. By convention, the DNA sequence is written in a 5' to 3' direction. As discussed later, both the **replication** of new DNA and the **transcription** of DNA to RNA progress in the 5'-to-3' direction. In addition, the conversion of RNA to protein, a process called **translation**, proceeds from the 5' end of the RNA to the 3' end. Double-stranded DNA in living cells is generally found as a right-handed, B-DNA helix, which has specific dimensions. Each turn of the helix is 3.4 nm long and consists of 10 bases. The DNA sugar-phosphate backbone is on the outside of the helix with the internal bases bound to their complement on the other strand by hydrogen bonds. Non-B DNA also occurs and can affect transcriptional control and genetic instability; it can also be disease-associated.

Fig. 47.3 Structural organization of human chromosomal DNA. Double-stranded DNA is wound around the octamer core of histone proteins to form nucleosomes, which are further compacted into a helical structure called a *solenoid*. Nuclear DNA in conjunction with its associated structural proteins is known as *chromatin*. Chromatin is the most compact state of chromosomes. The primary constriction of a chromosome is the centromere, and the chromosome's ends are the telomeres. (From Jorde, L. B., Carey, J. C., & Bamshad, M. J. [Eds.]. [2010]. *Medical genetics* [4th ed.]. Philadelphia: Mosby.)

Composition and Structure of Ribonucleic Acid

The composition of RNA is similar to that of DNA because it contains four nucleotides linked together by a phosphodiester bond, but with several important differences.

RNA consists of a ribose sugar with a hydroxyl group at the 2' carbon instead of the hydrogen atom in DNA. The bases attached to the ribose sugar are adenine, cytosine, and guanine but not thymine, because RNA uses another

pyrimidine—uracil—as a substitute for thymine. Another difference between DNA and RNA is that RNA does not normally exist as two strands bound to one another, although a single strand can bind internally to itself, creating functionally important secondary structures. Although in the past several decades the complexity and number of different RNAs has greatly expanded, the most important cellular RNAs include mRNA, rRNA, and tRNA.

Ribonucleic Acids Associated With Protein Production

mRNA is the most diverse group of the three major types of RNAs, but it constitutes only a small percentage of the total RNA. mRNAs are transcribed from DNA that codes for proteins and therefore are used as the template for the translation of proteins. mRNA is often modified by the addition of a 5' end cap, which protects the mRNA from degradation, and a polyadenosine (polyA) sequence at the 3' end. The production and processing of mRNA takes place in the nucleus, followed by transport to the cytoplasm, where it is translated.

rRNA is associated with ribosomes, which are the primary structures that produce protein through the biologic process of translation. rRNA, unlike mRNA, does not code for proteins. In **eukaryotes**, the ribosome is composed of two structures, the 60S and 40S subunits, where the “S” stands for Svedberg units and is determined by the centrifugal sedimentation rate. The ribosome is a mixture of RNA and protein. rRNAs have secondary and tertiary structures that are well conserved with various loops, stem loops, and pseudoknots that contribute to their function. rRNA and protein, as the components of ribosomes, function to carry out the translation of proteins. The structure of the ribosome is now known, and the rRNA is more important than ribosomal proteins in ribosome functioning. The RNA acts as a catalytic agent called a *ribozyme*.

Another important group of RNAs are the tRNAs. These are molecules with a unique cloverleaf structure that translate the **genetic code** from nucleic acid triplets into amino acids that make up proteins. The 3' ends of tRNAs are covalently attached to specific amino acids. In the middle of the tRNA structure is the anticodon sequence that binds to a specific codon in the mRNA. Therefore the codon directs the binding of a specific tRNA linked to its corresponding amino acid. The genetic code, which consists of 64 three-base codes ($4^3 = 64$), specifies the appropriate amino acid in the growing polypeptide chain.

CENTRAL DOGMA OF MOLECULAR BIOLOGY

The “central dogma” of molecular biology describes the transfer of genetic information into functional macromolecules. Genetic information moves from DNA to RNA via transcription using RNA polymerase and is further translated into protein via ribosomes. Since the initial introduction of the central dogma, a number of other postulated transfers have been described. DNA can enzymatically replicate itself by DNA polymerase, and RNA can be made into DNA using reverse transcriptase.

Fig. 47.4 DNA replication. Double-stranded DNA is separated at the replication fork. The leading strand is synthesized continuously, whereas the lagging strand is synthesized discontinuously but is joined later by DNA ligase.

Deoxyribonucleic Acid Replication

Synthesis or replication of new DNA uses one of the two original DNA strands as a template to make a new homologous strand and is termed *semiconservative replication*. Since DNA can be supercoiled into complex structures, a topoisomerase is required to first unfold the **chromatin** and nucleosomes so that the DNA is accessible. A DNA helicase then binds to the double-stranded DNA and separates the two strands, providing two single-stranded DNA templates. Replication progresses in a 5'-to-3' direction; therefore one strand, the leading strand, is synthesized as one continuous strand. The other strand, called the *lagging strand*, is synthesized discontinuously in small segments. The small fragments on the lagging strand are then linked by a ligase (Fig. 47.4).

DNA polymerases of various types have been identified; they function in many different roles, the most important being the replication of new DNA and the repair of existing DNA. Using the template strand as a guide, the DNA polymerase binds a nucleotide triphosphate to the primer at a free 3' hydroxyl group, releasing pyrophosphate. The specific nucleotide selected depends on the base on the template strand; for example, an adenine nucleotide is used if a thymine nucleotide is in the template strand. In summary, a complementary sequence is synthesized opposite the template strand. Mistakes occur approximately every 100,000 nucleotides and a major function of some DNA polymerases is error correction or proofreading, accomplished by an intrinsic 3'-to-5' **exonuclease** activity. DNA polymerases are important in molecular diagnostics because they are used in the polymerase chain reaction (PCR) and DNA sequencing.

DNA replication is part of the cell cycle and defines the synthesis (S) phase. Before the S phase is a first growth phase (G_1). After the S phase is a second growth phase (G_2), followed by a mitosis (M) phase. The M phase, which involves the splitting of one cell into two cells, occurs after the G_2 phase and before the next G_1 phase. Important control points

in the cell cycle are between the G_1 and S phases, just before it begins DNA replication, and between G_2 and M phases, just as the cell commits to creating two cells from one. The G_1/S boundary control point is disrupted in many cancers.

Deoxyribonucleic Acid Repair

DNA can be damaged in a variety of ways that culminate in changes or **mutations** in the DNA sequence. DNA bases may be damaged, removed, cross-linked, or incorrectly paired with one another; single- or double-stranded breaks may also occur. When the cell senses that its DNA has become damaged, it stops the progression of its cell cycle and initiates DNA repair processes. Cells repair these lesions by employing multiple repair mechanisms that are specific for the type of DNA lesion and include base excision repair, nucleotide excision repair, mismatch repair, and homologous recombination repair.

Base excision repair removes bases that are chemically altered or damaged. Deamination of guanine, cytosine, and adenine transforms them into bases that cause incorrect base pairing, creating transition mutations, which are changes between similar nitrogenous bases such as a purine to a purine. A transversion mutation is a change from a purine to a pyrimidine or vice versa. DNA glycosylases, such as uracil-DNA-glycosylase, cleave the damaged base, and a 5'-deoxyribose phosphate lyase removes the nucleotide upstream of the removed base. DNA polymerase and ligase then add a new nucleotide, repairing the damage.

Nucleotide excision repair removes base modifications that change the helical structure of DNA, including bulky DNA distortions and covalently bound structures that may be created by ultraviolet radiation and certain cancer drugs. After the repair is initiated, DNA is unwound and the gap is filled by DNA polymerase and finally sealed by DNA ligase.

Mismatch repair recognizes base incorporation errors and base damage. The mismatched nucleotides must be repaired on the newly synthesized strand of DNA. These mutations are corrected with DNA mismatch repair proteins that excise the surrounding sequence and then repair the excision with new sequence.

Double-stranded breaks may destabilize the genome, resulting in gross chromosomal changes such as translocations, which are frequently found in cancer. Double-stranded breaks are caused by ionizing radiation and chemotherapy drugs and are repaired by either homologous recombination or nonhomologous end joining. The homologous recombination repair pathway is initiated by recognition of a double-stranded break, followed by resection using exonucleases to create a 3' single-stranded overhang. With the assistance of many proteins, the overhang invades the intact homologous double-stranded DNA of the sister chromatid and uses it as a template for new double-stranded DNA repair.

DNA repair mechanisms operate independently to repair simple lesions. However, the repair of more complex lesions involves multiple DNA processing steps regulated by the DNA damage-response pathway. When single- and double-stranded DNA breaks occur, a cascade of responses is

initiated that culminate in either DNA repair, stopping the cell cycle, or programmed cell death.

Deoxyribonucleic Acid Modification Enzymes

There are two groups of **nucleases**, the endonucleases that cut through the sugar-phosphate backbone and exonucleases that digest the ends of DNA. The commercially important restriction endonucleases, which bacteria have acquired to protect themselves from viral infections, are used to cleave DNA at a specific nucleotide sequence or restriction sites. Several thousand restriction endonucleases have been characterized and are used extensively to manipulate DNA in molecular biology and molecular diagnostics. Recent work has described new nucleases, such as the RNA-guided engineered nuclease CRISPR/Cas system, which can precisely cleave genomic DNA.

DNA glycosylases are a family of enzymes associated with base excision repair; they are used in the first step of DNA repair to remove the damaged base without disrupting the sugar-phosphate backbone. An important member of that family, uracil DNA glycosylase, repairs the most common mutation found in humans, the spontaneous deamination of cytosine to uracil, by removing the uracil base.

Gene Structure

The structure of prokaryotic genes is straightforward; almost all of the gene sequence is used to make protein; however, this is not the case with eukaryotic genes. One of the unique hallmarks of eukaryotic genes is that the protein-coding DNA is interspersed with regions that do not code for DNA. A mature mRNA retains only the protein-coding sequences, called *exons*; the sequences between the exons are non-protein-encoding sequences called *introns*, which are removed during mRNA maturation (Fig. 47.5).

Ribonucleic Acid Transcription and Splicing

RNA transcription involves synthesizing an RNA strand using DNA as a template. This requires many different proteins, the most important being a RNA polymerase. Additional proteins function in combination to recognize and regulate the transcription of different genes. The synthesis of RNA proceeds in a 5'-to-3' direction using DNA as a template, and a specific DNA sequence acts as a transcription start site. Transcription progresses through three phases: initiation, elongation, and termination. The initiation phase includes the binding of transcription factors to promoters upstream from the start site and includes the core promoter immediately upstream and the ancillary promoters further away. Transcription factors binding to upstream promoters act as regulators of the transcription of genes.

Important recurring sequences are found in some promoters. For example, some core promoters contain a TATAAA sequence, called a *TATA box*, located 25 to 40 nucleotides upstream from the transcriptional start site. Transcription factors bind to the TATA box, which in turn promotes the binding of RNA polymerase and additional proteins. A functional transcription complex forms when the double-stranded DNA in the promoter region separates and the transcription complex moves away from the core promoter region. Once started, the

Fig. 47.5 DNA transcription and messenger RNA (*mRNA*) processing. A gene that encodes for a protein contains a promoter region and variable numbers of introns and exons. Transcription commences at the transcription start site. Pre-mRNA is processed by capping, polyadenylation, and intron splicing to become a mature mRNA.

RNA polymerase adds nucleotides to the free 3'-hydroxyl group in a manner similar to that of DNA replication. Transcription is eventually terminated by a polyadenylation step (see Fig. 47.5).

Transcription initially produces RNA that contains both exons and introns. This pre-RNA transcript must be processed or spliced into mature mRNA for it to be properly translated into protein. RNA splicing involves the cleavage and removal of intron RNA segments and splicing of exon RNA segments. Splicing requires the effort of a number of proteins and small RNAs that come together to form a **spliceosome**, which directs the splicing of exons and removal of introns.

An important modification of the splicing process, alternative splicing, allows for the generation of different mRNAs from the same primary RNA transcript by the cutting and joining of the RNA strand at different locations. Among the types of alternative splicing are exon skipping, alternative 3' and 5' splice sites, and intron retention. Approximately 92% to 95% of all human genes are alternatively spliced, resulting in additional protein complexity that may be tightly regulated and specific to different cells and tissues.

Translation

The final phase of the transfer of information from DNA is to proteins, the structural and functional molecules that make up most of a living organism. Proteins are long single strands of various amino acids and are synthesized by a process called *translation*, which requires the functioning of many protein factors, tRNAs, and ribosomes.

Amino acids have a common structure consisting of a carbon atom bound to amino and carboxylic acid groups with a side chain. There are 20 amino acids, each with a different side chain that gives them their unique properties. The side chains can be divided into four types: nonpolar (hydrophobic), polar (hydrophilic uncharged), negatively charged, and positively charged. A protein's amino acid makeup and sequence in the polypeptide chain determine the overall structure and function of the protein. Some amino acids commonly induce structural changes, such as proline, which disrupts secondary structure, and cysteine, which can cross-link to another cysteine through disulfide bonds. For additional information on protein structure, see Chapter 18.

The genetic code, which was deciphered in the early 1960s, is required to convert a nucleic acid sequence into an amino acid sequence. Humans have four unique nucleotides, which are arranged into sets of three per codon. Theoretically there are 64 combinations; however, rather than encoding 64 amino acids, humans have 20. A hallmark of this genetic code is that it is redundant, meaning that there are several codes for one amino acid. That is the case for most amino acids but not all; for example, methionine and tryptophan have only one code. The redundancy is usually in the third base of the code. All of the 64 three-nucleotide codon possibilities code for an amino acid except for the three that serve as stop codons (UAA, UGA, and UAG) (Fig. 47.6).

Protein synthesis or translation occurs in the cytoplasm and proceeds in three steps: initiation, elongation, and termination. The process requires tRNA and rRNA molecules as well as ribosomes and initiation, elongation, and termination factors. The first codon (AUG) always codes for methionine; therefore, to initiate translation, a methionine tRNA first binds to the ribosome. The tRNA specific for the next three-base codon—for example, lysine—binds to the ribosome, and a peptide bond is created between the amino group of one amino acid and the carboxyl group of the next amino acid. The ribosome moves forward one codon and the next tRNA specific for the next codon binds in the ribosome; this process is repeated until a termination codon is reached (Fig. 47.7). Protein synthesis occurs in the endoplasmic reticulum, where multiple ribosomes called *polyribosomes* are involved in translating an individual mRNA.

POINTS TO REMEMBER

- The two strands of DNA are bound together by hydrogen bonds and stacking forces that can be broken and reformed without permanent damage to the DNA.
- The conversion of DNA information into protein is facilitated by aminoacyl tRNA synthetases and their ability to create amino acid-specific tRNAs.
- The genetic code is redundant; the three-base code can have 64 different combinations, but only 20 amino acids are recognized.

Fig. 47.6 Genetic code. Translation of messenger RNA to amino acids during protein synthesis.

Fig. 47.7 Translation. Shown is a ribosome bound to a messenger RNA (*mRNA*) converting the *mRNA* triplet code (codon) via a specific amino acid-bound transfer RNA containing a complementary anticodon sequence. There are three transfer RNA positions. A new amino acid-bound transfer RNA first arrives at the ribosome at the A or acceptor site, at the front of the moving ribosome, and then moves to the P or peptidyl site, where the amino acid on the newly arrived transfer RNA combines with the growing polypeptide chain. Finally the now empty transfer RNA moves to the E, or exit site, where it prepares to leave the ribosome. (Modified from Huether, S. E., & McCance, K. L. [2017]. *Understanding pathophysiology* [6th ed.]. St. Louis: Elsevier.)

EPIGENETICS

Global and mRNA-specific regulation of translation often occurs by **epigenetic** changes—that is, changes that do not modify the DNA sequence. Currently there are three major types of epigenetic modifications: (1) DNA methylation, (2) histone modifications, and (3) noncoding RNAs.

DNA methylation is a well-known epigenetic change. Methylation of cytosine to 5-methylcytosine occurs frequently; about 70% of CpG dinucleotides in the human genome are methylated. CpG islands are about 1000 bases in length and are often found near the 5' end of genes. These regions consist of clusters of CG dinucleotides that are usually not methylated in normal cells. However, CpG methylation

Fig. 47.8 Epigenetics. *Top*, DNA methylation of CpG island regions indicated by *Me* in and around gene promoters is associated with loss of gene expression and silencing of the gene. When CpG islands are unmethylated, shown by absence of *Me*, gene expression is unaffected. *Bottom*, Modifications of the tails of histone proteins, such as methylation, acetylation, and phosphorylation, shown as *Me*, *Ac*, and *P*, respectively, can increase gene expression. (Modified from Zaidi, S. K., Young, D. W., Montecino, M., van Wijnen, A. J., Stein, J. L., Lian, J. B., et al. [2011]. Bookmarking the genome: maintenance of epigenetic information. *Journal of Biological Chemistry*, 286, 18355–18361.)

correlates with condensed chromatin structure and promoter inactivation (Fig. 47.8). Cancer is the most common human disease associated with aberrant DNA methylation.

DNA replication, repair, and transcription require free access to DNA. However, DNA is usually wound around **histones** to form nucleosomes and is further condensed into chromatin. Therefore the conformation of chromatin is tightly regulated and is very dynamic; at any one point in time portions of the DNA are being exposed and other portions are being covered. For example, reversible phosphorylation at serine, threonine, and tyrosine residues adds negative charges to histones that can repel them from the negatively charged DNA. Similarly, specific histones may be reversibly modified by acetylation to remove the positive charge on lysine residues and thus to lower histone attraction to DNA. Histone, lysine, and arginine residues can also be mono-, di-, and trimethylated. Although the charges are unchanged, methylation further serves to promote DNA transcription, replication, and repair.

Noncoding RNAs also function in the regulation of translation. In addition to noncoding ribosomal and tRNAs, there are many forms of noncoding RNA, including long (>200 nucleotides) and short (20 to 200 nucleotides) noncoding RNAs. Long noncoding RNAs are diverse and highly regulated during the development of an organism. At least 93% of the genome is transcribed, producing more than 10 times the amount of RNA than is produced from the coding segments of genes. Both strands of DNA may be transcribed, and long noncoding transcripts may overlap coding regions, producing a complex transcriptome of functional RNA molecules that may variably regulate transcription, RNA processing, mRNA stability, translation, protein stability, and secretion.

Small noncoding RNAs include **microRNAs (miRNAs)** that are particularly interesting as potential markers for disease. miRNAs are functional single-stranded RNAs 21 to

22 bases long that are expressed in a tissue-specific manner. There are thousands of different miRNAs that inhibit mRNA expression by either mRNA degradation or by blocking of translation.

Human Chromosomes

Cellular DNA is bound by many proteins to form chromatin (see Fig. 47.3). The proteins in chromatin consist of histones, which are bound in precise amounts per length of DNA, and other proteins called *nonhistone proteins* that are bound more irregularly. The histone proteins consist of two copies of four proteins that bind as a unit to 147 **base pairs** (bp) of DNA to make up a nucleosome. One additional protein binds between the nucleosomes (Fig. 47.9). Access to DNA by transcription factors is controlled by proteins that remodel the histone proteins through phosphorylation, acetylation, and methylation. The nucleosomes are condensed into filaments and even more compact structures to form a chromosome (see Fig. 47.3). The DNA in chromosomes is continuous for each chromosome and can be as much as several hundred million base pairs in length.

Chromosome regions can be classified by their transcriptional activity. The ends of chromosomes, called *telomeres*, contain the repeat sequence TTAGGG, which shortens with age. The centromeres, at the centers of most chromosomes, are important during mitosis and contain mostly repeated segments of DNA.

THE HUMAN REFERENCE GENOME

One of the defining achievements of the early 21st century is the sequencing and **assembly** of more than 90% of the human genome. Of course there is not a single human genome; individuals differ from each other by about 0.1%, based on differences in **single nucleotide polymorphisms (SNPs)**.

Fig. 47.9 Schematic illustration of a nucleosome unit. A segment of DNA is wound around a nucleosome core particle consisting of an octamer containing two copies of histone proteins H2A, H2B, H3, and H4. Tails with modifications (indicated by a blue star) are shown to protrude from H3 and H4. Adjacent nucleosomes are separated by a segment of linker DNA and the linker histone H1.

Variation comes in many different forms, including single base changes and copy number changes in large segments of DNA. Even more challenging than sequencing the whole genome is documenting and understanding the clinical significance of human sequence variation.

Throughout the 1990s, there was an international effort to sequence the human genome. The first draft was released in 2001, followed by a more complete version in 2004. The 2004 version contains 2.85 billion nucleotides (bases) and was considered 99% complete for actively transcribed DNA. The overall size of the genome is estimated to be 3.08 billion nucleotides including highly repeated regions such as telomeres and centromeres. Within the genome are 19,438 known genes and an additional 2188 predicted genes. The portion of the genome encoding proteins, known as the *exome*, comprises only 1.2% of the genome. The 2004 genome has been used as the reference sequence for most subsequent sequencing projects, although periodic release of improved versions has occurred since its initial release. A reference is required because commonly used next-generation DNA sequencing technologies produce relatively short read lengths and hence require a scaffold onto which these short sequences are aligned prior to variant identification.

Statistics for the human genome and its variations are summarized in Table 47.1. Three-quarters of human DNA is **intergenic**, or between genes. More than 60% of this intergenic sequence consists of “parasitic” DNA regions of mostly defective transposable elements 100 to 11,000 bases in length. Between 2 and 3 million of these “retrotransposons” are present in each copy of the genome. They contribute to genetic recombination and chromosome structure and provide an evolutionary record of sequence variation and selection.

Segmental duplications constitute 5.3% of the human genome. They are more than 1 kilobase (1000 bases or 1 kb) in length, have a sequence identity of at least 90%, and are

TABLE 47.1 The Human Genome and Its Sequence Variation

The Human Genome

not transposable elements. Segmental duplications are common in the human genome and are prone to **deletion** or rearrangement (or both), often with phenotypic consequences. Intergenic DNA also carries most of the **simple sequence repeats (SSRs)** present in the genome. A subset of SSRs, the **short tandem repeats (STRs)**, have repeat units of one to several bases that may tandemly repeat up to thousands of times. STRs have played a large role in genetic linkage studies and in forensic and medical identity testing. They are formed by slippage during replication and are highly polymorphic among individuals. The most common STRs are dinucleotide repeats, such as ACACAC and ATAT. On average, one STR occurs every 2000 bases.

Approximately 2% of the genome is required to maintain the structure of chromosomes and is located at chromosome centers (centromeres) and ends (telomeres). Centromeric DNA includes many tandem copies of nearly identical 171-bp repeats encompassing 0.24 to 5.0 megabytes (MB) per chromosome. Each chromosome end is capped with several kb of the telomeric 6-base repeat TTAGGG. Although intergenic DNA does not code for protein and was originally considered “junk,” much of this DNA is transcribed to RNA, producing a complex “transcriptome” network of RNA control elements whose function and mechanics are active areas of investigation.

One-quarter of the human genome consists of genes. The average gene covers 27,000 bases, but only about 1300 of these bases code for amino acids. The primary RNA transcript is processed by splicing to retain exons that are interspersed throughout the gene and have a higher GC content than non-coding regions. On average, 95% of a gene is excised as introns, retaining a mean of 10.4 exons, of which on average 9.1 are translated into proteins. Exons make up only 1.9% of the total genome, with 1.2% of the genome coding for proteins. Some important genes are present in many copies, so that overall protein expression is not affected if a chance variation occurs in one copy. If extra copies of genes lose their function, they are known as **pseudogenes**. At least as many pseudogenes as functional genes are present in the human genome. It is important to distinguish pseudogenes from functional genes because variants in pseudogenes are seldom of clinical importance and often complicate DNA diagnostic assays.

PROJECTS INSPIRED BY THE HUMAN GENOME PROJECT

Genome-wide association studies (GWAS) use microarray tests that type large numbers of **single nucleotide variations (SNVs)** to find associations between genetic variations and diseases. DNA variants are often clustered into regions that are inherited as a unit, such that a unique SNVs pattern or haplotype can be passed from generation to generation. The International HapMap Project used SNVs to investigate haplotype associations with disease.

The 1000 Genomes Project sequenced a large number of diverse human samples from around the world. The goal was to build a comprehensive catalog of the most common human

genetic variants, which included SNVs as well as **insertions**, deletions, copy number and structural variants that are found in the populations studied. The Exome Aggregation Consortium (ExAC) has amalgamated sequencing data for over 60,000 exomes to delineate common genetic variation within human exomes. The SNP database, International HapMap Project, 1000 Genomes Project, ExAC, and GWAS have helped to define genetic variability within individuals and populations to understand the basis of many genetic diseases.

A more fundamental biology project is the encyclopedia of DNA elements, or ENCODE, whose goal is to catalog the functional elements of the genomes of humans and other species. The functional elements include promoter and enhancer regions, all expressed RNA forms, and epigenetic modifications.

NONHUMAN GENOMES

The genomes of different organisms vary greatly in size and complexity. There is overlap in genome size among eukaryotes (animals, plants, fungi), viruses, and bacteria (Fig. 47.10). Human disease is caused by fungi, bacteria, and viruses with smaller and less complex genomes.

Bacterial genomes have only one chromosome, usually a circular DNA double helix of 2 to 5 million base pairs, or ~1000 times less than the amount of DNA in a human cell. About 90% of the DNA in bacteria codes for protein. There are no introns, but there are multiple small intergenic regions of repetitive sequences that are dispersed throughout the genomes. *Escherichia coli*, a common bacterium in the human intestinal tract, has about 4300 genes. In addition to the large circular chromosome that carries essential genes, bacteria also carry accessory genes in smaller circles of double-stranded DNA (dsDNA) known as **plasmids**. These range in size from 1000 to more than 1 million base pairs. Plasmids are important in the molecular diagnosis of bacterial infections because they often encode pathogenic factors and antibiotic resistance.

Viral genomes are considerably smaller and less complex than bacterial genomes. Common viruses that infect humans vary in size from about 5000 to 250,000 bases, or 20 to 1000 times less than the *E. coli* genome. Because viruses use the host's cellular machinery, they do not need as many genes as bacteria. Small viruses may encode only several genes, but the larger viruses can encode hundreds. The viral genome consists of either DNA or RNA, and the nucleic acid may be single- or double-stranded, linear or circular, with one or multiple fragments or copies per viral particle. As in bacteria, viral genes have no introns. In fact, in some viruses the genes overlap, with different reading frames coding different products from the same nucleic acid sequence. Noncoding regions are usually present at the terminal ends of linear viral genomes. Repeat segments are often found as terminal or internal repeats and may be inverted.

Sequence alterations in viruses are common. Areas of high sequence variation may be interspersed between

Fig. 47.10 Range of genome sizes. There is a wide variation in genome size among different organisms. In this plot of publicly available genomes, the y-axis is in megabases and the x-axis lists various organisms: Eukaryota (animals, plants, fungi), bacteria, and viruses. On average, Eukaryota have larger genomes compared with bacteria and viruses; however, there are exceptions, in which viral genomes are larger than those of bacteria or Eukaryota. The difference between the smallest and largest known genomes is more than six orders of magnitude. Several specific genome sizes are illustrated in Mb (megabases, million). (Data extracted from the National Center for Biotechnology Information. <http://www.ncbi.nlm.nih.gov/genome>.)

conserved domains. Higher frequencies of variation correlate with lower polymerase fidelity and may allow escape from antibody recognition and antiviral drugs. Common sequence variants in viruses include single base changes, insertions, and deletions. Sequence diversity within a viral species may be so great that consensus sequences for molecular assays are difficult to find.

VARIATION IN THE HUMAN GENOME

About 99.9% of human genome sequence is identical between randomly chosen individuals in a population in considering the simplest SNPs. However, **copy number variants (CNVs)** greater than 50 kb involve up to 0.5% of the genome. That is, between individuals, at least five times as many bases are affected by copy number changes as by small sequence differences.

Most human genetic material is present in two copies with the exception of the unpaired sex chromosome in males and **mitochondrial DNA**. The presence of only single gene copies on the X and Y chromosome in males leads to well-known sex-linked disorders. In contrast, the 16,500-bp mitochondrial genome is present in multiple copies per cell, constituting about 0.3% of human DNA depending on the tissue source. Allele fractions may vary over a wide range when all mitochondria in a cell are considered. That is, sequence variations in mitochondrial DNA are **heteroplasmic**, meaning that the ratio of the wild-type allele to a variant allele can vary almost continuously, sometimes resulting in a wide range of symptoms even when only one sequence variant is involved.

Any sequence change from a reference sequence is called a **sequence variant** or **variation**. Many variations do not affect human health and are benign or silent. For example, most (1) CNVs, (2) SNVs, and (3) STRs found between genes are

seldom associated with disease. Sequence alterations that are known to cause disease are often called **mutations**, **pathogenic variants**, or **disease-causing variants**. About 68% of known disease-causing variants involve only a single base change. Most of the remaining disease-causing variants (24%) are small insertions or deletions. The remainder (8%) includes more complex **structural variations** (see Table 47.1).

Single Nucleotide Variants

The most common sequence variations are single base variants, also known as SNVs. More than 40 million SNVs have been described, and many new SNVs continue to be reported. Some SNVs are common in the population, with allele frequencies of 0.1 to 0.5 (i.e., present in 10 to 50 of every 100 copies studied), but other single base changes are very rare. The vast majority of SNVs (97%) occur in noncoding regions; only 3% of SNVs are associated with exons. Similarly, most of the SNVs within introns except for splicing and regulatory variants are not known to affect gene function. In addition, some of the SNVs within exons are silent alterations that do not code for a change in amino acid sequence because of the redundancy in the genetic code. Still other SNVs in exons code for amino acid changes that do not affect protein function.

Most SNVs that cause disease are missense and result in an amino acid substitution; significantly fewer are nonsense variants that result in a termination codon and premature polypeptide chain termination. Approximately 10% of disease-causing variants are SNVs that affect splicing sites and result in altered concatenations of coding sequences or intron retention. Finally, fewer than 2% of known disease-causing variants are SNVs that affect the regulatory efficiency of transcription by altering promoter and/or enhancer regions in introns or the stability of the RNA transcript.

Small insertion and/or deletion variants account for 24% of variants that cause disease. An insertion refers to the presence of extra bases, and deletion implies the absence of certain bases in comparison with a reference sequence. Insertions and deletions (**indels**) often cause a shift of the codon reading frame, resulting in altered amino acid sequence downstream of the variation—commonly followed by chain termination from a nonsense codon.

The remaining 8% of variants that relate to health and disease are mostly structural variants, including (1) duplications or deletions of entire exons or genes; (2) gene fusions, including chromosomal translocations and inversions; (3) STR expansions (e.g., an increased number of trinucleotide repeats); (4) gene rearrangements (e.g., rearrangements of immunoglobulin genes in B cells); (5) complex polymorphic loci related to health and disease (e.g., human leukocyte antigens); and (6) CNVs.

Copy Number Variation (Gains and Losses)

Although SNVs are the most common sequence variant, CNVs cover more of the genome than SNVs. An average of 12.4 large CNVs are present per individual. Some CNVs affect up to 2 million bases of DNA in phenotypically normal individuals. CNVs may be duplicated in tandem or may involve complex gains or losses of homologous sequences at multiple sites in the genome. CNVs can involve single genes or contiguous sets of genes. When the normal dosage of the gene is two but more than two functional copies of a gene are present, then the gene is “amplified.” If a dosage-sensitive gene is amplified, it usually leads to overexpression of mRNA and protein, resulting in cellular abnormalities and possible progression to diseases such as cancer. When the normal gene dosage is two and loss of one of the functional copies of the gene occurs, disorders such as mental retardation and developmental delay may result. Loss of both copies is also deleterious and may lead to cancer development or result in embryonic lethals.

Fusions

Gene **fusions** from deletions, duplications, inversions, and translocations are commonly found in cancer. Often they arise by balanced translocations, whereby a chimeric protein is created by the fusion of two coding regions. Gene fusions promote tumor proliferation by either activating an oncogenic driver or inactivating a tumor suppressor. By identifying gene fusions that act as primary oncogenic drivers, targeted therapies may become available for precision treatment.

NAMING OF CHROMOSOMES, GENES, AND VARIANTS

Autosomes are numbered from 1 to 22 in descending order of length. The sex chromosomes are named X and Y. The symbols p and q designate the short and long arms of the chromosomes, respectively. A chromosome band is the part of the chromosome that is clearly distinguishable from adjacent segments that are darker or lighter in appearance. G bands are the bands resulting from Giemsa dye staining. Additional

BOX 47.1 Nomenclature for Naming Small Sequence Variants

The position of single nucleotide substitutions can be referenced to the genome (g.), amino acids in the protein (p.), or nucleotide bases in the cDNA transcript (c.). In all cases, the genome build (e.g., Genome Reference Consortium human genome build 38 or “GRCh38”) should be specified.

For genomic coordinates, specify the chromosome and the base position followed by the base change. For example: GRCh38 **Ch17**: g.3424566C > T. Genomic coordinates are the only option for most intergenic variants, as well as deep intronic variants.

When the variant is within the protein coding region of a gene and protein coordinates (p.) are preferred, give the gene name followed by the number of the amino acid affected starting with the initiating methionine as 1. The wild-type amino acid is listed to the left of the number, and the variant amino acid is listed to the right. For example, *CYBB* p.T42R (or *CYBB* p.Tyr42Arg) are listed for the one- and three-letter codes of amino acids, respectively. The protein coordinates best specify the phenotype, but it is a challenge to convey the results of frameshifts and the exact nucleotide change is often ambiguous.

When the variant is in or near the exons of a gene, cDNA coordinates (c.) can be used. List the gene name followed by the base number using the A in the ATG initiation codon as 1 and then the base change. For example: *CYBB* c.125C > G. If the base change is in an intron (e.g., a splice site mutation), the number is counted from the nearest intron-exon boundary. For example, *CYBB* c.141 + 2T > C or c.142 – 12C > T. If the variant is 5' of the ATG initiation sequence, use negative numbers (*CYBB* c.–64C > T), or if it is 3' of the last exon, use an asterisk (*CYBB* c.*67G > A). With c. coordinates, you know the exact base change even though it may not affect the amino acid sequence.

rules for naming chromosomal rearrangements such as inversions, deletions, and translocations are also standardized.

Genes are named descriptively, along with a gene symbol which is a short abbreviation in upper case Latin letters and Arabic numbers that are both italicized (e.g., collagen type II, alpha 1 chain, *CT2A1*). Sequence variants are described at the DNA level without indication of disease potential. Preferred terms include sequence variant, CNV, and SNV. Basic naming recommendations for SNPs are introduced in [Box 47.1](#).

VARIANT DATABASES

Some commonly used variant databases are detailed in [Box 47.2](#); they include dbSNP (Database of Single Nucleotide Polymorphisms), OMIM (Online Mendelian Inheritance in Man), HGMD (Human Gene Mutation Database), and ClinVar (Clinical Variant). dbSNP is a systematic catalog of SNVs including small insertions and deletions is dbSNP. The reference identifier for variants in dbSNP begins with the prefix “rs.” OMIM is a catalog of genes and variants related to disease. As of April 2017, some 24,000 diseases or syndromes were described in OMIM, along with 15,600 genes.

In contrast to OMIM, HGMD seeks to be a comprehensive database of all variants with reported disease association. As of 2017, there were 203,885 variants from 8271 genes cataloged in HGMD. The types of variants included 114,703 missense or nonsense variants, 18,386 splicing variants, 30,169 small deletions, 12,557 small insertions, and 15,272 gross deletions. The chief limitation of databases such as OMIM and HGMD is that they rely on published reports. As new variants of known genes are discovered in research or clinical laboratories, they are rarely published. This has led to the ClinVar (<https://www.ncbi.nlm.nih.gov/clinvar/>), which includes annotated variants by clinical laboratories, research laboratories, and the literature within a publicly available database.

BIOINFORMATICS

Although a single human genome is approximately 3 billion bases, the amount of massively parallel sequencing (MPS) data needed to accurately determine an individual's genotype may exceed 90 billion bases. This is true because short reads require a specific depth of read coverage across the genome in order to confidently genotype each variant and variant type. The data storage requirements are typically more than 0.5 terabytes per human genome. Fortunately, as the scale of sequencing has increased, tools have been developed to manage and analyze the information derived from these analyses. Often both publicly available tools and commercial software are assembled into what is referred to as a pipeline. In the pipeline, the aligned sequence data are processed in a serial manner (Fig. 47.11). Raw sequencing data from millions of short sequencing reads are aligned to the reference genome. Depending on the coverage required, there may be tens to thousands of sequencing reads at a single nucleotide position. After alignment, the bases are "called" or determined by a software algorithm. The base call is dependent on a variety of factors, including the quality of the reads (Q score; Box 47.3) and the percentage of reads at the nucleotide position that are in agreement. Postcall filtering removes sources of known false positivity such as variants called only on one strand or only at the ends of reads, where data quality is poorer. After the bases are called for each nucleotide position, a variant call format file (VCF) is generated. The VCF includes the nucleotide positions of the variants that differ from the reference genome and are tabulated by the genomic coordinate of the variant. The VCF is then examined by another set of software algorithms that query multiple databases; the examination by databases is sometimes referred to as filtering or interpretation. A standard filter is to further examine only variants that are predicted to change protein coding (e.g., missense or nonsense variants). Other filters may be based on the frequency of specific variants in various populations. If the variant occurs in a gene implicated in a rare disease that occurs in fewer than 1 in 100,000 individuals, that variant should occur much less frequently than 1% in any population. In addition to population databases, there are databases that catalog variants with clinical **phenotype** information or based on reports in the published literature. Finally, rather than an examination of databases, tools that predict the importance of variants to protein structure or function may be used. These predictive tools may be helpful to prioritize the examination of a long queue of variants from a sequencing study.

CANCER GENOMICS

An important clinical application of genomics is cancer diagnostics. The first whole genome sequencing (WGS) of a cancer was an acute myeloid leukemia (AML) in 2008; many others have subsequently followed. The combination of phenotypic information and molecular profiling provides an opportunity for new therapeutic targeting of specific cancer-associated genes.

Modern-day cancer diagnostics are based on the cumulative knowledge gained from large-scale cancer genomics

Fig. 47.11 Bioinformatics pipeline. The analysis of data from massively parallel sequencing can be broadly considered to occur in three phases. *Primary analysis:* The raw output (e.g., optical or electronic signals) from the sequencing instrument is transformed into data that describe the individual bases of DNA as well as the quality and confidence of the base call at each position. These reads of DNA are assembled into a FASTQ data file. *Secondary analysis:* The data file is then assembled onto a reference sequence. For human DNA sequencing, this is typically a reference genome such as *GRCh38*. If the fragments of DNA were prepared by randomly sheared fragments, then the sampling of a wide diversity of fragments improves quality and is ensured by sequencing that is from exact duplicates. When the fragments are assembled against the reference genome, the quality of each of the base calls at specific nucleotide positions can be determined. The variant at each position is then determined and reported in a single variant call format file (VCF). *Tertiary analysis:* The variants are then queried against multiple databases that have information on population frequency and clinical significance. Based on these queries, the variants can be prioritized in terms of importance to the given scientific question or clinical scenario. (Modified from Oliver, G. R., Hart, S. N., & Klee, E. W. [2015]. Bioinformatics for clinical next generation sequencing. *Clinical Chemistry*, 61, 124–135.)

discovery efforts. These studies of tens to thousands of cancers across many tissues of origin have cataloged the genomic landscape of human cancers by MPS and often include data from RNA expression and DNA methylation.

BOX 47.3 Phred Quality Score (Q Score)

In the 1990s, Phil Green at the University of Washington developed software to automatically read the fluorescent sequence chromatograms generated from Sanger sequencing. The original software, **Phred** (Phil's read editor), used the following basic parameters:

1. Find the predicted location of peaks.
2. Find the observed location of peaks.
3. Match predicted and observed peaks.
4. Find missing peaks.

A component of Phred was an estimator of the error probability of a base call. A quality value (Q score) was generated from the formula:

$$q = -10 \times \log_{10}(p)$$

q = quality value

p = estimated error for a base call

Some representative examples of quality value (q) scores: Q score of 30 (Q30): The probability (P) is 1/1,000 of being incorrect.

Q score of 20 (Q20): The probability (P) is 1/100 of being incorrect.

Q score of 10 (Q10): The probability (P) is 1/10 of being incorrect.

Although massively parallel sequencing does not generate a Sanger sequencing type of chromatogram, the convention of a Phred Q score is still used to calculate the quality (and accuracy) of a sequenced base. Under ideal conditions, current massively parallel sequencing can achieve more than 90% of bases at Q30.

Sampling and Preservation Methods for Solid Tumor Genomics

Solid tumors can be sampled using either fine-needle aspiration or core biopsy procedures. These are often done in advance of surgery or in patients with unresectable tumors as determined by imaging to provide a sample for pathology-based examination and diagnosis. Fine-needle aspiration (using a 21- to 25-gauge needle) generates a minimal amount of tissue consisting of a few tumor cells in a fluid that is coaspirated into the needle. Core biopsies (using an 18- to 21-gauge needle) can obtain intact and solid cores from the tumor mass. If imaging is used to guide the biopsy needle to the tumor mass, several passes are made for better sampling. Alternatively, in patients with resectable cancer, the tumor mass is removed at surgery and may be preserved in bulk or sampled with core needle biopsies.

Tissue fixation by soaking in formalin or formaldehyde stabilizes cellular proteins and preserves tissue structure for microscopic examination. Subsequent embedding in paraffin wax creates an impervious, room temperature-stable substrate that can be cut for subsequent characterization and diagnosis. However, formalin cross-links proteins to cytosine residues in DNA and RNA. Subsequent oxidation results in breaks in the nucleic acid sugar-phosphate

backbone, thereby degrading the nucleic acids. Because diagnostic assays of solid tumors include nucleic acids, alternative preservatives and preservation methods are now being developed. These methods include flash freezing tissue at -80°C (in a dry ice acetone bath) or immersion in nucleic acid stabilizers.

Staining and Selection of Tumor Cells

A hematoxylin and eosin stain (H&E) is often used to identify tumor and normal cells in a tissue section under a light microscope and to estimate the percentage of tumor nuclei present. Because solid tumors are a mixture of tumor cells and various normal cells, this estimate of tumor “cellularity” indicates how tumor-rich the sample is relative to other needle biopsies or other portions of the bulk tumor. Tumor features such as necrotic areas may be also identified in the microscopic evaluation. In sections with evident necrosis, a process of macrodissection to cut away the nonnecrotic sections for subsequent nucleic acid isolation can be used. In tumor types such as prostate and pancreatic adenocarcinomas, there is a low proportion of tumor nuclei relative to the surrounding normal cells (e.g., stroma and immune cells). In these tumor types, laser capture microdissection can be used to isolate tumor cells from surrounding normal cells before nucleic acid isolation in order to enhance the yield of tumor-derived nucleic acids.

Cancer Is a Genomic Disease

Although we have known for many decades that cancer’s origins lie in changes to the cellular genome, only recently have technologies become available to profile the mutations in genes. Initial gene cloning efforts in the early 1980s identified the chromosomal locations and sequences of many oncogenes and tumor suppressors in the human genome. The decoding of the human genome opened the door to genome-wide studies of cancer. For example, learning the sequences of human genes enabled the construction of microarrays to query RNA expression in tumors. By using advanced bioinformatic analysis approaches (e.g., clustering algorithms), similarities and differences in **gene expression** across tumors of a single tissue type (e.g., lung adenocarcinoma) were revealed. Clusters of gene expression correlated with other pathology-based categories revealed subtypes within a given cancer, such as the intrinsic subtypes of breast cancer. Similarly, SNP microarrays can be used to identify chromosomal aberrations by comparing normalized signal strength between tumor and normal DNA. Research-based inquiries of cancer genomes with rich clinical data such as information regarding treatments and outcomes have led to the clinical utility (diagnosis, prognosis, treatment decisions) of the resulting classifications.

The first application of MPS to decode a cancer genome compared the WGS data from a bone marrow aspirate of a patient’s AML to a matched normal skin sample. This comparison identified several somatic point mutations that were unique to the tumor genome and were termed single nucleotide variants, or SNVs, to distinguish them from constitutional

SNPs. The second WGS case published was also on a single patient’s AML sample; it revealed an unexpected somatic mutation in the gene *IDH1* (a metabolic enzyme in the glycolytic pathway). This *IDH1* mutation was then characterized as a recurrent mutation in a panel of 188 AML samples and also associated with a poor prognosis. From these single-patient beginnings, the field of cancer genomics has exploded to characterize tens of thousands of cases across the predominant adult and pediatric cancer types.

Large-Scale Discovery Efforts

One consequence of rapid, high-throughput, and inexpensive sequencing has been the production of large data sets that explore the mutational, transcriptional, and methylation landscape of thousands of tumors representing major human cancer types. Examples of these large-scale discovery projects include The Cancer Genome Atlas (<http://cancergenome.nih.gov>), the International Cancer Genome Consortium (<https://icgc.org>), the Pediatric Cancer Genome Project (<http://www.pediatriccancergenomeproject.org/site>). Unexpectedly, many commonly mutated genes were identified in multiple tumor types and different tissue sites had widely different mutational burdens. New classes of genes—including those involving the spliceosome complex, cellular metabolism, and DNA packaging in histones—were identified that contained previously unknown mutations. Many of these mutations discovered by genomic methods have yet to be functionally studied to determine their effects on the resulting protein.

Meta-analyses of these catalogs were pursued, further reinforcing the similarities and differences between tissue sites by virtue of integration across various “omic” data sets. The similarities, in particular, challenged long-held notions about tissue site specificity of therapeutic approaches and introduced the concept that oncogenic “drivers” present in cancers from different tissues could respond similarly to targeted therapeutic interventions. The impact of gene alterations on protein function results in activated or repressed cellular pathways. Hence cancer is a disease of pathway alterations rather than a specific gene and/or protein alteration, and therapeutic decision making should occur using this framework.

Cancer “Hot Spot” Characterization

The discovery of oncogenes and their activating mutations (also known as “hot-spot” or “gain of function” mutations) emerged from gene cloning efforts in the 1980s and 1990s. By combining PCR and sequencing, mutations in these hot spots could be detected in a few days’ time. The clinical usefulness of hot-spot characterization to identify a drug target arose from studies of patients with lung cancer who carried mutations in the tyrosine kinase domain of the epidermal growth factor receptor (*EGFR*) gene and who responded to a new class of targeted therapies called tyrosine kinase inhibitors. The correlation of these mutations to treatment response initiated a paradigm in which the clinical assay for hot-spot mutations became the companion diagnostic for the targeted therapy.

MASSIVELY PARALLEL SEQUENCING OF SOLID TUMOR SAMPLES

Clinical assays of solid tumors using MPS to identify somatic mutations in multiple genes (“gene panels”) or in exomes have been developed because (1) large-scale, MPS-based discovery efforts have identified mutated genes in the major adult and pediatric cancers; (2) specific genes and/or mutations have been studied in clinically annotated sample sets and their mutational status correlates with outcome; and (3) novel small molecule- and antibody-based targeted therapies have been developed to address specific somatic alterations; therefore the mutational profile of a patient’s somatic genome can indicate a therapy based on predicted gene-drug interactions.

Although testing multiple genes from a single tumor DNA isolate could be accomplished using combinations of individual clinical assays to evaluate individual gene and/or hot-spot mutation status, often tumor material is limited owing to the size of a biopsy and the need to use the material for other, more conventional pathology assays. Hence MPS-based assays make more efficient use of diagnostic material, especially when so many genes that are potentially mutated can provide important information regarding patient care.

Because of the heterogeneity of solid tumors and the increasing knowledge that certain mutations in genes, if present at low levels in the tumor cell population, can predict early onset of acquired resistance to targeted therapies, MPS-based assays must provide a high depth of tumor sequence coverage for each gene in the assay. High coverage can be defined as 300- to 1000-fold read depth and can be challenging to obtain when MPS libraries are constructed from low amounts of input DNA. In general, with 500-fold or higher coverage, mutations can be detected even from samples with low percentage tumor cellularity (10% to 20%), but detecting low-prevalence mutations becomes less likely with decreasing tumor cell percentages. High coverage is also important to attain because not all probes capture complementary sequences with the same avidity. When this deficiency is combined with representation bias from MPS processes downstream of capture, lowered coverage at certain sites may result. Hence higher coverage overall may reduce or eliminate low and/or no coverage sites, thereby reducing the incidence of false-negative results, wherein a mutation is missed due to lack of coverage.

Whole Genome Sequencing

Ideally the most unbiased characterization of each cancer sample by MPS-based methods should be pursued to optimize the likelihood of identifying all drug-targetable portions of the genome. This is best accomplished using WGS, which can deliver the totality of point mutations, small insertions and deletions, structural variants (including copy number alterations), and other large chromosomal rearrangements in a tumor-to-normal genome comparison. However, WGS is seldom performed as a clinical assay for several reasons. First, the genome is very large, and although new MPS instrumentation can produce the data rapidly (up to 30-fold coverage

for 48 human genomes in 2 days), the postsequencing efforts to analyze a whole genome comparison of tumor tissue to matched normal tissue and compile a clinical report is in conflict with the time frame needed to inform the oncologist’s decision-making process (2–4 weeks). Second, owing to the need for high coverage of the tumor genome, generating the necessary 100-fold or higher WGS coverage needed for confident variant detection remains prohibitive in terms of cost. Third, most of the somatic variants will be uninterpretable in terms of their impact on tumor progression because they will lie outside of genes. Fourth, many variants in the coding sequences will not be interpretable in terms of their impact on the protein’s function as a potential driver of disease development (i.e., gain or loss of function).

Enrichment by Hybridization Capture

Locus-selective or hybridization capture methods use synthetic probes designed to hybridize to human loci and/or genes of interest as a means of selectively isolating sequences from a whole human genome library. MPS of the captured sequences is followed by alignment of the reads to the genes of interest for mutational analysis. Depending on the assay, either a select set of genes or hot spots, or the exome, can be captured. As the number of loci assayed by this approach increases, so do both the analysis time and the complexity of the mutational signature. The decision to include drug-targetable genes that carry novel, noncanonical mutations with untested drug interactions is one challenge that can arise in producing the clinical interpretation of these assays.

Enrichment by Multiplex Polymerase Chain Reaction

Because hybrid capture works best when many genes are analyzed, multiplex PCR is often used when the number of targets is low. In this type of assay, careful design of PCR primer pairs that target the selected loci for mutation detection achieves the coincident amplification of all loci in a single reaction. Multiplex PCR has the distinct advantages of (1) selectively amplifying smaller target regions of the genome below that which is optimal for selective hybridization capture, (2) requiring only 5 to 10 ng of DNA for the PCR, and (3) focusing mutation detection on a relatively small portion of the genome in an efficient manner. These assays are also relatively inexpensive to perform, and by post-PCR addition of DNA barcoded linkers for MPS, they can be multiplexed with other patients onto a single sequencing instrument run. There are obvious limitations to multiplex PCR that include (1) the ability to design PCR primers with similar T_m , uniqueness and lack of interprimer complementarity to diminish amplification artifacts (e.g., primer dimers, hybrid amplicons) and (2) the presence of pseudogenes and highly conserved regions of gene families may preclude unique amplification of specific gene sequences. PCR primers are often designed with formalin-fixed paraffin-embedded (FFPE)-associated degradation in mind to produce small products of less than 100 bp; therefore, these require a large number of primers to cover a large gene, which further complicates the design process and/or

complicates obtaining complete coverage from the resulting amplicons. Despite the limitations, multiplex PCR assays are widely used in the clinical testing of solid tumors.

Ribonucleic Acid Sequencing of Solid Tumor Isolates

RNA isolates from cancer samples can be assayed using MPS technologies—with a variety of preparatory methods generally referred to as RNA-seq—by converting the RNA to DNA by reverse transcription before library construction. Reasons to assay transcribed genes in a solid tumor include the following: (1) DNA sequencing assays do not reflect higher order changes in the tumor genome, such as methylation or chromatin packaging, that can influence the amount of RNA produced from a gene; (2) in high-mutation-load tumors such as melanomas and lung squamous or adenocarcinomas, RNA-seq can indicate which of the thousands of mutations identified from DNA sequencing assays are actually being transcribed and could therefore be targeted with a specific therapy; (3) alternatively spliced transcript (isoform) expression can be detected only at the level of RNA and may be important in a diagnostic, prognostic, or therapeutic context; and (4) predicted gene fusions from DNA assays can be verified by the presence of the predicted fusion transcript in the RNA-seq data. RNA is an unstable molecule, and preservation techniques such as FFPE degrade RNA more noticeably than DNA. Despite the disadvantages of RNA as an analyte, RNA-seq is emerging as a clinical tool for identifying gene fusions in cancer.

Interpreting Somatic Alterations in a Clinical Context

The use of MPS-based solid tumor diagnostics is increasing across clinical laboratories, both commercial and academic. This is largely due to the increasing knowledge of somatic alterations in cancers, the increasing numbers of targeted therapies designed to interact with known cancer-relevant alterations, and the demands of patients and oncologists to add this information to the evidence being considered in determining the treatment regimen. Progress in this area is confounded by the need to relate somatic alterations to other clinical data, such as the diagnosis of a specific tumor type or subtype, the range of possible patient outcomes, and therapeutic response. Additional studies of the functional impact of a somatic alteration, how that functional impact may contribute to the onset or progression of the cancer, or how and/or whether the alteration interacts with a variety of potential therapies based on putative drug–gene interactions are often needed. Drug studies typically involve preclinical testing in cell lines or other disease models, followed by clinical trials that require a year or more to compare patient outcomes when patients carrying the gene alteration(s) are treated with a specific therapy as compared with patients treated with the standard of care. In essence, there is often a significant delay between the research-based discovery of a somatic alteration and when its full clinical implication can be established. The clinical sequencing pipeline and how to determine which of

the identified mutations in a cancer biopsy should be evaluated further in terms of their prognostic, diagnostic, or therapeutic value is an area of active investigation. Publicly available curated cancer mutation databases permit look-up of known cancer genes and mutations and offer prognostic, diagnostic, and therapeutic information. These include TARGET (www.broadinstitute.org/cancer/cga/target) and CIViC (www.civicdb.org), cBioportal, and GENIE.

Prognostic Interpretation

Understanding the prognostic or outcome-related value of a specific gene alteration depends on the prevalence of the disease, the time to establish outcome, the specific outcome measure, and the uniformity of patient care in each group. The time to establish outcome can vary widely; for example, patients with lung squamous cell carcinoma or glioblastoma typically present with metastatic disease or progression in 6 to 18 months after a primary diagnosis, whereas ER+ breast cancer may relapse after 15 to 20 years. The defined outcome may be overall survival, disease-specific survival, complete pathologic response, or other response metrics. Some examples of tumors where mutations provide prognostic information include gliomas as well as colorectal, endometrial, and ovarian cancers.

Diagnostic Interpretation

Multigene capture panels that detect alterations in known cancer susceptibility genes such as *TP53*, *APC*, *BRCA1/2*, and others in germline DNA can be used to identify inherited cancer susceptibility. Diagnostic characterization of solid tumor DNA based on somatic alterations is taking on increased significance owing to the availability of targeted therapies that correspond to these somatic (or germline) alterations. Non-small cell lung cancers, especially adenocarcinomas, perhaps provide the richest example of sequencing-based diagnosis and therapeutic option guidance among the solid tumors. In 2012, the spectrum of genomic alterations in genes that drove the development of non-small cell lung adenocarcinomas encompassed approximately 50% of the disease, of which approximately 40% were therapeutically targeted (Fig. 47.12). Increasingly, a gene panel assay is pursued to sequence these genes or gene fusions, and can indicate one or several targeted therapies that represent the first line of therapy. This paradigm shift represents a remarkable transition in medical practice over just a 10-year period from when lung adenocarcinoma mutations that predicted response to tyrosine kinase inhibitors were first described and is indicative of the directions in diagnostic molecular pathology for other solid cancers. However, there are several challenges to this paradigm that merit further discussion.

Challenges of Variants of Uncertain Significance

As somatic gene panel assays expand to generate sequence data across the length of each gene rather than from focused hot spots, more variants are identified. In particular, the resulting breadth of variant discovery permits the detection of variants for which no clear indication of response for a

Fig. 47.12 Molecular subsets of lung adenocarcinoma. The clinically important driver mutations and fusions identified to date from molecular studies of lung adenocarcinoma. The width of the chart wedge for each driver event corresponds to its percentage distribution in the disease. (Reprinted by permission from Macmillan Publishers Ltd. From Pao, W., & Hutchinson, K. E. [2012]. Chipping away at the lung cancer genome. *Nature Medicine*, 18, 349–351.)

given therapeutic indication might be available. These variants of uncertain significance (VUS) raise issues with regard to whether the result should be reported because the therapeutic indication is uncertain. Although basic science experiments may eventually characterize the functional impact of all variants in all cancer-related genes, most molecular pathology groups that are conducting selective hybridization capture panel assays of cancers are instead developing local databases to catalog VUS in an effort to initially provide a record of whether the variant has been seen in previously completed assays. Over time, data mining of electronic medical records for patients with variants, targeted therapy, and response data may transition VUS to therapeutic indications.

Challenges of Off-Label Indications

The current process for clinical trials of new therapies in cancer toward approval by the US Food and Drug Administration (FDA) rests on a paradigm in which trials compare each new therapy in a specific tumor type to the standard of care. Hence, cancer therapies are tested and approved in a disease site-specific manner. By contrast, cancer genomics efforts have demonstrated that known cancer-initiating gene alterations occur in multiple disease and/or tissue sites. This fact, in turn, raises the possibility that a given targeted therapy might be effective for multiple solid tumor types that all carry the same somatic alteration. There is support for multiple-tissue-site therapeutic effectiveness, including the FDA-approved use of the kinase inhibitor imatinib (Gleevec) in both chronic myeloid leukemia

targeting *ABL* kinase and gastrointestinal stromal tumors targeting *KIT*. Another example is EGFR-targeting therapies with FDA approval for use in lung adenocarcinomas, head and neck squamous cell carcinomas, and colorectal cancers with somatically altered *EGFR*. These approved tissue sites each required a separate series of clinical trials to gain FDA approval. However, in solid tumor assays with gene panels, off-label indications will arise due to the shared nature of cancer-initiating mutations across different tissue sites. This challenge occurs when a gene with a functional mutation is detected that indicates a therapy not yet approved in the specific tissue site of origin.

TRENDS IN CANCER GENOMICS

Solid tumor gene-based assays are in a dramatic transition to multigene testing. This trend is driven by (1) the increasing use of selective hybridization capture or other targeting approaches coupled with MPS, (2) the discovery of somatic alterations in the genomes of cancer cells, and (3) the emerging number of targeted therapies that address specific cancer-initiating genes or gene families. The comprehensive nature of multigene assays creates specific challenges, mainly due to the impedance mismatch between cancer mutation discovery and the functional characterization of those alterations that either contribute to the development and progression of cancer or do not contribute to it. The need to accelerate testing of new therapeutics across multiple tissue sites at once is slowly being addressed by new clinical trial designs to identify the most effective therapies for a given gene, alteration, and tissue site. Ultimately the widespread use of multigene testing for cancer diagnosis, prognosis, and therapeutic decision making rests on the demonstration of clinical utility and clinical benefit, which are established for some tissue sites but as yet not for all.

POINTS TO REMEMBER

- Gene expression microarrays were initially used to characterize large numbers of human cancers.
- Cancer gene cloning efforts and the completed Human Genome Reference Sequence enabled the use of PCR and sequencing efforts to catalog cancer mutations.
- Massively parallel sequencing enables the identification of somatic alterations in targeted gene panels in all known genes or the whole genome.

SUMMARY

The field of molecular diagnostics is an important and exciting area that is going to have an even greater impact on medicine in the future. As an increasing number of diseases are characterized at the molecular (e.g., nucleic acid and protein) level, new therapeutics and diagnostics specifically targeting these molecular changes will continue to emerge.

REVIEW QUESTIONS

1. The number of human proteins is greater than the number of genes because
 - a. alternative splicing and posttranslational modifications occur.
 - b. of the 3' polyadenylation of mRNA.
 - c. only some genes are expressed.
 - d. the ribosome adds additional noncoded amino acids to some mRNAs.
2. How much of the human genome is transcribed into RNA?
 - a. 0.1%
 - b. 1%
 - c. 10%
 - d. 80% to 100%
3. If there were only 12 amino acids in proteins, what would be the minimal length of nucleotides needed for a complete genetic code?
 - a. 1
 - b. 2
 - c. 3
 - d. 4
4. The number of DNA bases in a human cell is about
 - a. 3 billion
 - b. 6 trillion
 - c. 20,000
 - d. 64
5. How would the sequence GAATATGCCAGCATATTAG translate?
 - a. MetProAlaTyr
 - b. GluTyrAlaSerIle
 - c. It would not translate because the number of bases is not divisible by 3.
 - d. It would not translate because it will not be transcribed.
6. Nucleotides that encode protein account for what percentage of the genome?
 - a. 1%
 - b. 10%
 - c. 50%
 - d. 90%
 - e. 8%
7. What approximate percentage of the human genome comprises transposable elements?
 - a. 1%
 - b. 10%
 - c. 20%
 - d. 30%
 - e. 40%
8. When massively parallel sequencing generates data with a Phred quality score of Q20, the probability of being incorrect is which of the following?
 - a. 1 in 10
 - b. 1 in 100
 - c. 1 in 1000
 - d. 1 in 10,000
 - e. 1 in 100,000
9. What is the correct nomenclature for the variant in the following sequence if the base in *blue boldface text* is converted to a C? Hint: The sequence includes the initiation codon of the gene.
ACAGCATAGCATATGACGCATCAGCACATT
 - a. GRCh37/hg19 g.32335623
 - b. p.W4A
 - c. c.12G > C
 - d. c.-7G > C
 - e. p.T12P
10. Hydrogen bonding between which DNA elements is required for most molecular diagnostic assays?
 - a. Bonds between ribose sugars on different nucleotides of a strand of DNA
 - b. Bonds between ribose and nucleotide bases
 - c. Bonds between two cysteine residues
 - d. Bonds between the complementary nucleotide bases
11. What nucleotide base is methylated in DNA and at what specific location?
 - a. Adenine and polyadenylation
 - b. Guanine and RNA transcription start site
 - c. Thymine and the production of thymine dimers
 - d. Cytosine and upstream CpG islands
12. Mutations can be generated by incorporating the wrong base into DNA during replication, and the mechanism to repair this error is
 - a. mismatch repair
 - b. nucleotide excision repair
 - c. base excision repair
 - d. homologous recombination repair
13. The structure of a human mRNA encoding gene generally contains promoters that are upstream from the transcriptional start site; however, there are other promoters that can be both upstream and downstream of the gene. Which of the following is one of these promoters?
 - a. The TATA box
 - b. The polyadenylation site
 - c. The enhancer
 - d. The proximal core promoter
14. An important group of DNA modification enzymes, the restriction endonucleases, are used to manipulate DNA fragments. What is their function in the organisms from which they are isolated?
 - a. They digest the ends of DNA to prepare them for ligation
 - b. They are used to protect themselves from viral infections
 - c. They are used in the base excision repair found in bacteria
 - d. They are RNA-guided nuclease that can precisely cleave genomic DNA
15. Solid tumors may consist of
 - a. 100% tumor cells
 - b. a mixture of variable proportions of tumor and normal cells

- c. a mixture of blood vessels, tumor, and normal cells of different types
 - d. only chromosomal DNA
16. Cancer is considered a disease of the genome because
- a. cancer cell nuclei contain no chromosomal DNA
 - b. alterations to genes in cancer cells disrupt cellular pathways
 - c. the genome in cancer cells does not express any genes
 - d. the DNA of cancer cells is cross-linked to proteins
17. Multiple gene testing of cancer DNA may determine
- a. tumor cellularity
 - b. mutations in driver genes that predict a response to therapy
 - c. prognostic mutations that predict outcome
 - d. b and c

Molecular Techniques

Carl T. Wittwer, G. Mike Makrigiorgos

OBJECTIVES

1. Define the following:
 - Amplification
 - Hybridization
 - Melting analysis
 - Primer
 - Probe
 - Polymerase chain reaction (PCR)
 - Massively parallel sequencing
 - Real time PCR
 - Hydrolysis probe
 - Hybridization probe
2. Describe the steps involved in the PCR. Reason why a short defined PCR product is produced.
3. State the difference between target amplification and signal amplification.
4. Describe the different ways that fluorescence can be generated during real-time PCR.
5. Describe the differences between transcription mediated amplification (TMA) and the PCR.
6. Describe how digital PCR is different from regular PCR.
7. Detail the steps required for massively parallel sequencing using reversible terminators.
8. Describe one method for direct quantification of nucleic acids without amplification.
9. Detail how to perform high-resolution melting analysis.
10. Describe the kind of controls needed for the PCR.

KEYWORDS AND DEFINITIONS

Adapter Oligonucleotides that are ligated to library fragments in order to provide consensus priming sites.

Allele-specific PCR A version of polymerase chain reaction (PCR) in which only one allele at a locus is amplified. Specificity is achieved by designing one or both PCR primers so that they overlap the site of sequence variance between alternative alleles.

Asymmetric PCR A version of PCR that preferentially amplifies one strand of the target DNA.

cDNA Complementary DNA, usually refers to the DNA formed by reverse transcription; that is, DNA that is complementary to the original RNA.

Comparative genomic hybridization A technique in which reference and test DNA are respectively labeled with green and red fluorochromes. Abnormalities are detected by changes in the green-to-red ratio.

Deoxyribonucleoside triphosphates (dNTPs) Usually dATP, dCTP, dGTP, and dTTP; the building blocks of DNA.

Dideoxy-termination sequencing (Sanger sequencing) A method of DNA sequencing based on the selective incorporation of chain-terminating dideoxynucleotides by DNA polymerase during in vitro DNA replication.

Digital polymerase chain reaction (digital PCR or dPCR) A modification of PCR with the sample separated

into many partitions so that some partitions have no template (0) and others have one or more (1).

DNA microarray An array of microscopic spots of different DNA molecules attached to a solid surface. Also known as DNA chips or biochips.

Electrophoresis Movement caused by an electrical field, often through a gel matrix. Polyacrylamide and agarose are common matrices used to separate DNA and RNA under an electric field.

Flow cytometry A technique for counting cells or particles suspended in fluid as they flow one at a time past a focus of exciting light.

Fluorescence A physical property of some molecules to emit light at a longer wavelength when excited at a shorter wavelength.

Fluorescence in situ hybridization (FISH) A genetic mapping technique using fluorescent tags for analysis of chromosomes and genetic abnormalities. FISH can also be referred to as chromosome painting.

Heteroduplex A DNA duplex with internal mismatches or loops.

High-resolution melting analysis (HRMA) A simple method for genotyping that compares fluorescence against temperature using a dye that detects double-stranded but not single-stranded DNA.

Homoduplex A perfectly matched DNA duplex.

Hybridization The annealing or pairing of two DNA strands.

Insert Part of the original DNA that has been fragmented before ligation to adapters.

Loop-mediated isothermal amplification (LAMP) A single tube technique for the amplification of DNA that uses a single temperature incubation.

Massively parallel sequencing (MPS) Sequencing of many fragments of DNA simultaneously.

Melting temperature (T_m) The temperature at which half of the DNA strands are in the duplex form.

Multiplex ligation-dependent probe amplification (MLPA) A variation of the multiplex PCR that assesses the copy number of several targets by permitting multiple targets to be amplified with only a single primer pair.

Oligonucleotide A short single-stranded polymer of nucleic acid.

Oligonucleotide ligation assay (OLA) A technique for determining the presence or absence of a specific nucleotide pair within a target gene, often indicating whether the gene is wild type (normal) or mutant (defective).

Polymerase chain reaction (PCR) An in vitro method for exponentially amplifying DNA.

Primer An oligonucleotide that serves to initiate polymerase-catalyzed addition of nucleotides by annealing to a template strand.

Probe A nucleic acid used to identify a target by hybridization.

Pyrosequencing A method of DNA sequencing based on the “sequencing by synthesis” principle that relies on the detection of pyrophosphate release on nucleotide incorporation.

Read The nucleotide sequence inferred by sequencing of a template.

Real-time PCR Observation of PCR during amplification at least once each cycle.

Restriction fragment length polymorphism (RFLP) A genetic polymorphism revealed by changes in the sizes of DNA fragments after restriction enzyme digestion and electrophoresis.

Rolling circle amplification (RCA) A probe amplification method with a linear probe that is ligated to form a circle in the presence of template. The circle is replicated continuously by a polymerase and one or more primers.

Sanger sequencing See dideoxy-termination sequencing.

Single nucleotide variant (SNV) Any change in a nucleic acid that involves only a single base, including substitutions and single base insertions/deletions. Favored over the related term “single nucleotide polymorphism” (SNP) and not limited to variants present at a frequency of greater than 1% as is SNP.

Strand displacement amplification (SDA) An amplification technique that uses two types of primers, DNA polymerase, and a restriction endonuclease to exponentially produce single-stranded amplicons asynchronously.

Transcription-mediated amplification (TMA) An amplification method that uses RNA polymerase and DNA reverse transcriptase to produce RNA amplicon from a target nucleic acid. TMA is used to amplify both RNA and DNA.

Whole-genome amplification (WGA) A nonspecific amplification technique that produces an amplified product representative of the initial starting material (whole genome).

The expansion and power of molecular diagnostics is enabled by techniques that modify, amplify, detect, discriminate, and sequence nucleic acids (NAs). Molecular diagnostic techniques are getting faster, better, and less expensive as a rapidly progressing and highly competitive field, both in academics and in industry. This growth is reflected in the number of publications in molecular diagnostics in recent years (Fig. 48.1). In this chapter, our intent is to focus on understanding the mechanisms of NA techniques in use today.

We begin by considering the amplification techniques that are often necessary to observe or quantify NA sequences of interest. Next, the tools used to detect or visualize NAs are discussed, along with methods that allow identification, quantification, and segregation of individual NA species. Finally, we end with the extraordinary power of **massively parallel sequencing (MPS)**.

NUCLEIC ACID PREPARATION

Conventional NA testing requires (1) isolation of DNA, RNA, or both from the clinical sample; (2) amplification of the NA; and (3) detection, analysis, or quantification. Sometimes one step can be eliminated or two steps can be combined, depending on the sample type and quantity of the target. In addition to NA isolation, sometimes it is necessary to prepare samples for amplification or analysis by enzymatic or nonenzymatic means. For example, the enzyme reverse transcriptase may be needed to convert RNA to DNA. MPS usually requires library preparation.

Bisulfite treatment of DNA is often used to analyze the methylation status of cytosine (C) residues in DNA. Sodium bisulfite (NaHSO_3) converts C into uracil (U), but does not affect 5-methylcytosine. DNA polymerases used for amplification will

Fig. 48.1 Molecular diagnostics publications, 1970 to 2013. (Reprinted with permission of the publisher from Chiu, R. W. K., Lo, Y. M. D., & Wittwer, C. T. [2015]. Molecular diagnostics: A revolution in progress. *Clinical Chemistry*, 61, 1–3. Copyright 2015 AACCC.)

recognize 5-methylcytosine as C (no change), but an unmethylated C is converted to U by the bisulfite and will be recognized as a T (sequence change of C to T). One limitation of bisulfite treatment is significant degradation of DNA. Depending on the protocol, as much as 90% of the DNA can be lost.

AMPLIFICATION TECHNIQUES

Molecular diagnostics requires techniques to detect extremely low concentrations of NAs in a background of complex genomic structure. Achieving sensitive detection is a central concern for clinical applications of NA analysis. Techniques that increase the amount of the NA target or the detection signal are referred to as *amplification methods*. Examples of amplification methods are listed in Table 48.1 and the Points to Remember box. In *target amplification*, a well-defined segment of the NA (the target sequence) is copied many times. Areas outside the target are not amplified. In *signal amplification*, the amount of target stays the same, but the signal is increased. Amplification techniques often can achieve more than a million-fold amplification in less than 1 hour.

Polymerase Chain Reaction—Target Amplification

When the amount of target NA is increased by synthetic in vitro methods, target amplification occurs. **Polymerase chain reaction (PCR)** is the best known and most widely

POINTS TO REMEMBER

Nucleic Acid Amplification Methods

- May amplify the target, the signal, or the probe
- May be isothermal or cycle through different temperatures
- Cycling speed is limited by instrumentation, not biochemistry
- May be analyzed on gels or in real time
- May be qualitative, quantitative, or digital
- Require positive and negative controls

TABLE 48.1 Common Amplification Techniques

Techniques	Type	Enzymes Required
Polymerase chain reaction (PCR)	Target	DNA polymerase (thermostable)
Transcription-mediated amplification (TMA)	Target	Reverse transcriptase, RNA polymerase, RNase H
Strand displacement amplification (SDA)	Target	<i>HincII</i> , DNA polymerase I (5'-exo-deficient)
Loop-mediated amplification (LAMP)	Target	DNA polymerase
Helicase-dependent amplification (HDA)	Target	Helicase, DNA polymerase
Recombinase polymerase amplification (RPA)	Target	Recombinase, single-strand binding protein, polymerase
Whole-genome amplification (WGA)	Target	Φ 29 DNA polymerase
Antisense RNA amplification (aRNA)	Target	T4 DNA polymerase, Klenow, S1 nuclease, T7 polymerase
Branched DNA (bDNA)	Signal	Alkaline phosphatase
Rolling circle amplification (RCA)	Probe	Φ 29 DNA polymerase

applied of the target amplification methods. Because of the commercial availability of thermostable DNA polymerases, kits, and instrumentation, this method has been widely adopted in research and is routinely used in the clinical laboratory.

Polymerase Chain Reaction Process

PCR requires (1) a thermostable DNA polymerase, (2) deoxynucleotides of each base (collectively referred to as **deoxyribonucleoside triphosphates [dNTPs]**), (3) a DNA strand that includes the sequence to be amplified, and (4) a pair of **oligonucleotides** (referred to as **primers**) that are complementary to opposite strands that define the target sequence. In the first step, target duplexes are denatured into single strands by heat (Fig. 48.2). When the mixture is cooled, primers provided in great excess (usually over 1 million times the concentration of the initial target) specifically anneal to complementary sequences on the target. After the primers are annealed, the action of the polymerase synthesizes two new DNA strands by extending each of the two primers at their 3' end. The primers are designed to recognize sequences of the target that are close enough together such that the polymerase extends each strand far enough to include the priming site of the other primer. Usually, the optimal temperature for polymerization (or DNA synthesis) is an intermediate temperature between the annealing temperature (at which primer hybridizes to its target) and the denaturation temperature (at which the newly generated DNA strand dissociates from its

Fig. 48.2 Simple schematic of the polymerase chain reaction. Amplification of the initial template requires denaturation by heat, allowing primers to anneal at a lower temperature, followed by primer extension at an intermediate temperature. In each cycle, a doubling of the DNA product occurs. After 20 to 40 cycles, the product accumulates more than 1 million-fold.

template). The second cycle also begins with denaturation, but now twice as many strands (the original genomic DNA and the extension products from the first cycle) are available for primer annealing and subsequent extension. Temperature cycling (typically) uses three temperatures: (1) a high temperature sufficient to denature the target sequence, typically 90°C to 97°C but can be lower depending on the **melting temperature** of the product; (2) a low temperature that allows annealing of the primers to the target, typically 50°C to 65°C; and (3) a third temperature, which is optimal for polymerase extension, typically 65°C to 75°C.

Repetitive thermocycling results in the exponential accumulation of the short product (consisting of primers and all intervening sequences). If the efficiency of each cycle is perfect, the number of target sequences doubles each cycle (the efficiency is 100% or 1.0). PCR efficiency depends on the primers, the temperature-cycling conditions, and any inhibitors that might limit amplification. Amplified products accumulate exponentially in the beginning cycles of PCR. At some point, however, the efficiency of amplification falls and eventually the amount of product plateaus (**Fig. 48.3**) as the result of exhaustion of the components or competition between the primer and the product annealing (i.e., the single strands of the product are at such high concentrations that they anneal to each other rather than to the primers). The S-curve shape is similar to common models of population growth. In a typical PCR using 0.5 $\mu\text{mol/L}$ of each primer, the maximum DNA concentration typically achieved is about 100 billion copies/ μL .

With the addition of reverse transcriptase, RNA targets can be converted into **cDNA** and then successfully amplified. Reverse transcription and DNA amplification are most often catalyzed by two different polymerases. In one-step reverse transcriptase PCR (RT-PCR), both enzymes are present in a common buffer, and typically PCR primers are used for both reverse transcription and DNA amplification. Some thermostable enzymes have both DNA polymerase and reverse transcriptase activities so that both steps can be

DNA amplification

Fig. 48.3 Exponential and logistic curves for DNA amplified by polymerase chain reaction (PCR). Starting with only one target copy, it takes 46 cycles to amplify the target to saturation when the doubling efficiency is 100% (Modified with permission of the publisher from Wittwer, C. T., Kuskawa, N. [2004]. Real-time PCR. In D. H. Persing, F. C. Tenover, J. Versalovic, [Eds.], *Molecular microbiology: diagnostic principles and practice* [pp. 71–84]. Washington, DC: ASM Press. Copyright 2004 ASM Press.)

performed in the same tube with the same enzyme. In two-step RT-PCR, the reverse transcription is performed first, usually with random hexamers or a poly-dT oligonucleotide (to prime the poly-A tail of most mRNAs). After reverse transcription, the second PCR step is performed on cDNA with specific primers.

After amplification, the products can be detected by various methods. Gel **electrophoresis** with ethidium bromide staining is a classical method that separates products by size and may suffice for many applications. For fine size discrimination down to a single base, one of the primers can be fluorescently labeled and the post-PCR fragments separated in capillaries on instruments that are typically used for conventional **dideoxy-termination (Sanger) sequencing**. Alternatively, some form of **hybridization** assay can be used to verify or analyze the amplified product. Automated methods are always attractive, and closed-tube methods, in which amplified products are never exposed to the open environment, are particularly advantageous to avoid contamination of future reactions with the products of a prior reaction. Adding a fluorescent dye or **probe** before amplification allows optical monitoring to follow the reaction as it progresses (**real-time PCR**) or after the reaction is complete (endpoint melting) without the need to process the sample for a separate analysis step.

Polymerase Chain Reaction Kinetics

It is natural to think about PCR in terms of three events—denaturation of double-stranded target, annealing of primers

Fig. 48.4 A visual demonstration of polymerase chain reaction (PCR) kinetics. The three phases of PCR (denaturation, annealing, and extension) occur as the temperature continuously changes (A). Toward the end of temperature cycling, the reaction contains single- and double-stranded PCR products. When different points of the cycle (B) are sampled and analyzed, the transition from denatured single-stranded DNA to double-stranded DNA appears as a continuum (C). Progression of the extension reaction can be followed by additional bands appearing between the single- and double-stranded DNA (time points 5 to 7). (Modified with permission from Wittwer, C. T., & Herrmann, M. G. [1999]. Rapid thermal cycling and PCR kinetics. In M. Innis, D. Gelfand, J. Sninsky [Eds.], *PCR applications* [pp. 211–229]. San Diego: Academic Press. Copyright 1999 Academic Press.)

to their targets, and extension of the DNA strand from the primer—that occur at three different temperatures, each requiring a certain amount of time. Indeed, it is common to perform PCR by holding the reaction mixture at three different temperatures (e.g., denaturation at 94°C, annealing at 55°C, and extension at 72°C). Standard thermocyclers that use conical tubes focus on accurate temperature control of the heating block at equilibrium, not on dynamic control of the sample temperature throughout cycling. As a result, sample temperatures are not well defined during transitions, and long cycle times have become standard to ensure that samples reach target temperatures. Reproducibility between instruments and manufacturers is poor, and PCR may require an hour or more to complete 30 cycles of amplification.

The kinetics of denaturation, annealing, and extension suggest that rapid transitions between temperatures with minimal or no pauses (temperature plateaus) provide a better paradigm of PCR amplification (Fig. 48.4). Denaturation, annealing, and extension are very rapid reactions as shown by experiments in capillaries. The use of temperature “spikes” at denaturation and annealing, instead of extended temperature plateaus, allows for rapid cycling with the right instrumentation. The actual time required for PCR depends on the size of the product, but when it is less than 500 base pairs (bp), 30 cycles can be easily completed in 15 minutes.

Initial denaturation of genomic DNA may be required before PCR cycling, depending on how the DNA sample was prepared. Prior boiling of the sample or an initial denaturation step of a few seconds at 95°C to 99°C may be necessary to denature very long strands of genomic DNA. During PCR, however, denaturation of the shorter products occurs very rapidly. Even for long

PCR products, denaturation is complete in less than 1 second at temperatures greater than 3°C above the PCR product T_m .

Product specificity is optimal when annealing times are less than 1 second. Longer annealing times may be required if the primer concentrations are low. The required extension time for each cycle depends on the length of the PCR product. Extension is not instantaneous, although it is much faster than common practice would suggest. Extension rates of typical polymerases under typical conditions are 50 to 100 bases per second. Molecules are fast; people and PCR instruments are slow. By increasing the primer and polymerase concentrations, good PCR can be performed in less than 15 seconds.

PCR products can be as small as 40 bp to over 40 kilobases (kb). To amplify long products, mixtures of polymerases that include some 3'-exonuclease activity to edit polymerase mis-incorporations that lead to base mismatches are usually used. Instead of separate annealing and extension temperatures, both processes can be carried out at the same temperature, resulting in two-temperature, instead of three-temperature, cycling.

Polymerase Chain Reaction Optimization

In addition to temperature-cycling conditions, the specificity of PCR depends on the choice of primers and the Mg^{2+} concentration. Mg^{2+} is a polymerase cofactor and stabilizes the DNA double helix. Low concentrations of Mg^{2+} favor specificity, but high concentrations favor sensitivity.

PCR sensitivity and specificity can be compromised by the formation of unintended low molecular weight artifacts. This process is initiated before PCR, when the primers, template, and polymerase are all together at temperatures below the annealing temperature of the PCR primers. This can be

prevented by limiting the activity of polymerase until the temperature is increased (thus the strategy is often collectively called a *hot start*). One method of hot start involves the use of antibody (or an aptamer) to bind and inactivate the polymerase at room temperature. The binding agent is released upon heating, allowing polymerase extension. Another method uses wax or paraffin to create a physical barrier between the essential components in the reaction. Finally, the polymerase, primers, or dNTPs can be chemically blocked so that extension cannot occur until activated by heat, which usually requires an initial denaturation period of 2 to 20 minutes.

Polymerase Chain Reaction Contamination, Inhibition, and Controls

Because PCR typically produces about 1 trillion copies of the target, a small amount of previously amplified product in a new reaction will result in false-positive results. Thus, minute aerosol droplets contain enough PCR product for robust amplification. PCR products can contaminate: (1) reagents, (2) pipettes, and (3) glassware. Simple laboratory precautions can minimize contamination by using (1) physically separated areas for pre- and postamplification steps, (2) positive-displacement or barrier filter pipettes to minimize aerosol contamination, and (3) prior preparation and storage of individual or combined (“master mix”) reaction components in small aliquots. The most effective way of preventing contamination is to contain the product within a closed tube as in real-time PCR. Even with contamination precautions, a negative control or blank reaction (including all reactants except target DNA) is one of the most important controls for PCR.

One advantage of PCR is that it does not require highly purified NA to achieve a successful amplification. In practice, however, clinical samples may contain unpredictable amounts of impurities that can inhibit polymerase activity. Consequently, to ensure reliable amplification in clinical analyses, some form of NA purification is typically used. The diverse nature of PCR inhibitors within clinical specimens requires demonstration that the sample (or preparation of NA purified from it) will allow amplification. Although such confirmation is automatic with genotyping assays, detection and quantification reactions typically use a control NA sequence different from the target, which is added to the sample (or to NA extracted from the sample). Failure to amplify this process control indicates that further purification of the sample is required to remove inhibitors.

Multiplex Polymerase Chain Reaction and Nested Polymerase Chain Reaction

Multiplex PCR refers to amplifying more than one target simultaneously in the same solution. This can be done by using consensus primers that bind to and amplify more than one bacterial species, for example, ribosomal sequences with high variation internal to the primers, but flanking identical sequence that can be used for consensus primer binding. Usually, however, multiple primer sets are designed for multiple targets and are amplified in the same solution at the

same time. Although potential primer interactions increase exponentially with multiplex PCR, it works surprisingly well most of the time as long as the number of PCR cycles is kept low. If lower primer concentrations are used, the annealing time may need to be increased to maintain efficient annealing. Multiplex PCR can be called “preamplification” if it is followed by an additional amplification reaction.

If PCR is performed with a pair of outer primers and then that PCR product is amplified yet again with a set of inner primers, it is referred to as *nested PCR*. Typically, the first round PCR product is diluted 1000 to 1 million times before the inner (nested) primers are added. The advantage of nested PCR is that both sensitivity and specificity increase. The disadvantage is increased potential for contamination, particularly if the first round of PCR products is handled manually for dilution and transfer. Multiplex PCR followed by nested PCR can be used in a closed-tube system for multiplex detection of infectious agents.

Asymmetric Polymerase Chain Reaction

Conventional PCR uses primers that are present in equal amounts, thereby ensuring that most of the DNA products are double stranded. **Asymmetric PCR** uses different concentrations of the two primers to generate more of one strand than of the other. For instance, the use of one primer at 0.5 $\mu\text{mol/L}$ and the other at 0.005 $\mu\text{mol/L}$ produces mostly ssDNA. However, yield of the product may be low with this technique. With less extreme ratios (e.g., one primer at 0.5 $\mu\text{mol/L}$ and the other at 0.2 $\mu\text{mol/L}$), the yield is mostly preserved, with one strand produced in enough excess to make it readily available for probe hybridization.

Selective Amplification of Sequence Variants by Polymerase Chain Reaction

Allele-specific PCR enables preferential amplification of one genetic allele over another by placing the 3'-end of one primer at the polymorphic site. The variant that is better matched to the primer extends more readily than the other allele. This strategy can be used to distinguish a gene from its pseudogenes and for genotyping **single nucleotide variants (SNVs)**. Allele-specific PCR also can be used to determine haplotypes. In another approach, the minor T_m differences created when single base changes occur on one allele, anywhere along the sequence, can be exploited for preferential amplification of a mutant allele versus a wild-type allele. This strategy is combined with a lower denaturation temperature during PCR and can be used to identify low levels of mutant alleles.

Detection Limits of Polymerase Chain Reaction

When PCR is performed under optimal conditions, a single copy of the target can be detected. In practice, however, the statistical probability of distributing at least a single copy from a dilute template solution into the PCR must be considered. The Poisson distribution indicates that if, on average, one target copy is present per tube, 37% of the tubes will have no target, 37% will have one target, and the remainder will have more than one target. If there is an average of two

copies per tube, approximately 14% of the tubes will have no template and will be false negatives. About three copies on average are necessary for 95% of the tubes to include at least one copy. Therefore, the limit of detection (95% probability) of any single PCR cannot be lower than three copies per reaction. About five copies on average are necessary for 99% of the tubes to include at least one copy. This limitation of low copy analysis holds true for any amplification technique. However, digital PCR analyzes many reactions in parallel and can quantify less than one copy (on average) per reaction.

Digital Polymerase Chain Reaction

Conventional PCR averages the amplification results of many individual template molecules. Digital or single-molecule PCR is a technique that uses a dilute solution of template distributed across many reaction compartments or “partitions.” Each partition either has or does not have PCR template molecules to amplify. After PCR, the partitions are scored as either positive (one or more initial templates) or negative (no initial template) for a digital readout. Thousands or even millions of partitions are typically scored. The partitions may be aqueous PCR droplets in oil or formed on chips by microfluidics.

Digital PCR can identify and quantify rare sequence variants, precisely determine copy number changes, establish the concentration of PCR standards, and determine the haplotype of variants that are on the same PCR product. When properly performed, digital PCR does not require the standard curves routinely used in quantitative PCR. Digital PCR is less prone to background DNA competition because competing DNA is divided between positive and negative partitions. Furthermore, common PCR inhibitors may not be as apparent in digital PCR because a positive threshold is reached even under conditions of moderate inhibition that would affect bulk quantitative PCR. Single-molecule amplification and digital analysis also has been reported for other amplification methods including **loop-mediated isothermal amplification (LAMP)** and recombinase polymerase amplification (RPA).

Additional Target Amplification Methods

In addition to PCR, many other methods of target amplification have been developed; some have found clinical use and are described in the next sections.

Transcription-Based Amplification Methods

Transcription-mediated amplification (TMA) is modeled after the replication of retroviruses (Fig. 48.5). As in PCR, amplification is exponential with completion in less than 1 hour. Unlike PCR, temperature cycling is not required (except for an initial heat denaturation if a DNA template is used). TMA is particularly advantageous when the target is RNA (e.g., human immunodeficiency virus [HIV] and hepatitis C virus [HCV] in blood bank NA testing).

Loop-Mediated Amplification Methods

Instead of producing products of a defined length, LAMP produces a wide range of different DNA structures with

Fig. 48.5 Schematic diagram of transcription-mediated amplification. Starting with a single-stranded RNA target, a primer with an RNA polymerase promoter on its 5'-end is extended by reverse transcriptase to form a DNA–RNA hybrid. The reverse transcriptase also has RNase H activity that subsequently degrades the RNA strand to leave single-stranded DNA (ssDNA). A second primer then binds to the ssDNA, and extension forms double-stranded DNA (dsDNA) with the attached RNA polymerase promoter. RNA polymerase then makes 100 to 1000 copies of RNA, some of which are again primed by the second primer. Repeated cycles of reverse transcription, DNA–RNA hybrid degradation by RNase H activity, dsDNA formation by reverse transcriptase, and further transcription by RNA polymerase exponentially produce ssRNA amplicons. Single-stranded targets are amplified isothermally, and double-stranded targets are first denatured to single strands.

branches and loops. Starting with 6 primers, the chain reaction includes both extension of free 3'-ends and additional priming from inner primers to the exposed single strands in the loops. The amplification results in a mixture of products with ever more loops and branching structures of increasing complexity.

Strand Displacement Amplification

Strand displacement amplification (SDA) requires four primers: two outer displacement primers and two inner primers. Exponential amplification occurs at 37°C by repetitive strand synthesis and displacement catalyzed by a restriction enzyme.

Variants of Polymerase Chain Reaction That Do Not Require Heat Denaturation

Variants of PCR have been developed that replace the need for heat denaturation with enzymatic separation of the double helix. These methods do not require thermal cycling and better reflect the normal DNA replication process, although the end products are the same as in the PCR. For example, helicase-dependent amplification (HDA) uses the unwinding

enzyme, helicase, to separate the double helix into single stands. Another technique, RPA, uses a recombinase to scan dsDNA for priming sites, causing strand exchange to anneal the primers and single-stranded binding proteins to stabilize the loop structure long enough for strand displacement primer extension. Two opposing primers exponentially replicate a short DNA fragment as in PCR, but the reaction is performed at 37°C without temperature cycling.

Whole-Genome and Whole-Transcriptome Amplification

Instead of specific amplification of one target to improve sensitivity, methods that amplify all genomic DNA or mRNAs are useful when the target is in short supply. For example, *multiple-displacement amplification* uses exonuclease-resistant random hexamers and a highly processive polymerase to amplify DNA nonspecifically. Initial DNA denaturation is not necessary, and the reaction proceeds isothermally. Similarly, messenger RNA can be generically amplified with a poly(T) primer modified with an RNA polymerase promoter. After reverse transcription, second-strand DNA synthesis and transcription, antisense RNA is produced. Both whole genome and antisense RNA amplification are also useful as NA purification methods before amplification or detection.

Signal Amplification: Branched-Chain DNA

Instead of increasing the concentration of target, signal amplification techniques use NAs to magnify the detection signal. The branched-chain DNA (bDNA) method is one of these techniques in common use. The bDNA approach hybridizes the target NA to multiple capture probes affixed to a microtiter well. This is followed by hybridization to a series of “extender,” “preamplifier,” and “amplifier” probes. The final, highly branched amplifier probe includes multiple copies of signal-generating enzymes that act on a chemiluminescent substrate to produce light.

Rolling Circle Amplification

If a primer is annealed to a closed circle of DNA in the presence of a processive, displacing polymerase, the complement of the circle will be synthesized over and over again with displacement of the tandem repeats. If two primers are used in opposite orientation, progressively more complex branches will be formed in an exponential reaction. The rolling circle can be formed by ligation of the two ends of a linear probe on template DNA. Ligation may happen directly, after polymerization through a gap, or after annealing of an additional, allele-specific oligonucleotide.

Endpoint Quantification in Amplification Assays

Molecular diagnostic assays may be qualitative (detect the presence or absence of a target or identify a genotype) or quantitative (quantify the original concentration of a target sequence in the sample). When amplification is part of the assay, many variables need to be controlled carefully for accurate and precise quantification. Variation in extraction efficiency, the presence of enzyme inhibitors, lot-to-lot variation in enzyme and reagent performance, and day-to-day variation

in reaction and detection conditions need to be addressed by quantitative methods. With reverse transcriptase assays, even more variables (reverse transcription efficiency and choice of reference genes) need to be considered.

DETECTION TECHNIQUES

Molecular diagnostics uses both generic and specific methods of NA detection. NAs can be quantified in bulk by optical techniques of absorbance and **fluorescence**. Specific methods of detection and quantification usually use sequence-specific primers or probes with fluorescent or electronic detection. Specificity in NA assays almost always comes from the hybridization of two complementary NA strands.

Fluorescent Labels

Advances in oligonucleotide synthesis and fluorescence detection have made fluorescently labeled probes the preferred reporter for NA analysis. Many fluorescent labels are now available, allowing color multiplexing for applications such as DNA sequencing, fragment length analysis, DNA arrays, and real-time PCR as reviewed later in this chapter. Techniques such as fluorescence polarization, fluorescence resonance energy transfer (FRET), and fluorescence quenching can provide additional detection specificity (see **Chapter 9**). Molecular rotation primarily depends on the size of the molecule, so binding of a small probe onto a large target results in a polarization increase that can be measured. FRET techniques depend on the distance between two spectrally distinct fluorescent labels. Two labeled probes may be brought closer together by adjacent hybridization. Alternatively, two labels on the same probe may end up farther apart by hydrolysis or hybridization. Fluorescence quenching or augmentation does not always require FRET. For example, fluorescence may change merely by hybridization of a fluorescent oligonucleotide to its target, or quenching moieties can be directly incorporated into probes.

Electrochemical Detection

Electrochemical detection of NAs recognizes the DNA duplex by conductivity or capacitance. Usually, PCR amplification is performed before detection, so that many molecules are available and a bulk signal is generated to increase sensitivity. Electronic detection is also used in one type of MPS, in which single nucleotide extension (SNE) from a clonally covered DNA bead produces a change in pH that is detected by electronic sensors. Direct sequencing of single molecules is also possible by detecting current changes that occur when a single strand of DNA passes through a nanopore.

DISCRIMINATION TECHNIQUES

NA discrimination techniques are divided into three categories: (1) electrophoretic methods that physically separate NAs based on molecular size or shape; (2) methods that determine the size, base content, or sequence of NAs without electrophoresis, including high-performance liquid chromatography (HPLC), mass spectrometry, and **pyrosequencing**; and (3)

Fig. 48.6 A photograph of multiple DNA fragments after agarose gel electrophoresis (1% w/v, SeaKem LE agarose gel) showing the separation of double-stranded DNA molecules by size. *MW*, Molecular weight. (Photograph courtesy Lonza Rockland Inc., Rockland, ME.)

hybridization assays that identify specific NAs by the annealing or melting of complementary NAs. Some techniques use both electrophoresis and hybridization.

Electrophoresis

Both DNA and RNA are negatively charged and migrate toward a positively charged electrode when an electrical field is present within an appropriately buffered solution. Separation of different NAs occurs when mixtures are allowed to travel through a gel under an electrical field. Separation is based primarily on molecular size, with smaller molecules traveling faster through the gel than larger ones (Fig. 48.6). The shape or physical conformation of the molecule also affects migration, so that mismatches and hairpins can be detected. Separation based on shape can provide useful information, but it can also confuse size-based analysis.

RNA electrophoresis is commonly performed as a quality control check before transcript quantification or microarray expression analysis. Microfluidic chips with integrated microelectrophoresis channels are commercially available to rapidly assess RNA integrity by inspection of ribosomal RNA peaks (Fig. 48.7). Although specific transcripts are not detected by this method, only small amounts of starting RNA are needed.

Agarose and polyacrylamide are the two types of gel polymers commonly used in electrophoresis. Agarose gels can separate NA fragments as small as 20 bp to more than 10 mb (10,000 kb), including chromosomes of yeast, fungi, and parasites. However, the resolution of agarose is limited to about 2% to 5%. Polyacrylamide gels are suited for high-resolution separation (down to about 0.1% size differences) of short molecules (up to about 2 kb) and are the primary polymers

Fig. 48.7 Microelectrophoresis of human white blood cell (WBC) RNA. After isolation of WBCs and extraction of total RNA, samples were denatured, stained with a fluorescent dye, and applied to a commercial microelectrophoresis platform for assessment of RNA quality. Prominent 18S and 28S bands of ribosomal RNA suggest the RNA is largely intact. Also indicated are a reference marker (M) and the 5S ribosomal band. Note that electrophoresis was performed in less than 1 minute.

TABLE 48.2 Commonly Used Electrophoresis-Based Techniques		
Techniques Using Electrophoresis	Abbreviation	Primary Application
Polymerase chain reaction (or reverse transcriptase polymerase chain reaction) length	PCR RT-PCR	Detection
Polymerase chain reaction/restriction fragment length polymorphism	PCR/RFLP	Detection
Dideoxy-termination sequencing (Sanger)		Sequencing
Single-nucleotide extension assay	SNE	Genotyping
Oligonucleotide ligation assay	OLA	Genotyping
Multiplex ligation-dependent probe amplification	MLPA	Quantification

for single-stranded NA separation, such as in dideoxy-termination sequencing. The optical clarity of polyacrylamide gels makes them ideal for visualizing fluorescent emission using laser-induced fluorescence detection. Table 48.2 lists common electrophoresis-based techniques.

Polymerase Chain Reaction Product Length

PCR product analysis by electrophoresis is frequently used to query the product size and specificity of PCR. PCR products are visualized by staining the gel with a fluorescent DNA-binding dye, such as ethidium bromide. In some cases, the presence of an amplification product is directly diagnostic (e.g., detection of sequences found only in a bacterium, virus, or fungus in a human sample). The specificity of the amplification reaction is verified by the known size of the fragment

and the lack of extraneous bands. Internal negative and positive controls are used to control for potential contamination and PCR inhibitors.

Small insertions, deletions, rearrangements, and changes in the number of repeated sequences also can be detected by monitoring PCR product length on gels. Length differences may be large and easily visualized with agarose gel electrophoresis, or they may be small enough to require a denaturing polyacrylamide matrix. Fluorescent primers may be incorporated into the product during PCR to simplify detection of fragment lengths. These techniques are commonly used in the diagnosis of inherited diseases and in identity assessment.

Restriction Fragment Length Polymorphism

DNA extracted from a cell is extremely long and is usually cut into shorter fragments before electrophoresis to enhance mobility. Restriction endonucleases cut dsDNA into fragments of reproducible size; the same enzyme produces the same fragments in different specimens if they contain the same DNA sequence. If an alteration in the DNA abolishes or creates a cleavage site recognized by the enzyme (or changes the spacing between two cleavage sites), different sized fragments will be produced. These changes in fragment lengths (or polymorphisms) that result from restriction digestion are called **restriction fragment length polymorphisms (RFLPs)**. However, restriction digestion of genomic DNA produces thousands of fragments. To be useful, specific fragments need to be visualized with probes.

Polymerase Chain Reaction/Restriction Fragment Length Polymorphism

Many sequence alterations (e.g., single base changes) do not affect the length of DNA. However, they can be amplified easily by PCR, and many can be detected as RFLPs after treatment with restriction enzymes. After PCR, the products are digested with one or more enzymes and analyzed by electrophoresis. For example, if a sample has a variant that disrupts an enzyme recognition site, it can be distinguished from a sample that does not have the variant. Such an assay will produce one uncut PCR fragment when the variant is present and two shorter fragments with normal DNA (Fig. 48.8). If the variant is present as a heterozygote (one normal and one variant copy of DNA), then one long and two shorter fragments will be observed. Usually it is possible to design the assay so that the fragments can be easily resolved by agarose gel electrophoresis. One variant of this method uses reverse-transcribed mRNA, which lacks the introns that would be present in the DNA. In this way, multiple exons can be analyzed in a single PCR.

Dideoxy-Termination Sequencing (Sanger Sequencing)

Dideoxy-termination sequencing of DNA is routinely performed in the clinical laboratory. RNA can also be sequenced by first converting RNA to DNA by reverse transcriptase. NA sequence is determined and compared with a reference sequence with an error rate of approximately 0.1% (1 misidentified base in 1000). Often the sequence is analyzed on both strands (sense and antisense) for even greater accuracy. Any deviation from the reference sequence is identified by using computer software. Base changes, including synonymous changes that do not alter the protein

Fig. 48.8 An example of polymerase chain reaction (PCR) restriction fragment length polymorphism (PCR-RFLP). A DNA fragment amplified by PCR carries a site (a unique sequence of generally four or more bases) that is recognized and cleaved by a restriction endonuclease. If a mutation is present, this site is altered and is no longer recognized by the enzyme. Electrophoresis reveals that the fragment from a normal specimen was indeed cut by the enzyme, generating two fragments shorter than the original length, but the fragment from a homozygous mutant was not cut, and the original length of the PCR product is preserved. In a heterozygous mutant, both the original fragment and the shorter fragments are visible. MW, Molecular weight.

Fig. 48.9 A dideoxynucleotide. Notice the absence of the 3'-OH that is usually present in standard deoxynucleotides. This lack of a 3'-OH prevents polymerase extension because no phosphodiester bond can form. Incorporation of a dideoxynucleotide forces termination of polymerase extension.

sequence, as well as nonsynonymous changes resulting in altered amino acids, stop codons, and small insertions and deletions, are identified. However, larger deletions and rearrangements spanning the sequencing primer binding sites are not detected.

The most common sequencing strategy uses PCR in the first step to amplify the region of interest followed by a chain-termination reaction developed in the late 1970s. This reaction generates fragments that are terminated at various lengths by incorporation of one of the four dideoxynucleotide base analogs during extension from a sequencing primer. Dideoxynucleotides lack both 3'- and 2'-hydroxyl groups on the pentose ring (Fig. 48.9). Incorporation of dideoxynucleotides terminates chain extension. The most common method for generating these terminated fragments is *cycle*

Fig. 48.10 The dideoxy-termination reaction for sequencing. A polymerase chain reaction (PCR) product is denatured and hybridized to a specific oligonucleotide primer. As the DNA polymerase extends the primer by incorporating bases (deoxynucleotides [dNTPs]) complementary to the template, it occasionally incorporates a terminator dideoxynucleotide base analog (ddA, ddG, ddT, or ddC) that stops further extension. The result is a mixture of extended products of varying lengths. Each terminator base may be labeled with one of four different fluorescent tags (shown as different symbols in the diagram).

sequencing, repeating the steps of annealing, chain extension-termination, and denaturation by temperature cycling, similar to PCR (Fig. 48.10). The fragments generated are tagged and terminated with a fluorescent dideoxynucleotide, separated by electrophoresis, and detected by fluorescence as the fragments travel past a detector (Fig. 48.11). About 600 to 800 bases can be resolved in less than 2 hours by capillary electrophoresis, and 96 or 384 samples can be run in parallel.

Single Nucleotide Extension

Also known as *single-base primer extension* or *minisequencing*, SNE assays involve the annealing of an oligonucleotide primer to a single-stranded PCR product at a location that is immediately adjacent to the site of the single base variant, followed by enzymatic extension of the primer in the presence of polymerase and dideoxynucleotide terminators. For example, each of the four terminators can be labeled with a unique fluorescent label so that it is possible to detect which base was incorporated. SNE assays can be multiplexed on capillary electrophoresis instruments by varying the lengths of the primers so that each SNV is resolved by size in one electrophoresis run. Many SNE detection methods are available other than electrophoresis, including (1) photometric detection on microtiter plates, (2) product capture detection systems on DNA microarrays, (3) bead hybridization assays detected by flow cytometry,

(4) solution-based fluorescence polarization detection systems, and (5) mass spectrometry. SNE assays are particularly useful when the target of interest contains 5 to 50 disease-causing single base variants. SNE assays do not work well if variants are present in the primer-binding site. Nor are they usually designed to detect variants at a position other than immediately adjacent to the 3'-end of a primer.

Oligonucleotide Ligation

Another assay format frequently used for variant detection is the **oligonucleotide ligation assay (OLA)**. Two oligonucleotide probes are hybridized to adjacent sequences of amplified target DNA, with the variation site positioned at the end of one probe (Fig. 48.12). DNA ligase covalently joins the two probes only if both probes are perfectly hybridized to the target, including the polymorphic base. A probe matching the normal base and another probe matching the variant base are usually prepared. These two can be discriminated through differential electrophoretic mobility by varying the length of their 5'-tails. The probe hybridizing to both alleles (the *common probe*) provides the reporter molecule, usually a fluorescent label. Multiplexing is achieved by attaching different fluorescent labels to the common probes and by varying the length of the tails on the allele-specific probes. After ligation, probes for multiple variants are separated by denaturing capillary electrophoresis.

Fig. 48.11 Schematic of dideoxy-termination DNA sequencing. Extension products (see Fig. 48.10) are labeled with different color dyes for each of the four terminator reactions and are separated by electrophoresis. The four-color strategy allows automated endpoint fluorescence detection (*eye icon*). The direction of fragment migration is from top to bottom. The sequence is read from left to right in the electropherogram generated by the sequencer. Examples of a reference sample (homozygous T at the polymorphic site), a mutant sample (homozygous C), and a heterozygous mutant sample (T and C, reported as Y) are shown.

Fig. 48.12 Oligonucleotide ligation assay of a heterozygous single nucleotide variant. A mutant probe with a 3'-T (*upper left*) hybridizes to the mutant DNA with an opposing A, and a normal probe with a 3'-C (*upper right*) hybridizes to the normal DNA with an opposing G. The probes are also attached to mobility modifying tails of different lengths (*wavy lines*). Hybridized next to these probes is the common probe with a 5'-phosphate (Pi) and a 3'-fluorescent tag. In the presence of ligase, adjacent probes are covalently joined to generate longer probes, each with a fluorescent tag and a mobility-modifying tail. Probes that are mismatched to the target at their 3'-ends may hybridize, but they are not ligated. Electrophoresis and endpoint, laser-induced detection of ligated probes reveal the different alleles by their different mobility.

Multiplex Ligation-Dependent Probe Amplification

Multiplex ligation-dependent probe amplification (MLPA)

is a convenient method for relative quantification of up to 10 to 50 targets. This method is particularly useful in screening for deletions or duplications of exons, multiple exons, or whole genes. For each target, two probes are designed that hybridize adjacent to each other so that they can be ligated. The two probes have unique tails that do not hybridize to the target and that are the same between targets. After hybridization and ligation, the probes are amplified by PCR with a common primer pair (complementary to the tails). One of the primers is fluorescently labeled at its 5'-end. Because probes of different lengths are used, multiple PCR products of different sizes are produced and separated by capillary electrophoresis. Relative peak heights or areas are compared for relative quantification.

Alternatives to Electrophoresis

Electrophoresis is not the only method to determine the size, base content, and/or sequence of NAs. Some of these alternatives to electrophoresis are attractive in the clinical laboratory because of compatibility with automation and capacity for high throughput. Some examples include pyrosequencing, mass spectrometry, and HPLC.

Pyrosequencing is a sequencing-by-synthesis method that does not require dideoxy-termination or electrophoresis. One of the four dNTPs is added to the reaction, and if the base is complementary to the template strand, DNA polymerase catalyzes its incorporation. Each incorporation event is accompanied by release of a pyrophosphate (PPi), which is coupled through enzymatic reactions to the generation of visible light. The light produced is proportional to the number of nucleotides incorporated. As the process is repeated by adding one dNTP at a time, the complementary DNA strand is built, and the nucleotide sequence is determined.

Matrix-assisted laser-desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry can be used to genotype sequence variants. With mass spectrometry, no label is necessary because the alleles differ in mass. After isolation of genomic DNA, a specific DNA fragment, including the variant site, is amplified by PCR. After purification of the PCR product, an extension primer is hybridized directly or closely adjacent to the polymorphic site. Unlabeled deoxynucleotides are incorporated and terminated with a dideoxynucleotide, generating allele-specific diagnostic products of different mass. MALDI-TOF then measures the mass of the extension products. After the mass is measured, the genotype is determined (Fig. 48.13). Despite the complexity, automated systems processing 384 to 1536 samples at once are available.

HPLC is commonly used to separate and purify oligonucleotides. A variant of this technology is denaturing HPLC (dHPLC). dHPLC is run at a single elevated temperature to partially denature dsDNA. dHPLC reveals the presence of **heteroduplexes** as additional peaks that are shifted in retention compared with **homoduplexes**. DNA detection is most often performed by ultraviolet absorbance, although fluorescence or mass spectroscopy can also be used. Analysis by dHPLC is sequential (one at a time).

Fig. 48.13 Sequence polymorphism analysis by mass spectrometry. The underlined base is the polymorphic site in the template (T or C). The single-stranded template is primed and extended in the presence of three deoxynucleotides (dNTPs) and one dideoxynucleotide triphosphate (ddNTP), producing fragments of different mass depending on the sequence. The boxed "A" in this example indicates the incorporated terminator adenine base. The mass of terminated products is precisely measured by matrix-assisted laser-desorption/ionization time-of-flight mass spectrometry.

Hybridization Assays

All hybridization assays are based on the ability of single-stranded NAs to form specific double-stranded hybrids. The process requires (1) that probe and target NAs are mixed under conditions that allow specific complementary base pairing, and (2) that a method is available to detect any resulting double-stranded NAs. A *probe* indicates a NA whose identity is known, and the *target* or *sample* is a NA whose identity or abundance is revealed by hybridization. In some of the methods discussed here, hybridization occurs between a target in solution and a probe that is tethered to a solid surface. In *homogeneous* or *real-time* techniques, both the probes and the targets are in solution, and hybridization and detection occur without the washing steps. Some of the homogeneous methods also monitor the dissociation of hybridized duplexes under controlled heating, revealing the identities of the hybridized duplexes by *melting curve* signatures.

The noncovalent binding between two DNA strands is sequence dependent and reversible. Denaturing agents (e.g., high temperature, formamide, or extremes of pH) favor dissociation of the double-stranded molecule into two separate random coils (Fig. 48.14). On removal of the denaturant, single strands reform duplexes. Because temperature is the denaturant most easily manipulated, double-to single-strand transformation is referred to as *melting*, and the temperature at which half of the DNA is melted is the **melting temperature (T_m)** of the duplex. Duplexes with mismatched base pairs are less stable than those with a perfect sequence match and thus melt at lower temperatures. The reverse process, in which two complementary strands recombine to form a stable duplex molecule, is referred to as *annealing* or *hybridization*.

Fig. 48.14 Fluorescence melting curve of a polymerase chain reaction (PCR) product. PCR-amplified DNA was melted in the presence of a dye that fluoresces in the presence of double-stranded DNA, but not single-stranded DNA. (A) Fluorescence gradually decreases as the temperature is increased until a more rapid decrease occurs near the DNA melting temperature (T_m) of the PCR product. (B) The data are normalized between 0% and 100% after background removal to obtain constant fluorescence outside of the transition. (Modified with permission of the publisher from Wittwer, C. T., & Kuskawa, N. [2011]. Real-time PCR and melting analysis. In D. H. Persing, F. C. Tenover, Y.-W. Tang, J. Versalovic, T. J. White, & E. Unger [Eds.], *Molecular microbiology: diagnostic principles and practice* [2nd ed., pp. 63–82]. Washington, DC: ASM Press. Copyright 2011 ASM Press.)

Probes

Similar to antibodies in immunoassays, probes in NA hybridization assays can be labeled in many ways to detect hybridization. Probes may be cloned (recombinant), generated by PCR, or synthesized (oligonucleotides). They may be DNA, RNA, or NA analogs and single or double stranded. Oligonucleotide probes are the most common probes used today. These probes are usually 20 to 80 bases of single-stranded NA that are chemically synthesized. Automated, efficient, and accurate methods of synthesis

BOX 48.1 Hybridization Assays

Solid-Phase Hybridization

Dot blot and line probe assays
Arrays (microarrays and medium-density arrays)
Micro-bead assays
In situ hybridization
Massively parallel sequencing on beads or planar flow cells

Solution-Phase Hybridization

Real-time (or homogeneous) polymerase chain reaction
Melting analysis
Single-molecule sequencing
Many classical techniques

continue to lower the cost of production. Sequence information is now routinely available in public databases. Probe sequences must be carefully chosen to minimize cross-hybridization with pseudogenes (eukaryotes) or related species (bacteria and viruses). The hybridization temperature of the probe should allow both favorable hybrid stability and discrimination against related sequences. Oligonucleotide probes are often prepared with covalent attachment of a reporter molecule (e.g., a fluorescent dye) or a reactive linker that allow them to be attached to solid supports. Probes used in homogeneous (real-time) PCR are usually oligonucleotides with a fluorescent label.

Examples of Hybridization Assays

Hybridization reactions can be divided into two broad categories: (1) *solid phase*, in which either probe or target is tethered to a solid support while the other is in solution, and (2) *solution phase*, in which both are in solution (Box 48.1). Several classical methods first hybridize in solution and then separate the bound from the unbound labeled probe. Exclusion chromatography and binding by hydroxyapatite, magnetic particles, or other capture methods allow selective measurement of the labeled probe–target hybrid.

Solid-Phase Hybridization

Solid-phase assays are useful because multiple samples can be processed together, which facilitates (1) control, (2) washing, and (3) separation procedures. However, hybridization on a solid support is less efficient than solution-hybridization, and the kinetics are slower and more difficult to predict. Both solid-phase and liquid-phase assays are used routinely in the clinical laboratory. Solid-phase assays include (1) dot blots, (2) line probes, (3) microspheres, and (4) microarrays.

Dot blot and line probe assays. Conventional hybridization assays on membranes are known as dot blot or line probe assays, depending on the geometry of the individual spots. The NAs are applied with suction, forming a shape that is either round (dot) or elongated (line or slot). After immobilization, the membrane is incubated with complementary NA at a constant temperature followed by one or more washes to discriminate matched from mismatched NA. The method allows multiple simultaneous hybridizations under identical conditions.

Fig. 48.15 A two-color microarray experiment. An array of DNA oligonucleotides with sequences of messenger RNA are affixed to a glass slide. Messenger RNAs in the test and reference specimen are converted into differentially labeled cDNA by reverse transcription and incorporation of two different fluorescent dyes. The two samples are hybridized together onto the array. The array is washed, and the image is captured twice, each time with a laser of a wavelength that excites one of the dyes but not the other. The monochromatic images are then converted to two colors (*green [G]* for the test sample and *red [R]* for the reference), and the images are combined. If the abundance of cDNA is the same in each of the two samples, then the composite spot will be shown as *yellow (Y)*. If one is in greater abundance, then that color will be preserved.

Medium-density arrays. Dot blot and line probe assays have largely been replaced by medium-density arrays that typically analyze 20 to 500 spots. The bound NAs are often oligonucleotides 20 to 80 bases in length that may be conventionally synthesized and spotted onto the chip or directly synthesized on site. Medium-density arrays are used for testing multiple mutations simultaneously in genetic diseases, oncology, and pharmacogenetics. These arrays do not need to be attached to a two-dimensional surface as long as their “address” can be decoded. For example, microspheres can be coded by fluorescence intensity in two different channels, and fluorescence in a third channel monitors hybridization. All channels can be read simultaneously using a flow cytometer.

Microarrays. Microarrays (also called DNA arrays, DNA chips, or Biochips) were introduced in the mid-1990s. Compared with medium-density arrays, spot sizes in microarrays are decreased (typically to <200 microns in diameter) such that one array contains thousands to millions of spots. This dimensional change requires (1) specialized detection equipment, (2) software, and (3) informatics to analyze the data. Because of their high density, microarrays have attracted intense interest among researchers who wish to monitor the whole genome for (1) SNVs, (2) gene expression, or (3) copy number variation.

Because SNVs represent the most common genetic difference among individuals, much effort has focused on correlating SNV genotypes to phenotype and disease association. SNV microarrays have been used in many genome-wide association studies (GWAS). Microarrays that analyze human SNVs (“SNV chips”) provide the technology to genotype most known human SNVs in one experiment. Nearby SNV alleles tend to cluster together as haplotypes, so disease association by haplotype simplifies the analysis.

Gene expression microarrays quantify the relative amounts of different messenger RNAs in test and reference samples. An example of a two-color microarray for gene expression is shown in Fig. 48.15. Probes that hybridize to mRNA are usually directly synthesized on microarrays. Modern gene expression arrays have been used to measure the mRNA transcribed from all human genes in one experiment. Most arrays are used in marker discovery projects for selection of a smaller panel of expression targets that are then analyzed by other quantitative methods, such as real-time PCR, that provide greater precision and dynamic range.

Another important clinical application of microarrays is the genome-wide analysis of deletions and duplications, referred to as copy number variants (CNVs). CNV analysis using microarrays is replacing traditional cytogenetic

Fig. 48.16 Copy number variation identified with a comparative genomic hybridization array made from oligonucleotides. DNA from a subject is fragmented, labeled with Cy5, and hybridized onto a microarray, together with Cy3-labeled reference DNA. On the array are nearly 44,000 oligonucleotide probes, each about 60 bases long and tiled across the whole genome at an average spacing of 75 kb. Shown on the *left panel* are results of probes on chromosome 15 (all other chromosomes are analyzed in this assay but are not shown). Each *dot* represents a specific probe to which the subject's DNA hybridizes. Their positions (0, -1, +1, and so on) reflect the dosage of the subject's DNA relative to the reference DNA. A majority of the probes line up on "0," indicating no quantitative difference compared with the reference DNA. Probes in the 15q11 to 15q13 region, however, are on the "-1" line, indicating that the subject has a deletion of that region in one of the chromosomes. *kb*, Kilobases. (Courtesy Sarah South, PhD, ARUP Laboratories.)

chromosome analysis (**karyotyping**) and **fluorescence in situ hybridization (FISH)** analysis for the detection of genome-wide copy number alterations. Similar to gene expression arrays, many of the CNV arrays use two-color comparative hybridization to determine the gene dosage in a specimen compared with a normal reference genome (array **comparative genomic hybridization** [aCGH]). Arrays for CGH use oligonucleotide probes for very high resolution and data density. An example of CNV analysis using aCGH is shown in Fig. 48.16. Unlike aCGH, SNV arrays have the advantage of analyzing the specimen without the need to mix in a reference genome. SNV arrays also are able to detect copy number neutral changes caused by inversions or uniparental disomy that are not detected by aCGH methods.

Single-copy visualization. If an NA probe is labeled with many fluorescent molecules, it is possible to see a single copy of the NA target by fluorescent microscopy. One technique uses reporter probes that are labeled with a long string of multicolored fluorescent labels. Several tandem color segments are placed on the reporter probe with each segment consisting

of about 100 fluorophores. The combination of different color segments uniquely identifies the target. The target NA is hybridized to capture probes that are (1) washed, (2) immobilized, (3) stretched, and (4) oriented on the surface of an optical slide. Each captured target is then identified by the color code of the reporter and is counted (Fig. 48.17). Although the sensitivity of this technique is not as high as that of real-time PCR, up to 150 reporter probes have been multiplexed in one reaction.

Solution-Phase Hybridization

Real-time PCR and melting analysis are considered "dynamic" hybridization assays in which the formation or dissociation of the probe–target duplex (or product duplex) is monitored in solution in real time. Data are collected throughout NA amplification rather than just at the endpoint. The technique uses fluorescent reporters and instruments to record hybridization during thermal cycling. The data obtained provide information on the (1) identity, (2) quantity, and (3) melting characteristics of the NA sample. Fluorescent dyes or probes are added to the PCR mixture

Fig. 48.17 Single copy visualization. A pair of probes (capture and reporter probes) hybridize to the messenger RNA (mRNA) target in solution through gene-specific probe sequences (A). The reporter probe has seven color segments, each segment is made of ~900 RNA bases that are labeled with about a hundred fluorophores of one color. The labeled portion of the probe is a DNA/RNA hybrid that can be observed as a ~3 nm fluorescent spot. Excess probes and unbound DNA are removed and the target complex is immobilized on a slide (B, top). An electrical current is applied, and the complex is stretched (B, middle) and immobilized in extended form (B, bottom). The color code of each probe is read through a microscope and counted (C).

before amplification. By measuring the fluorescence at each cycle of amplification, the amount of initial template present before PCR can be calculated.

Real-time PCR monitors the accumulation of double-stranded PCR products with the fluorescence signal recorded once each cycle (Fig. 48.18). If target DNA is present, fluorescence increases. How early during PCR one begins to see a signal depends on the initial amount of target DNA, and this provides a systematic method of quantification. Furthermore, when fluorescence is continuously monitored as the temperature is raised, a melting curve can be generated. Melting analysis can be used to verify the identity of the amplified product and to detect sequence variants.

Dyes and probes. Many different fluorescence generating systems are used in real-time PCR; some of the more common ones are shown in Fig. 48.19. Many methods use probes complementary to the target, and others rely on dsDNA binding dyes and depend on the specificity of the PCR primers. Some have the additional option of melting analysis to measure the melting temperature of the probe or product. Points to remember about fluorescent indicators are summarized in the box.

POINTS TO REMEMBER

Fluorescent Indicators

- May be dyes or probes
- Dyes are less expensive and less specific
- Melting analysis increases specificity
- May function by hybridization, hydrolysis, ligation, or displacement
- Single base variants can be detected by probes or high-resolution melting
- Enable real-time PCR in a closed system

Some dyes increase their fluorescence in the presence of dsDNA, which is produced during PCR (see Fig. 48.19A). dsDNA binding dyes are commonly used for real-time quantification, particularly in the research setting when the specificity of a probe and its added cost is not needed. They also allow melting analysis of the product at the end of PCR.

Fluorescent probes are also commonly used in real-time PCR. They hybridize to PCR products during amplification and change fluorescence by two possible mechanisms: (1) a covalent bond between two dyes is broken by hydrolysis, or (2) the fluorescence change follows reversible hybridization of the probe to the target. Following this distinction, when an irreversible covalent bond is involved, the probes are called *hydrolysis probes*. When probes reversibly change fluorescence on duplex formation, they are called *hybridization probes*. One difference between the two probe types is that melting analysis is characteristic of hybridization probes, but hydrolysis probes usually have a weak, if any, melting signature.

Hydrolysis probes (exonuclease probes) are synthesized with an absorbing molecule positioned to quench the fluorescence of another label. If the probe is hydrolyzed between the fluorophore and the quencher during PCR, fluorescence will increase. The most common implementation uses the 5'-exonuclease activity of some DNA polymerases to hydrolyze the probe and to dissociate the labels (see Fig. 48.19B). Hydrolysis probes generate fluorescence through changes in covalent bonds. The change in fluorescence signal is irreversible, and melting analysis of the hydrolyzed probe is seldom useful.

Hybridization probes change fluorescence upon hybridization, usually by FRET. Two interacting fluorophores are typically placed on adjacent probes (see Fig. 48.19C). Only one probe with one fluorophore may be necessary if fluorescence is quenched by deoxyguanosine residues. The

Fig. 48.18 Real-time monitoring during amplification and melting analysis. The *bottom panel* shows a typical rapid-cycle temperature profile that is followed by a temperature ramp for melting analysis. When fluorescence is monitored once each cycle during amplification, the presence or absence and the quantification of the specific target are obtained. When fluorescence is monitored continuously through the melting phase (*shaded area*), melting analysis can verify target identification and establishes genotype. (Modified with permission of the publisher from Wittwer, C. T., & Kuskawa, N. [2004]. Real-time PCR. In D. H. Persing, F. C. Tenover, J. Versalovic, Y.-W. Tang, E. R. Unger, D. A. Relman, et al [Eds.], *Molecular microbiology: diagnostic principles and practice* [pp. 71–84]. Washington, DC: ASM Press.)

fluorescence change that occurs with hybridization is reversible upon melting.

Hairpin probes (molecular beacons) typically have a fluorophore and a quencher at the 3' and 5'-ends of a hairpin stem (see Fig. 48.19D). Fluorescence increases when the distance between the quencher and the reporter increases upon target hybridization. Hairpin probes of different colors can be combined with melting curve analysis for highly multiplexed assays.

Self-probing primers are modified at their 5'-end to include a hairpin probe with a fluorophore and quencher on opposite ends of the stem (see Fig. 48.19E). The hairpin loop is complementary to the primer extension product of the same strand that is generated during PCR. Through intramolecular hybridization, the quencher is separated from the fluorophore, and fluorescence increases. A blocker prevents copying the hairpin during PCR.

Highly quenched probes have a very efficient quencher at the 3'-end and a minor groove binder and fluorophore at the 5'-end (see Fig. 48.23F). Background fluorescence is very low because of the combined effect of the quencher and minor groove binders. Upon hybridization, fluorescence increases because the fluorophore and quencher are separated, a process that can be reversed by melting. The minor groove binders increase probe stability, allowing the use of smaller probes when sequence variation of the target is high.

Competitive displacement probes have a fluorophore and quencher on opposite strands, usually at 3'- and 5'- ends. Generation of target strands during PCR displaces one labeled strand, separating fluorophore and quencher, and generating fluorescence. In one design, partially double-stranded probes with one strand shorter than the other favor displacement (see Fig. 48.19G).

Detection and Quantification in Real-Time Polymerase Chain Reaction

When fluorescence is monitored once each cycle in the presence of a dye, the data closely follow the expected logistic shape discussed earlier (see Figs. 48.3 and 48.20, *top left*). However, with hydrolysis probes, fluorescence is cumulative and continues to increase even after the amount of product reaches a plateau (see Fig. 48.20, *top middle*). In contrast, reactions monitored with hybridization probes may show a decrease in fluorescence at a high cycle number (see Fig. 48.20, *top right*). Despite differences in the curve shape, all real-time systems follow the amount of product being produced during PCR, and this information is used for detection and quantification.

Detection. A fluorescent signal that increases during PCR and follows one of the expected curve shapes suggests that the specific target is present and was amplified. In contrast, a signal that stays at background even after 40 PCR cycles suggests

Fig. 48.19 Common probes and dyes for real-time polymerase chain reaction. (A) Double-stranded DNA dyes show a significant increase in fluorescence after DNA amplification. (B) Hydrolysis probes are cleaved between a fluorescent reporter and a quencher, resulting in increased fluorescence. (C) Dual hybridization probes. Fluorescence resonance energy transfer is illustrated between a donor and acceptor fluorophore. The *thin vertical oval* indicates termination of the 3'-end of the probe to prevent polymerase extension. (D) Hairpin probes are quenched in the native conformation but increase in fluorescence when hybridized. (E) Self-probing primers retain their native, quenched conformation until they are incorporated into a double-stranded product. (F) Highly quenched probes use a combination of minor groove binders and a very efficient quencher to limit background fluorescence. Upon hybridization, fluorescence increases. (G) Competitive displacement probes have reporters and quenchers on opposite strands. The quenching probe is displaced by the accumulating polymerase chain reaction product and fluorescence increases. There are several forms of this type of probe. (Modified with permission of the publisher from Nolte, F. S., & Wittwer, C. T. [2015]. Nucleic acid amplification methods overview. In D. H. Persing, F. C. Tenover, R. T. Hayden, M. Leven, M. B. Miller, F. S. Nolte, et al [Eds.], *Molecular microbiology: diagnostic principles and practice* [3rd ed.]. Washington, DC: ASM Press.)

that the target is absent and that no amplification occurred. Positive controls (to rule out inhibitory factors) and negative controls (to rule out product contamination and nonspecific signal generation) are necessary. If the fluorescent signal is reversible with hybridization, melting analysis can verify the expected T_m of the probe or product. Multiplex detection is possible with probes that are labeled with different colors or different melting temperatures. Examples in the clinical laboratory include probe multiplexing to detect the presence of more than one infectious organism, or to discriminate an internal control template from the target.

Quantification. Real-time PCR offers a convenient approach to quantification by monitoring the amount of product at each cycle. Digital PCR has some advantages over real-time PCR, including precision and rare-allele analysis. However, one of the advantages of real-time PCR is its large dynamic range. Fig. 48.21 shows an extended range of quantification standards in a typical real-time PCR. As the initial template concentration increases, the curves shift to earlier cycles. The extent of this shift depends on the PCR efficiency (Table 48.3). The cycle at which fluorescence rises correlates inversely with the log of the initial template concentration and is the quantification cycle or C_q . This “cycle” is actually a *virtual* cycle that includes a fractional component determined by interpolation, which can be calculated by several methods.

Accuracy and precision. The accuracy of real-time PCR quantification depends on the quality of the quantification standards used. Synthesized oligonucleotides, purified PCR products, plasmids, and genomic DNA can be used as calibrators. As previously mentioned, digital PCR is a great method to quantify PCR standards. Sometimes absolute quantification is not needed, and quantification relative to one or more reference genes is performed. In this case, selection of the reference genes and PCR efficiency are critical. The precision of quantitative real-time PCR depends on the initial number of template copies in the reaction. When the initial target concentration is low, imprecision is high. When this is the case, digital PCR may be a better choice.

Melting Analysis

When fluorescence is monitored continuously within each cycle of PCR, the hybridization characteristics of PCR products and probes can be observed. Continuous spirals of fluorescence versus temperature are produced (see Fig. 48.20, bottom panels). With dyes, the melting characteristics of the amplified DNA identify the product. With probes, melting occurs at a characteristic temperature that can be exploited to confirm target identity and to analyze sequence variants under the probe.

For routine testing in the clinical laboratory, a single melting curve is usually performed at the end of PCR instead of monitoring hybridization throughout the entire PCR process (see Fig. 48.18). Genotyping is best performed in the same tube by monitoring the melting of hybridized duplexes during controlled heating, producing a melting curve signature for the duplex. Such a signature monitors melting over a range of temperatures in contrast to the single-temperature analysis of conventional hybridization techniques, such as dot blots or microarrays. Real-time amplification and melting analysis make up a powerful combination that requires only temperature control and sampling of fluorescence.

High-Resolution Melting Analysis

An example of SNV genotyping by high resolution melting analysis is shown in Fig. 48.22. The PCR product is long enough that it melts in two domains because of unequal guanosine/cytosine content throughout the PCR product. Applications of **high-resolution melting analysis** include genotyping, mutation scanning, methylation analysis, sequence matching, and relative copy number assessment.

Fig. 48.20 Monitoring polymerase chain reaction (PCR) in real time. The *top row* shows data collected once each PCR cycle, and the *bottom row* shows data collected continuously (five times per second) during all PCR cycles. Three different reporter systems are shown. *dsDNA*, Double-stranded DNA; *T_m*, melting temperature. (Modified with permission of the publisher from Wittwer, C. T., & Kuskawa, N. [2004]. Real-time PCR. In D. H. Persing, F. C. Tenover, J. Versalovic, Y.-W. Tang, E. R. Unger, D. A. Relman, et al [Eds.], *Molecular microbiology: diagnostic principles and practice* [pp. 71–84]. Washington, DC: ASM Press.)

Fig. 48.21 Quantification by real-time polymerase chain reaction. Shown are typical real-time curves for amplification reactions of varying initial target concentrations (A) and the log of the initial concentration plotted against the quantification cycle (B). (Modified with permission of the publisher from Wittwer, C. T., & Kuskawa, N. [2004]. Real-time PCR. In D. H. Persing, F. C. Tenover, J. Versalovic, Y.-W. Tang, E. R. Unger, D. A. Relman, et al [Eds.], *Molecular microbiology: diagnostic principles and practice* [pp. 71–84]. Washington, DC: ASM Press.)

TABLE 48.3 Correlation Between Polymerase Chain Reaction Efficiency, the Slope of the Standard Curve, and the Percentage of Polymerase Chain Reaction Product After 30 Cycles

Slope of Standard Curve ^a	PCR Efficiency (%)	PCR Product After 30 Cycles (% Expected)
-3.32	100	100
-3.35	99	86
-3.38	97.5	69
-3.45	95	47
-3.59	90	22
-3.74	85	10
-3.92	80	4
-4.34	70	1
-4.90	60	0.1
-5.68	50	0.02

^aAssuming the log (initial template) is plotted on the x-axis as the independent variable and the quantification cycle is plotted on the y-axis as the dependent variable, the slope of the calibration curve is as follows: Slope = $\Delta\text{Cycle}/\Delta\text{Log} [\text{initial template}]$. Percent PCR efficiency is calculated as $(10^{-1/\text{Slope}} - 1) \times 100$.

PCR, Polymerase chain reaction.

Fig. 48.22 A single base change in a 544-bp fragment detected by melting analysis. Shown are high-resolution melting curves of polymerase chain reaction products from the gene *HTR2A* carrying a single nucleotide variant. Results are shown for six individuals, two different individuals for each of the three genotypes: wild-type homozygote (*TT*), mutant homozygote (*CC*), and heterozygote (*TC*). Two melting domains are present because of differing GC content. The single nucleotide variant was present in the lower melting domain. The *inset* magnifies a portion of the data, showing that all three genotypes can be discriminated. (Modified by permission of the publisher from Wittwer, C. T., Reed, G. H., Gundry, C. N., Vandersteen, J. G., Pryor, R. J. [2003]. High-resolution genotyping by amplicon melting analysis using LC Green. *Clinical Chemistry*, 49, 853–860. Copyright AACCC.)

TABLE 48.4 Characteristics of Massively Parallel Sequencing Methods						
Method	Principle	Detection	Clonal	Run Time	Output Per Run	Read Length (bp)

Massively Parallel Sequencing

Compared with dideoxy-termination sequencing, MPS generates up to 1 billion more bases of sequence data in one operation at 10,000 to 100,000 times lower cost per base. Several methods are available that continue to evolve. As the cost, turn-around time, and convenience of these methods continue to decrease, they will be used increasingly in the clinical laboratory. Characteristics of MPS methods are summarized in Table 48.4.

Sequencing From Clones

Clonal sequencing methods start with producing a shotgun (random) library of fragments that are typically 70 to 1000 bases in length, although some methods require 6- to 20-kb fragments. Fragmentation is usually physical or enzymatic. Physical methods include sonication, acoustic shearing, and hydrodynamic shearing. Enzymatic fragmentation can be from restriction endonucleases or nonspecific DNases.

Adapter sequences are typically added to each end of the random fragments. The primary role of these **adapters** is to provide common priming sites for each fragment to initiate MPS reactions. One primer set amplifies a massive array (beads or planer flow cell) of library **inserts**. Adapters also facilitate initial capture of DNA fragments onto solid surfaces and spatially restrict clonal amplification products generated from the fragments onto beads or spots on an array surface. If multiplexing of different DNA samples is desired, a sequence “barcode” is added to identify which DNA sample the clone arose from. A typical library insert with adapters and a barcode is shown in Fig. 48.23A. The libraries are then partitioned according to size to select a band optimal for the downstream sequencing technology. Clonal amplification is usually performed by either emulsion PCR or bridge amplification.

Fig. 48.23 Diagram of different library formats used in massively parallel sequencing. (A) Two adapters that include consensus polymerase chain reaction priming sites are ligated onto each end of the library inserts produced by fragmentation. If multiplexing different samples is desired, a barcode is added so that each read can be assigned to a specific sample. (B) A library insert is bounded by hairpin adapters that allow primer binding to the single-stranded loops on each end for rolling circle amplification.

Emulsion polymerase chain reaction. In emulsion PCR, one strand of a library element is captured on one bead and is clonally amplified inside a water-in-oil droplet, generating a bead covered with single-stranded PCR products (Fig. 48.24). The emulsion is formed by mixing beads (each covered with one primer), aqueous PCR components (including the other primer, polymerase, and dNTPs), and a mixture of oils under agitation to ideally form droplets that each contain only one bead and one library insert. The two primers are complementary to the adapters; one coats the bead surface, and one is free in solution. During emulsion PCR, all of the beads are amplified together in aqueous microdroplets dispersed in oil. After PCR and denaturation, millions of copies of identical single-stranded PCR products are on each bead with each bead carrying distinct, oriented inserts flanked by the adapters. The emulsion is then broken and, after the elimination of empty beads, is ready for sequencing.

Bridge amplification. Bridge amplification generates clusters of single-stranded PCR products tethered to the surface of a planar flow cell (Fig. 48.25). In contrast to the clonal bead generation of emulsion PCR, the amplification occurs on a flat surface. The primers, complementary to the adapters, are both attached to the surface, either randomly or in a fixed pattern. The library DNA is then denatured to form single strands that hybridize to the primers on the surface. After extension of the surface-bound primers, the original template strands are washed away under denaturing conditions. What follows is called bridge amplification, which is very similar to PCR except that both primers are bound to the surface, so that single strands bound to the surface must bend over to find their opposite primer, resulting in a double-stranded bridge after extension. Instead of denaturing with heat as in PCR, the flow cell is kept at 60°C, and a chemical denaturant is introduced to dissociate the two bridge strands, except now both strands are attached to the planar surface. When the flow cell is flushed with a polymerase and dNTPs under favorable extension conditions, both can find new primers to form additional bridges. The process repeats until about 1000 copies are formed. One of the bound primers can be designed to include a cleavable site (either chemical or enzymatic) so

that one strand can be removed after denaturation, providing an amplified template for sequencing.

Sequencing by Synthesis

Sequencing by synthesis can be detected by (1) pyrophosphate release, (2) a pH decrease, or (3) fluorescence. Clonal amplification methods allow parallel observation of thousands to millions of strand extensions, greatly increasing the signal strength. However, the extensions must be controlled at each step because continuous strand extension would not remain synchronous between strands. This is achieved by immobilizing the clones into arrays so that reagents can be applied sequentially (no pun intended).

Pyrosequencing. Clonal beads are fitted into picoliter reaction chambers formed in etched individual fibers of a fiberoptic cable. Solutions of nucleotides are passed over chambers one at a time under conditions that favor extension. If there is a base match, the nucleotide will be incorporated, and pyrophosphate will be released, producing light. The light is captured by the individual light fibers and is detected on a sensitive camera. If more than one base occurs in a row (a homopolymer stretch), multiple bases of that nucleotide will be incorporated, and the signal will be proportionately higher.

Semiconductor sequencing. Similar to pyrosequencing detection, clonal beads are used as templates. However, the beads are arrayed on semiconductor sensors modified to detect pH changes. The chip does not detect light but a slight change in pH as a consequence of dNTP incorporation. By leveraging semiconductor technology, these pH chips have rapidly increased in performance by decreasing the size of the beads and sensor wells, and increasing the size of the chip. Run times are as short as 3 to 4 hours.

Reversible fluorescent terminators. After bridge amplification on a planar flow cell, four fluorescent nucleotides are passed through the flow cell under conditions that favor extension. Each nucleotide has a different fluorescent label so that each can be distinguished by color. Furthermore, the fluorescent terminators are reversible, which means that the blocked 3'-end can be regenerated by simple chemical means

Fig. 48.24 Emulsion polymerase chain reaction (PCR). Two adapters (adapters A and B) are randomly ligated to DNA fragments. Adapter B has a biotin on its 5' end. Fragments with adapter B on one or both ends are captured by streptavidin beads, but fragments with only adapter A are washed away (not shown). Then the fragments are denatured, and the free strand with adapter A and adapter B at each end is collected (fragments with adapter B on both ends will not be released from the streptavidin bead). One molecule of the single-stranded template is then captured on a bead coated with adapter and is encapsulated inside a water-in-oil droplet that contains PCR reagents and primers. After PCR, the emulsion is broken, and the DNA is denatured. This generates a bead with a large number of clonal single strands tethered to it. The bead is then deposited into one of many wells on a fiber optic or onto a glass slide for sequence analysis (not shown).

provided in the flow cell. Each cycle involves (1) adding polymerase and dNTPs as fluorescently labeled terminators under conditions that favor extension, (2) washing the flow cell, (3) imaging the fluorescence, (4) cleaving the fluorescent terminator, and (5) washing the flow cell. Output per run is up to 600 gb in 1 day.

Fig. 48.25 Bridge amplification. Two adapters (adapters A and B) are ligated to a DNA template. After they are diluted and denatured into single strands, the template is captured onto a flow cell surface by annealing to one of the two surface-bound primers that share sequences with adapter A or B. The polymerase reagent introduced into the flow cell extends the primer and generates the complementary strand of the template. The denaturant (usually sodium hydroxide) is introduced to the flow cell to release the original template strand. The free end of the newly synthesized strand anneals to a nearby primer by bending over, and a second round of reagent addition catalyzes the synthesis of another complementary strand. By repeating many of these cycles, a clonal cluster that consists of about 1000 copies of single-stranded template tethered to the surface is generated. This cluster is still a mixture of both complementary strands. One of the strands is selectively eliminated by treatment with periodic acid that cleaves a diol linkage present in one of the surface-bound primers (open triangle on red primer). The cluster now contains only one of the template strands and is ready for sequence analysis.

Single-Molecule Sequencing

Single-molecule sequencing methods do not require template amplification. Base reads do not require syncing with other clonal strands because there are none. Sensitive optical or electronic methods are required to detect base sequence in a single molecule. If long reads and high accuracy are achieved,

advantages include efficient sequence assembly, analyses of repetitive sequences, de novo sequencing, mapping of chromosomal rearrangements, and fusions. In contrast, MPS methods usually generate short sequence reads (30 to 700 bases long) that have to be aligned and analyzed to derive a consensus, then stitched together by software, and compared with reference genome sequences.

Real-time single molecule sequencing with fluorescent nucleotides. Library preparation is unique for this method because fragmentation is tuned to provide 10-kb inserts, and the adapters are designed as hairpins. The result is a double-stranded insert bounded by identical 27 base single-stranded loops on each end (see Fig. 48.23B). Sequencing primers are annealed to the loop region and bound to a single polymerase molecule at the bottom of an optical waveguide. The waveguide allows single molecule detection of transient fluorescent labels that are covalently attached to the terminal phosphate of each dNTP. The four dNTPs are added to the wells with different labels that can be distinguished optically. When a fluorescent dNTP pairs with its complement near to

the polymerase active site, it is in a perfect position for fluorescence detection. After being incorporated into the growing strand, the terminal fluorescent label (attached to pyrophosphate) diffuses away from the polymerase. The fluorescent signals are acquired continuously at high speed as the primer proceeds around the loop by **rolling circle amplification**. The process can be stopped after one loop or continued for multiple reads.

Nanopore sequencing. Another single-molecule sequencing approach that does not require amplification and uses electronic, rather than optical, detection is nanopore sequencing. Single DNA strands are channeled through nanopores formed by immobilized proteins. Passage of DNA bases through the protein nanopore generates characteristic electrical signals that can reveal the identity of the bases traversing the nanopore. In essence, this is similar to a nanosized Coulter counter that quantifies base differences on a single strand of DNA. Kilobases of NAs can be sequenced in a single read. The method is non-destructive and can discriminate methylated DNA bases as well as normal bases.

REVIEW QUESTIONS

1. PCR requires:
 - a. Product annealing
 - b. Primer denaturation
 - c. Polymerase denaturation
 - d. Primer annealing
2. Restriction fragment length polymorphisms:
 - a. Restrict the length of polymorphisms
 - b. Require treatment with a restriction enzyme for visualization
 - c. Are polymorphisms in restriction enzymes
 - d. Are commonly visualized by massively parallel sequencing
3. Which method does not use electrophoresis?
 - a. Single nucleotide extension
 - b. PCR/RFLP
 - c. Dideoxy-termination sequencing
 - d. Pyrosequencing
4. Hybridization probes:
 - a. Are the same as hydrolysis probes
 - b. Can consist of one or two probes
 - c. Irreversibly lose fluorescence once hybridized
 - d. Never function by resonance energy transfer
5. Real time PCR:
 - a. Is a qualitative assay
 - b. Can be observed during amplification
 - c. Never uses fluorescence
 - d. Requires melting analysis
6. How fast can PCR be performed?
 - a. In about an hour
 - b. In 15 minutes
 - c. In 5 minutes
 - d. In less than 1 minute
7. Massively parallel sequencing:
 - a. Costs more per base than dideoxy sequencing
 - b. Is simpler than dideoxy sequencing
 - c. Is more descriptive than *next generation sequencing*
 - d. Has a fast turnaround time
8. Single molecule sequencing:
 - a. Can produce longer read lengths than typical massively parallel sequencing
 - b. Is less informative than massively parallel sequencing
 - c. Makes it difficult to haplotype 2 variants
 - d. Is impossible
9. DNA melting analysis:
 - a. Is expensive and time consuming
 - b. Is performed before PCR
 - c. Plots fluorescence and temperature to produce melting curves
 - d. Is destructive
10. Hydrolysis probes:
 - a. Are reversible
 - b. Increase fluorescence after the probe is hydrolyzed
 - c. Are very good for melting analysis
 - d. Are less specific than DNA dyes

Molecular Applications

*Frederick S. Nolte, D. Hunter Best, Todd William Kelley, Jay L. Patel,
Evi Lianidou, Dave S.B. Hoon, Rossa W.K. Chiu, Y.M. Dennis Lo*

OBJECTIVES

1. Describe the role of HIV-1 viral load testing in monitoring antiviral resistance testing.
2. List common organisms that cause upper respiratory infections and how they can be detected.
3. Describe the clinical specimens and procedures used for collecting specimens of *Chlamydia trachomatis* and *Neisseria gonorrhoeae*.
4. Discuss the role of the human microbiome in health and disease.
5. Describe the difference between autosomal dominant, autosomal recessive and X-linked diseases.
6. List common genetic disorders and their mode of inheritance.
7. Explain the advantages that massively parallel sequencing has over traditional testing methods.
8. List the types of genetic abnormalities that are recurrent in hematopoietic malignancies.
9. Describe the testing strategies that are necessary to reliably detect the spectrum of genetic abnormalities in hematopoietic malignancies.
10. Discuss the role of the *TP53* gene in cancer.
11. What are the different forms of ctDNA detectable in cancer patients?
12. Detail why viral ctDNAs are useful for cancer monitoring.
13. What are the differences in ctDNA and CTC in terms of assay merits?
14. Describe the biological properties of cell-free fetal DNA in maternal plasma.
15. Explain the methodological principles of fetal chromosomal aneuploidy assessment based on circulating cell-free fetal DNA analysis.
16. Detail the analytical issues pertinent to successful circulating cell-free fetal DNA analysis.

KEY WORDS AND DEFINITIONS

Antiretroviral therapy (ART) A regimen and schedule of drugs aimed at slowing or eliminating the replication of an RNA virus. Most effective therapies include multiple drugs.

Autosomal dominant A disorder where the dysfunction of a single allele is sufficient to result in a phenotype.

Autosomal recessive A disorder where the dysfunction of both copies of a gene (one inherited from each parent) is necessary for a phenotype to manifest.

Cell-free fetal DNA (cffDNA) DNA fragments derived from the fetus, mainly of the placenta, found in the circulation of pregnant women. The access of cffDNA allows for noninvasive DNA-based prenatal assessment of the fetus.

Circulating tumor cell free DNA(ctDNA) Circulating tumor cell-free DNA detected in body fluids such as blood. Can be used to detect actionable genomic aberrations such as mutations, deletions, amplifications, and fusions in cancer patients.

Circulating tumor cells (CTC) Circulating tumor cells detected in the blood of cancer patients. More prevalent in advance stages of disease; useful for the evaluation of disease recurrence, prognosis, and therapy response.

Fetal fraction The proportion of fetal DNA in relation to the total amount of DNA detectable in plasma of pregnant women.

Fluorescence in situ hybridization (FISH) A targeted technique for assessment of large scale chromosomal abnormalities such as translocations or large copy number variants.

Fusion transcript Abnormal mRNA transcript that contains a portion of one gene fused to a portion of another, which results from the presence of a chromosomal translocation.

Karyotype Low resolution pan-genomic technique for identifying large scale structural chromosomal abnormalities such as monosomies, trisomies, deletions, duplications, and translocations.

Liquid biopsy Real-time monitoring of cancer evolution in the peripheral blood of cancer patients, based mainly on CTC and ctDNA analysis.

Massive parallel sequencing (MPS) A high-throughput DNA sequencing technology capable of generating data on a genomic scale over a short period of time.

Massively parallel sequencing panel A targeted technique for identifying variants (mutations) by massively parallel sequencing in a series of genes that are clinically associated with the same or related conditions; for example, myeloid malignancies.

Metagenomics The study of genetic material recovered from the environment.

Methylated ctDNA Methylation status, typically of gene promoter regions that may be hypo- or hyper-methylated in ctDNA.

Microbiome The spectrum of microorganisms in a particular environment.

Microdeletion A reduction in copy number in a subchromosomal region.

Microduplication An increase in copy number in a subchromosomal region.

Nucleic acid amplification test (NAAT) A molecular assay that identifies or quantifies a pathogen by amplification of its RNA or DNA, most commonly by the polymerase chain reaction or transcription-mediated amplification.

Quantitative polymerase chain reaction (qPCR)

Amplification of a specific targeted short sequence, often to detect a genomic aberration, such as mutation, including single nucleotide variants, indels, deletions, or fusions.

Size-selection Methods to analyze DNA fragments of specified size ranges.

Syndromic testing Testing for a panel of microbes, any of which may cause a set of medical signs and symptoms.

Translocations An event that leads to the juxtaposition of a chromosomal segment to a region of a nonhomologous chromosome.

Viral load The number of viral genome copies per milliliter of blood.

Virologic failure A sustained viral load during antiviral therapy of more than a certain amount; for example, greater than 200 copies/mL for HIV-1.

Whole exome sequencing Targeted sequencing of all of the coding regions (and directly adjacent intronic regions) of all genes in the human genome.

X-linked A disorder caused by a gene located on the X chromosome.

There are many applications of nucleic acid molecular diagnostics in the clinical laboratory. Sometimes, the mere presence of DNA or RNA of a particular sequence provides a diagnosis. For example, HIV or *Escherichia coli* sequences are not expected in blood, allowing the diagnosis of infectious disease when their respective sequences are detected in blood. If sequence alterations in human genes affect function and can be passed to future generations, genetic diseases can be identified. Finally, sequence changes within an individual that develop during their lifetime that lead to malignant proliferations are useful to diagnose and monitor cancer. Currently, molecular diagnostics are most readily applied to infectious diseases, genetics, and cancer.

Here we describe specific applications of molecular diagnostics currently used to characterize and help treat patients with a variety of ailments, including infectious diseases, genetic diseases, and cancer. Included are hematologic malignancies and the study of circulating tumor cells (CTC) and circulating tumor cell free DNA (ctDNA). The chapter concludes with a description of using cell-free circulating nucleic acids for prenatal diagnostics.

INFECTIOUS DISEASE

Nucleic acid (NA) amplification techniques are now commonly used to diagnose and manage patients with infectious diseases. The growth in the number of US Food and Drug Administration (FDA)-approved test kits and analyte-specific reagents has facilitated the use of this technology in clinical laboratories. Technological advances in NA amplification techniques, automation, NA sequencing, and multiplex analysis have invigorated the field and created new opportunities for growth. Simple, sample-in, answer-out, molecular test systems are now widely available that can be deployed in a

variety of laboratory and clinical settings. Molecular microbiology remains the leading area in molecular diagnostics in terms of both the number of tests performed and the clinical relevance. NA-based tests have reduced the dependency of the clinical microbiology laboratory on more traditional antigen detection and culture methods and created new opportunities for the laboratory to impact patient care. A complete and current list of all FDA-cleared and FDA-approved microbial NA-based tests can be found at <http://www.fda.gov/Medical-Devices/ProductsandMedicalProcedures/InVitroDiagnostics/ucm330711.htm>. As examples of important applications, we focus on human immunodeficiency virus 1 (HIV-1) infection, sexually transmitted infections due to *Chlamydia trachomatis* and *Neisseria gonorrhoeae*, respiratory tract infections, and consideration of the human microbiome.

Human Immunodeficiency Virus 1

HIV-1, the causative agent of the acquired immunodeficiency syndrome (AIDS), is an RNA virus. Replication of the virus is complex and involves reverse transcription of the RNA genome into a double-stranded DNA molecule or provirus, which is integrated into the host genome. The HIV-1 reverse transcriptase (RT) enzyme does not have proofreading capabilities, leading to the significant genetic diversity of HIV-1.

The management of patients with HIV-1 infection was transformed by tests that measure the concentrations of HIV-1 RNA in blood (viral load testing) and tests for resistance to antiviral drugs. With these tools, it is possible to maximize the effectiveness of antiretroviral therapy (ART) for an individual, one of the earliest examples of “personalized medicine.”

The first HIV-1 viral load test was approved by the FDA in 1996 and rapidly became the standard of care for monitoring response to ART. Most clinical laboratories are currently

using real-time reverse transcription-polymerase chain reaction (RT-PCR) assays to monitor HIV-1 viral load. Early studies found that patients who have higher viral loads progressed more rapidly to AIDS and death than those with low viral loads. The intra-assay imprecision of HIV-1 viral load assays is approximately 0.12 to 0.2 log₁₀ copies/mL. The biologic variation of viral load in patients not receiving antiretroviral therapy is approximately 0.3 log₁₀ copies/mL. Consequently, changes in viral load greater than or equal to 0.5 log₁₀ copies/mL suggest a significant change in viral replication.

Viral load testing is now widely accepted as a marker of response to ART. After treatment is initiated, viral load testing is crucial for monitoring the response to therapy. The standard of care is to treat with a combination of antiretroviral drugs, which are classified based on their viral targets. After the initiation of appropriate therapy, there is typically a 2 log₁₀ or greater decrease in viral load within 2 to 3 months. Data have shown that the lower the absolute viral load, the better the clinical and virologic outcomes. Guidelines recommend quantifying plasma HIV-1 RNA immediately before initiating therapy and 2 to 8 weeks later, with the goal of achieving an undetectable viral load level (<20 to 50 copies/mL) within 16 to 24 weeks of initiating therapy. It is important to determine early in the treatment course if there is suboptimal viral load suppression, so that factors affecting adherence can be assessed and, if needed, the regimen altered. After the initial response has been characterized, the viral load should be monitored every 3 to 4 months to ensure that the response to therapy is sustained.

Of note, viral blips (defined as a detectable viral load usually <400 copies/mL) occur in successfully treated individuals and are not predictive of virologic failure. For this reason, *virologic failure* is defined as a sustained viral load of more than 200 copies/mL.

Viral load testing also aids in the diagnosis of acute HIV-1 infection (the window period after infection that occurs before detectable antibody production), although the currently available viral load assays are not FDA approved for diagnostic purposes. During this period of early infection, patients typically have very high viral loads ranging from 10⁵ to 10⁷ copies/mL.

A proviral, PCR DNA test, although not FDA cleared, is helpful in neonates born to HIV-1-infected mothers receiving ART. Both antiretroviral agents and maternal antibody cross the placenta. Antiretroviral agents can suppress the replication of the virus in neonates, and RNA tests can be falsely negative early after birth. Maternal HIV-1 antibody can persist in neonates for up to 2 years after birth and is therefore not a reliable marker of neonatal infection.

Viral load testing is routinely performed on plasma specimens, and ethylenediaminetetraacetic acid (EDTA) is the anticoagulant of choice. Acid-citrate-dextrose (ACD) is also an acceptable anticoagulant, but blood anticoagulated in heparin is unacceptable for most tests. It is critical to minimize the risk of RNA degradation during specimen collection and transport. Plasma should be separated within 6 hours of collection and ideally stored at -20°C, although plasma viral RNA is stable at 4°C for several days. Special blood collection containers, or tubes, are available that contain a gel that

provides a physical barrier between the plasma and cells after centrifugation. The tubes can be shipped without the need to transfer the plasma into a separate tube. Tubes should not be frozen before pouring off of the plasma because this may lead to falsely elevated viral load assays.

The clinical utility of antiviral resistance testing in HIV-1-infected individuals is well established and should be performed in the following situations: (1) before the initiation of ART in treatment-naïve patients, (2) to guide the selection of active drugs when changing antiretroviral regimens, (3) for the management of suboptimal viral load reduction, and (4) in all pregnant women before the initiation of therapy.

HIV-1 resistance testing can be done by genotypic or phenotypic methods. Genotypic assays identify specific mutations or nucleotide changes that are associated with decreased susceptibility to an antiviral drug. Phenotypic assays are performed by the creation of a pseudoviral vector, and by measuring its replicative capacity in varying concentrations of a drug and comparing it with replication of wild-type virus. Both genotypic and phenotypic methods are used clinically for assessing antiviral resistance in patients, with phenotypic testing usually reserved for drug-experienced patients with complicated resistance profiles.

The first step in genotypic assays is the isolation of HIV-1 RNA from plasma followed by RT-PCR amplification and sequencing of RT protease and integrase genes. Analysis of the results involves sequence alignment and editing, mutation identification by comparison with wild-type sequence, and interpretation of the clinical significance of the mutations identified.

A limitation of currently used genotypic and phenotypic assays is that they can detect only those mutants that make up at least 20% of the total viral population. Regimens that are chosen based on resistance testing may not always be effective because the minority populations will quickly predominate in the presence of the drug. Drug selection pressure is also needed for some resistance mutations to persist at detectable concentrations in the viral population; when drug therapy is discontinued, the wild-type virus may quickly predominate. For this reason, it is recommended that specimens for resistance testing be obtained while the patient is on ART. The minimum viral load required for reliable resistance testing is approximately 1000 copies/mL.

POINTS TO REMEMBER

- HIV exhibits genetic diversity globally and within individual patients
- HIV RNA is the earliest marker of infection
- Viral load testing is a widely accepted marker of response to therapy with the goal of suppression to undetectable amounts
- Special care should be taken in sample processing to avoid spurious increases in HIV viral load tests
- HIV resistance genotyping should be performed on all therapy naïve patients prior to the initiation of antiretroviral therapy and in the selection of active drugs when changing therapy

SEXUALLY TRANSMITTED INFECTIONS

Chlamydia trachomatis and *Neisseria gonorrhoeae*

Testing for *C. trachomatis* (CT) and *N. gonorrhoeae* (NG) is discussed together because several of the available NA amplification tests (NAATs) for these pathogens are duplex assays. Although both CT and NG can cause a variety of clinical symptoms, the focus here is on genital infections.

The detection of CT is a challenging and important public health issue. CT is a major cause of sexually transmitted infections (STIs), with an estimated 1 million cases occurring annually among sexually active adolescents and young adults in the United States. More than half of the infections are asymptomatic. Even when symptomatic, the diagnosis can be missed as the manifestations are protean. In men, CT infection may present as urethritis, epididymitis, prostatitis, or proctitis; in women it may present as cervicitis, endometritis, and urethritis, with 10% to 40% of infections in women progressing to pelvic inflammatory disease (PID) if untreated. Related complications include chronic pelvic pain, ectopic pregnancy, and infertility. In the United States, CT infection is the likely cause of most secondary infertility in women. In pregnant women, there is the additional risk of transmitting the infection to the newborn during labor and delivery, leading to pneumonia or conjunctivitis in the newborn.

N. gonorrhoeae infection, too, may present in various ways, and the clinical presentations overlap with those of CT. Men may have acute urethritis with discharge, epididymitis, prostatitis, and urethral strictures. In women, NG infection can produce cervicitis, which, if left untreated, can lead to PID, abscesses, or salpingitis.

Traditional methods for the diagnosis of CT infection include cell culture, antigen detection by immunofluorescence, enzyme immunoassay (EIA), and nonamplified NA probes. These traditional methods have been replaced in most laboratories by amplified NA tests, which provide greater sensitivity in detecting CT from genital specimens. For NG, which was traditionally diagnosed based on culture methods that relied on selective culture media, NA testing does not offer significant improvement in sensitivity compared with culture. However, NA testing for NG offers a sensitive and reliable alternative to culture since it is easier to maintain the integrity of the target NA than it is to maintain the organism's viability.

In addition to high diagnostic and analytical sensitivity and specificity, NA testing offers several advantages over conventional culture and antigen detection methods for the diagnosis of CT and NG. Testing for both pathogens can be done on a single specimen, and for some duplex assays, testing is performed in a single reaction. The stability of NA avoids the necessity of immediate transport to the laboratory, and specimens may be stored refrigerated or at room temperature before transport. Transport and storage requirements vary among tests, so it is important to refer to the package insert for specific details. An additional advantage of NA testing is the use of urine specimens, which for women allows testing

to be done without the need for a pelvic examination. In men, urine offers a convenient and diagnostically sensitive alternative to collection with a urethral swab and increases the likelihood that asymptomatic men will agree to be tested.

NAATs for the detection of CT and NG from clinical specimens use a variety of specimens, including cervical and vaginal swabs, urethral swabs, and urine from both asymptomatic and symptomatic individuals. The diagnostic sensitivity of the tests varies according to the specimen type and whether the patient is asymptomatic or symptomatic. Interpretation of the results of NA testing for CT can be challenging because these assays are more sensitive than culture, which was previously used as the gold standard for clinical trials. For men, the diagnostic sensitivity of testing urine specimens is nearly equivalent to that of testing urethral swabs. A limited volume (20 to 50 mL) of first-passed urine is preferred because larger volumes will lead to a decreased concentration of the organism in the sample and thus reduce the diagnostic sensitivity. With proper specimen collection, male urethral swabs and urine specimens have a sensitivity of nearly 100% for the detection of NG or CT infection. For women, vaginal and cervical swab specimens provide the highest sensitivity for the detection of NG and CT infection, with many studies showing a sensitivity of 90% to 95%. Vaginal swabs are preferred because they are easier to collect. Urine specimens can be used, but they generally result in a lower diagnostic sensitivity than cervical swabs (75% to 85%). An alternative to urine testing in women is the use of self-collected vaginal swabs, which have been shown in some studies to have a diagnostic sensitivity that is equal to that obtained with cervical swabs. Because DNA can persist in urine samples for up to 3 weeks after completion of therapy, test of cure using NA testing is discouraged. If this must be done, then testing should be delayed for at least 3 weeks after therapy is completed to allow time for clearance of the pathogen DNA.

Other important sexually transmitted infections for which NAATs are now the standard of care include the protozoan *Trichomonas vaginalis*, herpes simplex virus, and human papilloma virus.

RESPIRATORY TRACT INFECTIONS

The viruses that infect the respiratory tract consist of large and diverse groups that cause disease in humans, and new ones continue to be discovered. The more common viruses that infect humans include influenza A and B, parainfluenza virus (PIV) types 1 to 4, respiratory syncytial virus (RSV), metapneumovirus, adenoviruses (>50 different types), rhinoviruses (>100 different types), and coronaviruses (5 types). The disease spectrum ranges from the common cold to severe life-threatening pneumonia. It is difficult to differentiate the viral origin based on signs and symptoms alone, and treatment options vary depending on the viral etiology. Infection with these viruses has demonstrated the potential for global public health threats of epidemic and pandemic proportions. The 1918 influenza A pandemic, the avian influenza A H5N1 in 1997, the severe acute respiratory syndrome (SARS)

coronavirus outbreak in 2003, the 2009 pandemic of influenza A H1N1, and the emergence of Middle East respiratory syndrome (MERS) coronavirus in 2012 are all reminders of the potential threats to human health posed by novel respiratory viruses. Detection of emerging respiratory viruses will require multiple modalities, but molecular methods have been crucial to their discovery and characterization, and in the development of diagnostic tools.

Acute respiratory viral infection is (1) a leading cause of hospitalization and death in infants and young children; (2) contributes to problems of asthma exacerbation, otitis media, and lower respiratory tract infection; and (3) exacerbates acute disease in immunocompromised and elderly patients. Rapid diagnosis aids in effective treatment and management.

Rapid antigen-based EIAs provide short turnaround times (TATs; minutes) but are hampered by poor diagnostic sensitivity and low positive predictive values compared with culture methods or molecular assays. Direct fluorescent antibody (DFA) detection assays for viral antigens on centrifuged cellular material from nasopharyngeal swabs, aspirates, or wash specimens demonstrate greater rates of detection than the rapid antigen assays and provide results in a relatively short time frame of 2 to 4 hours. However, detection rates are lower for antigen detection methods than for NAATs.

Cell culture methods, although slower than antigen detection methods, have been considered the gold standard for detection of a wide range of viral pathogens. In recent years, culture methods have been optimized for detection by combining multiple cell lines and improving the TAT from weeks to days through the use of shell-vial spin amplification cultures. Here, the patient's specimen is concentrated onto cells grown on a coverslip, and fluorescent antibody detection is performed after 16 to 24 hours of incubation instead of waiting for the development of a cytopathic effect. Although this has hastened the time to detection, 1 to 2 days is still required along with significant technologist labor, and it is not quite as sensitive as molecular methods of detection.

Molecular detection of respiratory viruses offers several advantages over traditional virologic culture or antigen detection. Most important, analytical sensitivity of molecular assays, primarily using PCR or real-time PCR, is consistently better than traditional methods. Results from molecular testing are more accurate, and thus the patient benefits from the most appropriate treatment decision; also, infection control practitioners can more effectively implement strategies to prevent or reduce nosocomial transmission. Molecular assays can be designed to detect a wide range of viral pathogens, including viruses that are difficult to culture.

Despite the advantages of NAATs for respiratory virus detection, their adoption by clinical laboratories was initially slow because of the limited capacity of real-time PCR assays for multiplexing. To provide comprehensive coverage for respiratory viruses, a panel of assays needed to be deployed, which is an approach not practical for many laboratories.

Currently, there are several FDA-cleared multiplexed respiratory virus panels capable of detecting up to 20 different viral targets, thus providing simplified approaches

to comprehensive diagnostics for respiratory viruses. See [Table 49.1](#) for an overview of the important parameters of these respiratory virus panels. These tests are truly transformative for the laboratory in that they can replace the combination of limited multiplex NAATs, antigen detection tests, and culture-based methods that were traditionally used in clinical laboratories to detect respiratory viruses and thus dramatically increase diagnostic yield.

One approach is multiplexed RT-PCR with fluorescently color-coded microsphere (bead) hybridization for simultaneous detection and identification of 17 respiratory viruses and subtypes (see [Table 49.1](#), column 1). The multiplexed RT-PCR primers amplify conserved regions of the viruses, and the products are labeled with biotin-containing deoxynucleotides in a second target-specific primer extension reaction. The extension product has a proprietary tag sequence incorporated for hybridization to the virus-specific probe on the color-coded bead. After hybridization, fluorescently-labeled streptavidin is bound by the biotin-labeled primer extension products, and the fluorescent signal is quantified on a flow cytometer. The instrument contains at least two lasers to identify the microbe by a color-coded bead and to detect the primer extension product. The data are recorded as mean fluorescent intensities. Because there are a number of post-PCR processing steps, care must be taken to avoid amplicon cross-contamination and false-positive results.

Another system is automated and provides sample-to-answer results with freeze-dried reagents to perform NA purification, reverse transcription, and nested, multiplex PCR followed by high-resolution melting analysis (see [Table 49.1](#), column 2). The respiratory panel on this instrument simultaneously detects 17 viral and 3 bacterial respiratory pathogens. The test is initiated by loading water and an unprocessed patient nasopharyngeal swab specimen mixed with lysis buffer into a single use disposable that is placed into the instrument. The software has a simple interface that requires only identification of the specimen and pouch barcode to initiate a run. Multiplexed two-stage RT-PCR followed by high-resolution melting analysis of the target amplicons is used to detect each of the panel analytes. Results are reported in an hour; currently, the instrument is designed to test a single sample per run, though multiple instruments can be linked. A second version of the panel with 45-minute analysis time, and a scalable, higher throughput instrument have recently been cleared by the FDA. Because it is a completely closed system, false-positive results caused by amplicon cross-contamination are not an issue. A version of this system has been Clinical Laboratory Improvement Amendments (CLIA) waived.

Another respiratory multiplex system uses electrochemical-detection-based DNA microarrays to detect PCR products from a multiplex PCR reaction (see [Table 49.1](#), column 3). These microarrays are composed of a printed circuit board consisting of an array of gold-plated electrodes. Each electrode is modified with a multicomponent, self-assembled monolayer that includes presynthesized oligonucleotide capture probes. NA detection is based on a sandwich assay principle.

ADV, Adenovirus; COV, coronavirus; EV, enterovirus; INFA, influenza A virus; INFB, influenza B virus; MPV, metapneumovirus; PCR, polymerase chain reaction; PIV, parainfluenza virus; RSV, respiratory syncytial virus; RV, rhinovirus.

Signal and capture probes are designed with sequences complementary to immediately adjacent regions on the corresponding target DNA sequence. A three-member complex is formed between the capture probe, target sequence, and signal probe based on sequence-specific hybridization. This process brings the 5' end of the signal probe containing electrochemically active ferrocene labels into close proximity to the electrode surface. The ferrous ion in each ferrocene group undergoes cyclic oxidation and reduction, leading to loss or gain of an electron, which is measured as current at the electrode surface using alternating-current voltammetry.

A simple sample-to-answer, self-contained cartridge has been developed that automates and fully integrates nucleic acid extraction, amplification, and electrochemical detection of 19 respiratory viruses and subtypes, and 3 bacterial respiratory pathogens. The analysis time is approximately 90 minutes and it is performed on a moderate throughput instrument. Each instrument is modular and scalable with one to four towers with each tower capable of processing 192 tests in 8 hours.

Yet another respiratory multiplex system uses PCR amplification and gold nanoparticle-labeled probes to detect target NA hybridized to capture oligonucleotides arrayed on a glass slide (see Table 49.1, column 4). Silver signal amplification

is then performed on the gold nanoparticle probes that are hybridized to the captured DNA targets of interest. The reader optically scans the slide for silver signal, processes the data, and produces a qualitative result for 13 respiratory viruses and subtypes and 4 *Bordetella* spp.

Molecular testing for respiratory viruses will likely continue to include tests designed to detect a limited number of viruses of particular importance (e.g., influenza A and B viruses and RSV), as well as tests that detect a broad array of viruses because there are clinical needs for both types of tests. The use of comprehensive respiratory virus panels greatly increases diagnostic yield and the ability to detect mixed viral infections. However, the clinical significance of mixed infections is not well documented or understood. In addition, there are test options that range from simple, “sample in answer out” systems to complex tests that require multiple manual steps, meeting different niches for various clinical laboratory settings. In fact, point-of-care molecular testing for respiratory viruses is now possible with the recent development of a CLIA-waived tests for influenza A and B viruses and RSV. Using isothermal amplification or real-time PCR these systems deliver results within 20 minutes and can be performed by nonlaboratory personnel with performance characteristics similar to those of NAATs performed in laboratories.

HUMAN MICROBIOME AND METAGENOMICS

Microbial inhabitants outnumber our own body's cells by about 10 to 1 and at a genomic level have 100-fold greater gene content than the human genome. Interest in elucidating the role of resident organisms in human health and disease has flourished over the past decade with the advent of new technologies for interrogating complex microbial communities. The microbiome is the totality of microbes, their genetic information, and the milieu in which they interact. It includes bacteria, fungi, viruses and phages, and parasites, but most of the emphasis to date has been on the bacterial component of the microbiome. However, progress is being made toward defining the human virome and the role that it plays in complex microbial communities.

Metagenomics refers to the concept that a collection of genes sequenced from the environment could be analyzed in a way analogous to the study of a single genome. Facilitated by advances in NA sequencing technology, this technology has permitted the study of microbial communities directly in their natural environment, thus bypassing the need for isolation and cultivation of individual species. We now know that the majority of microorganisms from the human body cannot be cultured *in vitro*. Most taxonomic metagenomic studies have used targeted sequencing of the phylogenetically informative regions of the 16s rRNA gene from bacteria because it has long been the gold standard method for bacterial identification, and there are large sequence databases and sophisticated analysis tools available. However, 16s rRNA gene sequencing does not provide enough information for comprehensive microbiome studies. To overcome the limitations of single gene-based amplicon sequencing, researchers have used whole genome shotgun sequencing on massively parallel sequencing platforms (MSP, also known as NGS—next-generation sequencing). Whole-genome approaches permit identification and annotation of diverse sets of microbial genes that encode many different biochemical or metabolic functions, thus providing functional metagenomic information.

Alterations of the microbiome in many different disease states have been described (Table 49.2). Establishing a causal link between microbiome changes and a specific disease often is challenging because most studies have been observational, the disease entities themselves may not be well defined, and the pathogenesis may be multifactorial.

However, it seems clear that future approaches in medical microbiology will be shaped in part by developments in metagenomics and human microbiome research. The identification of single agents of infection will be supplemented by techniques that will determine the relative composition of microbiomes in the context of different infections and other disease states. Recent evidence that recurrent *C. difficile* infections can be treated by reconstituting the normal colon microbiota in the patient by transferring feces from a normal donor is a good example of how a better understanding of changes in the microbiome composition can lead to effective treatments options. Differences in the composition of the microbiome

TABLE 49.2 Association of Human Disease With Changes in the Microbiome

Disease	Relevant Change
Psoriasis	Increased ratio of <i>Firmicutes</i> to <i>Actinobacteria</i>
Reflux esophagitis	Esophageal microbiota dominated by gram-negative anaerobes; gastric microbiota with low or absent <i>Helicobacter pylori</i>
Obesity	Reduced ratio of <i>Bacteroidetes</i> to <i>Firmicutes</i>
Childhood-onset asthma	Absent gastric <i>H. pylori</i> (especially cytotoxin-associated gene genotype)
Inflammatory bowel disease (colitis)	Increased Enterobacteriaceae
Functional bowel diseases	Increased <i>Veillonella</i> spp. and <i>Lactobacillus</i> spp.
Colorectal carcinoma	Increased <i>Fusobacterium</i> spp.
Cardiovascular disease	Gut-dependent metabolism of phosphatidylcholine

Modified from Cho, I., & Blaser, M. J. (2012). The human microbiome: at the interface of health and disease. *Nat Rev Genet*, 13, 260–270.

that may cause or contribute to noninfectious diseases may offer new opportunities for clinical microbiology laboratories to impact other areas of medicine. Finally, metagenomic techniques will facilitate the discovery of previously unrecognized pathogens and increase our understanding of how changes in the microbiome may contribute to infectious diseases.

Molecular microbiology will continue to be one of the leading growth areas in laboratory medicine as it becomes less technically complex and more accessible. However, now more than ever, clinical and financial outcomes data will be needed to justify the use of this often expensive technology in an era of declining reimbursement and increased cost consciousness.

GENETICS

Advances in technology and bioinformatics have revolutionized the field of human genetics. Examples of common inherited autosomal recessive, autosomal dominant, and X-linked diseases are presented here as examples.

Autosomal Recessive Disorders

An individual with an autosomal recessive disease has inherited two abnormal alleles at a given locus by receiving one mutant allele from each carrier parent; the disease-causing gene is on one of the autosomes (1 to 22) and not on a sex chromosome (X or Y). Typically, the carrier parents with one abnormal allele have no clinical features of the disease yet possesses a 50% risk of donating the mutant allele to his or her offspring. Matings in which both partners are carriers of an abnormal allele have a 25% chance of producing a child with both normal alleles, a 50% chance of having a child that has received only one abnormal allele, and a 25% chance of having an affected child. The affected patient may

be homozygous for a specific mutation by receiving the same mutation from each parent or may be a compound heterozygote having received a different mutation from each parent. The specific mutations present influence the clinical severity of the disease and account for variability in the expression of the disease between patients, referred to as genotype–phenotype correlation. Modifier genes and environmental factors also play a role in determining the patient’s phenotype. Among pedigrees illustrating autosomal recessive disorders, males and females are equally affected, and for rare diseases, consanguinity is likely to be observed.

Cystic Fibrosis

Cystic fibrosis (CF; Online Mendelian Inheritance in Man [OMIM] #219700) is one of the most common autosomal recessive diseases in people of Northern European ancestry with an estimated incidence in the United States of about 1 in 2500 and a carrier frequency of about 1 in 25. Within other ethnic populations, the disease has an estimated incidence of 1 in 2300 Ashkenazi Jews, 1 in 8500 Hispanics, 1 in 17,000 African Americans, and 1 in 35,000 Asian Americans. CF is a multisystem disorder characterized by progressive pulmonary disease, pancreatic insufficiency, elevated sweat electrolytes, male infertility, and a predisposition to sinonasal disease. An abnormal sweat chloride concentration is considered the gold standard for the diagnosis of CF, and a result of 60 mmol/L or greater is considered diagnostic of CF. Interestingly, the phenotypic expression of the disease is heterogeneous, ranging from meconium ileus and severe respiratory disease in infants to mild pulmonary symptoms and no evidence of gastrointestinal problems in adulthood. Atypical CF patients with a nonclassic presentation may have involvement of only one organ, as in congenital bilateral absence of the vas deferens (CBAVD), pancreatitis, rhinosinusitis, or nasal polyps. Variability in expression is explained by both allelic heterogeneity at the CF gene locus and genetic variation in modifier genes. Loss or decreased amounts of the disease-associated protein cause mucous accumulation and airway obstruction, recurrent infection with pathogens and excessive inflammation with progressive lung damage, and ultimately respiratory failure. Because morbidity and mortality are most related to severe lung disease, daily management of these patients is to prevent bacterial lung infections through physical therapy of the chest and early or aggressive treatments to eradicate bacterial colonization. Although originally considered a fatal childhood disease, the US Cystic Fibrosis Foundation reported that in 2008, more than 45% of patients were older than 18 years of age. Furthermore, the median survival age among approximately 23,000 patients with CF who received care through one of the nationwide CF care centers was 37.4 years with the life expectancy of patients born now in their 50s. The increase in survival age is due to organ transplantation, improved nutrition, and new therapies.

The severity and frequency of the disease led to an intensive search for the gene, which was eventually cloned in 1989. The CF gene maps to chromosome 7q31.2 with 27 exons encoding a transcript of approximately 6.5 kb. The CF transmembrane

conductance regulator protein (CFTR) has 1480 amino acids and is a member of the ATP-binding cassette (ABC) transporter superfamily of membrane transport proteins. The wide clinical diversity of CF is based in part on the varying effects conferred on this protein from the more than 2000 mutations reported within this gene.

Because CF is an autosomal recessive disorder, patients with CF must have two mutant *CFTR* alleles to develop the disease. Some mutations are “private” and unique to a family; others may be common among CF patients. More than half of all mutations are missense or frameshift mutations, with exon 14 containing the largest number of different disease-causing mutations. The types of mutations and frequencies of each differ significantly among populations.

The most common mutation, p.Phe508del (c.1521_1523delCTT) is detected in about 70% of CF alleles in whites of Northern European descent. This CFTR protein is misfolded and not properly processed by the endoplasmic reticulum with the majority of the protein rapidly degraded. Understanding the effect of various mutations on the CFTR protein is important for choosing the corrective drug therapy required for each patient.

The *CFTR* genotype and clinical phenotype correlations are most closely related for pancreatic involvement rather than for pulmonary manifestations of the disease. Most patients with two “severe” mutations, which cause a “severe” CF phenotype have pancreatic insufficiency, but patients with one or two “mild” mutations, which cause a “mild” CF phenotype have pancreatic sufficiency but have an increased risk of developing pancreatitis.

DNA testing for the identification of *CFTR* mutations is performed for a variety of reasons (Box 49.1). It is performed to confirm the diagnosis of disease in patients with equivocal sweat chloride results or when an insufficient amount of sweat is collected and no results are obtained from the test. The presence of two known pathogenic *CFTR* mutations is diagnostic for CF. A diagnosis of CF can be considered in the patient with a *CFTR*-related disorder such as chronic pancreatitis, CBAVD, or sinusitis. In known CF patients, mutation

BOX 49.1 Referrals for Cystic Fibrosis Transmembrane Conductance Regulator Mutation Analysis

- Confirm diagnosis of cystic fibrosis
- Determine prognosis
- Screen patient with pancreatitis
- Family member testing
- Newborn screening
- Preconception couples
- Expectant couples
- Prenatal testing—at-risk fetus
- Prenatal testing—hyperechogenic bowel
- Preimplantation genetic diagnosis
- Infertile male with congenital bilateral absence of the vas deferens
- Semen and oocyte donors

analysis can be requested to help predict the prognosis based on genotype–phenotype correlations and initiate mutation-specific treatment options. At the same time, identifying the *CFTR* gene mutations that are present in the proband and how they segregate in the family enables preimplantation diagnosis or prenatal testing for subsequent pregnancies and enables carrier or diagnostic testing for other at-risk family members. Similarly, state-sponsored newborn screening (NBS) programs have detected infants with CF and at the same time have identified at-risk family members, and have enabled carrier or diagnostic genetic testing.

Cystic fibrosis carrier screening may be offered as a single gene-specific test or may be included within high-throughput large carrier screening panels that detect both common *CFTR* gene mutations as well as targeted mutations in other genes. Although these more extensive panels provide additional information to patients, they contain genes for inherited conditions for which population-based screening is not recommended in current practice guidelines. A core panel of the most common mutations includes disease alleles with an estimated prevalence of at least 0.1% of CF mutations and a carrier detection rate of about 88% for non-Hispanic whites. Although CF is more common in the white and Ashkenazi Jewish populations, the standard of care is to make CF testing available to all preconception or expectant couples, especially because it is becoming more difficult to assign a single ethnicity to a patient to best determine the carrier risk. Counseling for CF carrier testing is complex and should include information about CF and *CFTR*-related disorders and the a priori likelihood of having a child with CF based on personal and family history and ethnicity. Furthermore, it is important for the patient to understand the inability of the screening panel to detect all CF mutations and the residual risk of being a carrier despite a negative test result. This is especially important for patients in ethnic groups for which the *CFTR* gene mutation detection level is reduced. The genetics professional should discuss the possibility of stigmatization or anxiety associated with being a carrier of a genetic disease and how knowing this information may affect her pregnancy. After DNA testing, it is very important for the genetics professional to know relevant family history when interpreting and reporting the test results to the patient and reproductive partner to accurately assess the risk to the couple of having a child with CF.

In families at risk for a child with CF, prenatal testing of the fetus may be requested. In these prenatal cases and for all DNA testing of fetal DNA, it is the standard of care that the DNA obtained from the fetus be tested for the presence of maternal contamination because the presence of maternal DNA can interfere with test result interpretation. This is best performed by using PCR amplification for highly polymorphic short tandem repeat loci coupled with capillary electrophoresis.

CFTR gene mutation testing is performed using a laboratory developed test or one of a variety of commercially available platforms with kits cleared by the FDA. The number of mutations detected by each assay is variable, and the

median turnaround time is 14 days. Furthermore, because the detection rate of the 23-mutation gene panel is lower in some ethnicities, laboratories serving such populations should consider supplementing this screening panel with additional mutation analysis. Although full gene sequencing by Sanger or massively parallel sequencing can be done to detect *CFTR* gene mutations, current practice guidelines do not recommend this for CF carrier screening. Rather, sequencing of the *CFTR* gene should be performed to confirm the diagnosis of suspected CF when no or only one *CFTR* gene mutation was detected with the 23 common mutation panel. If *CFTR* gene mutations are identified by sequencing in the proband, targeted analysis to specifically screen for that mutation in at-risk family members may be performed.

Autosomal Dominant Diseases

In autosomal dominant disorders, a single abnormal allele is sufficient to cause disease despite the presence of a normal allele. An individual with an autosomal dominant disease may have inherited an abnormal allele from an affected parent, or the mutant allele may have arisen de novo as a new mutation during gametogenesis in an unaffected parent. The disease-causing gene is on one of the autosomes (1 to 22) and is not on a sex chromosome (X or Y). An affected individual has a 50% risk of donating the mutant allele to each offspring. Different mutations within the gene may have varying effects on the protein, causing variability in clinical expression between patients who have pathogenic mutations. In some instances, known mutant gene carriers have no clinical symptoms of the disease, a phenomenon referred to as *reduced penetrance*; however, they still possess a 50% risk of donating the mutant allele to each offspring. Differences in phenotypic expression of the disease between patients who share identical gene mutations are commonly explained by the effects of modifier genes or environmental influences (or both). Among pedigrees illustrating autosomal dominant inheritance, both males and females are affected, and male-to-male transmission is observed (unlike X-linked inheritance).

Huntington Disease

Huntington disease (HD; OMIM#143100) is an autosomal dominant, late-onset neurodegenerative disorder with an incidence of about 3 to 10 per 100,000 in most populations but may be as high as 10 to 15 in some populations of Western European origin. First described by George Huntington in 1872, this progressive disease is characterized by choreic movement, cognitive decline, and ultimately dementia and psychiatric disturbances. The mean age of onset is between 35 and 44 years, but subtle changes in personality may be evident before diagnosis. Approximately 25% of patients first display symptoms after the age of 50 years, and about 5% to 10% of patients have juvenile HD with the age of onset before 20 years. The median survival time is 15 to 20 years after the onset of symptoms.

The molecular basis for HD is an expansion of a glutamine-encoding CAG trinucleotide repeat in exon 1 of the HD gene, *HTT*. Normal CAG repeat lengths range from 10 to 26,

repeats of 27 to 35 are considered intermediate or “mutable,” repeats of 36 to 39 are considered HD alleles associated with reduced penetrance, and repeats of 40 or greater are diagnostic of HD (Fig. 49.1).

HD is one of many trinucleotide repeat expansion diseases associated with neurologic and neuromuscular dysfunction. In HD, the number of CAG repeats is inversely correlated with the age at onset of the disease. Patients with onset as early as 2 years of life have a repeat number approaching 100 or greater, and late-onset-disease patients have repeat numbers of 36 to 39. Although the CAG-repeat number accounts for the majority of variance in age of onset for HD ($\approx 70\%$), the remainder of the variance comes from modifier genes and environmental factors.

The *HTT* gene contains 67 exons and encodes a novel protein, huntingtin (htt), with 3144 amino acids and a molecular mass of approximately 350 kDa. Htt is ubiquitously expressed in both neural and nonneural tissue with highest levels in the brain. Htt is required for neuronal development with the complete absence of htt being lethal in mice. Htt is predominantly localized in the cytoplasm, but lesser amounts are also found in the nucleus. Mutant htt with expanded polyglutamine tracks are effectively transcribed and translated, but as a result of the increase in glutamine residues, the protein is misfolded. This abnormal folding conveys a gain of function and an increased amyloid-like ability to form protein aggregates, sequestering other cellular proteins preventing their normal function, thereby disrupting normal protein homeostasis and conferring neurotoxicity. Interestingly, patients with two expanded CAG-repeat alleles do not have more severe disease than heterozygotes.

DNA testing for HD is performed using PCR to determine the CAG-repeat number. The most common method includes PCR with fluorescently labeled primers coupled with capillary electrophoresis to size the PCR products and determine the number of repeats.

Fig. 49.1 Schematic representation of the polyglutamine-encoding CAG repeat in exon 1 of the Huntington disease (HD) gene and associated alleles. A CAG-repeat number of 26 or less is considered normal. CAG-repeat numbers of 27 to 35 are intermediate, and although they are not associated with an abnormal phenotype, these alleles are susceptible to meiotic expansion to an HD allele. CAG repeats of 36 to 39 are considered HD alleles with reduced penetrance, indicating that both unaffected and affected patients have been reported with alleles of this size. CAG repeats of 40 or more are associated with HD with complete penetrance.

Many ethical issues are associated with HD testing, primarily as they relate to presymptomatic testing (Box 49.2). The approach used for presymptomatic HD testing has become the model for late-onset single-gene disorders, and similar formats have been applied to other late-onset inherited diseases. This model includes a multidisciplinary team involving neurology, psychiatry, and genetics specialists; pretest evaluation and counseling; individual support from family members or close friends; and posttest follow-up sessions. Predictive testing should be performed for patients 18 years of age or older and only with informed consent. Informed consent implies that the patient has been thoroughly counseled and clearly understands both the advantages and the disadvantages of knowing the results. An advantage of having this test is the removal of uncertainty regarding whether patients have or have not inherited the mutant allele and thus a feeling of relief for those who have not inherited a mutant *HTT* allele. This knowledge can help patients plan their career goals and personal affairs involving marriage, children, and long-term care insurance. Disadvantages of knowing this information include, but are not limited to, (1) the feeling of “survivor’s guilt” in those who learn that they have not inherited a mutant allele while other family members have, (2) fear from learning that they have inherited a mutant *HTT* allele and will develop this incurable disease, (3) potential risk of discrimination in employment, (4) concern for passing this gene on to their offspring, and (5) uncertainty of developing the disease if a mutant *HTT* allele with 36 to 39 CAG repeats is identified.

Because HD is a delayed-onset disease, as the asymptomatic at-risk patient ages, the risk of testing positive with an expanded CAG repeat decreases. Thus if the patient elects not to have predictive testing, the genetic counselor can provide information regarding the probability that an HD mutation exists, which, based on the individual’s age, may provide some comfort to the patient.

Prenatal testing for HD, another complicated issue associated with this disease, may not be provided in all laboratories

BOX 49.2 Ethical Issues Associated With Presymptomatic DNA Testing for Huntington Disease

- Patients must be 18 years of age or older.
- The decision to proceed with testing must be voluntary and informed.
- Genetic counseling regarding the benefits and pitfalls of testing is required.
- A support partner is needed for the patient for counseling and the testing process.
- Diagnosis of Huntington disease in the family should be confirmed by DNA testing before presymptomatic testing.
- Psychiatric assessment of patient is necessary before testing.
- Follow-up genetic counseling is recommended after delivery of results.
- Prenatal testing of fetuses is controversial; preimplantation diagnosis is available.

that perform routine HD testing for several reasons. Ethical issues include possible pregnancy termination for a late-onset disorder, presymptomatic testing of the child if the parents choose not to terminate, and technical issues that may compromise testing of chorionic villus and amniocentesis samples. As an alternative for prenatal testing, preimplantation genetic diagnosis (PGD) can be performed. In PGD, in vitro fertilization is used to produce embryos that then undergo a single cell biopsy for genetic analysis. After PCR testing has been used to determine the *HTT* CAG-repeat numbers, embryos with normal HD alleles are implanted. This method, which combines direct mutation analysis and PGD, eliminates the necessity for subsequent prenatal testing to determine the HD status of the fetus. Exclusion testing whereby only embryos who have not inherited an affected allele are implanted without disclosing information regarding the *HTT* CAG repeat numbers in all tested embryos is an option for some families that do not wish to know the genotype of the asymptomatic at-risk parent.

X-Linked Diseases

In X-linked diseases, the mutant allele resides on the X chromosome. In X-linked recessive diseases, females are heterozygous carriers of the disease with one normal and one mutant allele and are typically not affected. Males receiving the mutant allele from their mothers are considered hemizygous with one mutant allele and no normal allele. All daughters of affected males are carriers of a mutant allele. A carrier female has a 25% chance of transmitting her normal allele to a son; a 25% chance of having an affected son; a 25% chance of having a daughter who carries the mutant allele; and a 25% chance of having a daughter who receives her normal allele. In the absence of a family history, an affected male can have a mutant allele that arose de novo as a new mutation during gametogenesis in the formation of the egg. Roughly one-third of all cases of X-linked disorders represent de novo new mutations with the absence of a family history. In these cases, the mother is not a carrier of a mutant allele and is not at risk for having subsequent affected children. In pedigrees associated with X-linked recessive conditions, typically only males are affected, and male-to-male transmission of the disease is not seen. In less frequent, X-linked dominant diseases, one copy of the mutant allele is sufficient to cause disease despite the presence of a normal allele. In these disease processes, females are affected, and in males with only a single mutant allele, these diseases are often lethal.

Duchenne Muscular Dystrophy

Duchenne muscular dystrophy (DMD; OMIM #310200) is a fatal X-linked recessive disorder characterized by progressive skeletal muscle wasting. The incidence of DMD is about 1 in 3500 male births, making it the most common severe neuromuscular disease in humans. Classic DMD presents in early childhood, with delayed motor skills or an abnormal gait. This is followed by progressive muscle weakness, calf hypertrophy, and grossly elevated serum creatine kinase ($>10\times$ normal) caused by degenerating muscle fibers.

Progressive weakness initially affects the lower extremities, causing most DMD patients to require wheelchairs between 10 and 15 years of age. Continual degeneration and regeneration and inflammation of muscle eventually lead to the replacement of muscle tissue by adipose and connective tissue. Scoliosis is common and affects respiratory function. Chronic respiratory insufficiency develops in all patients. Cardiac disease is most commonly dilated cardiomyopathy (DCM) caused by cardiac fibrosis or rhythm and conduction abnormalities. Cardiorespiratory failure is the primary cause of death. Clinical management of patients with DMD is complex, requiring a multidisciplinary team approach. In addition to healthcare professionals, team members in the areas of psychosocial, gastrointestinal, pain, and speech and language are required. Although elevated serum creatine kinase (CK) levels can be measured from blood spots, NBS for DMD, enabling early identification of affected children and potential better outcomes from early intervention has not been implemented in the United States.

Because DMD is an X-linked recessive disorder, most carrier females are asymptomatic. Similar to other X-linked diseases, the varying degree of clinical manifestations among carrier females depends on the degree of inactivation of the X chromosome harboring the mutant *DMD* gene in various tissues where the DMD protein is expressed. Up to as many as 20% of carriers can display some symptoms of DMD. Most frequently observed is muscle weakness with elevated serum CK levels or cardiac involvement.

The *DMD* gene (Xp21.2) is complex and is one of the largest genes in the human genome, spanning 2.4 megabases. *DMD* contains 79 exons, representing less than 1% of the gene, and encodes a 14 kb mRNA. The gene has multiple tissue-specific promoters that transcribe various full-length dystrophin isoforms differing in their amino terminal sequences. The full-length protein product, dystrophin, contains 3685 amino acids; has a molecular weight of 427 kDa; and contains four distinct domains, including an actin-binding domain, a central rod domain with spectrin-like repeats, a cysteine-rich domain, and a unique COOH-terminal domain. Dystrophin is predominantly expressed in skeletal, cardiac, and smooth muscle.

DMD gene mutations are heterogeneous. Intragenic deletions encompassing one or more exons represent 70% of mutations and affect the translational reading frame of the protein leading to a truncated and nonfunctional protein. Duplications of one or more exons are observed in about 5% of patients. Point mutations account for the majority of remaining mutations, but small insertions, deletions, or splice site mutations are also detected.

Because of the tremendous size and diversity of mutations within the *DMD* gene, DNA testing for DMD presents a challenge for clinical laboratories. DNA testing confirms the diagnosis, identifies the pathogenic mutations segregating in the family, and enables targeted analysis for carrier testing of at-risk females as well as prenatal or preimplantation testing as requested. Deletion and duplication testing for all 79 exons is most frequently performed by multiplex

Fig. 49.2 Deletion/duplication analysis of the Duchenne muscular dystrophy gene in a female patient by multiplex ligation-dependent probe amplification (MLPA). (A) Wild-type (normal) alleles demonstrate a peak ratio of about 1. In this example, the patient is positive for a deletion of exons 45 to 48 (blue squares). Note that the deleted exons show a peak ratio of approximately 0.5. (B) Electropherogram data showing the reduction in peak height (y-axis, relative fluorescence) for exons 45 to 48 (arrows) in one haplotype (gray peaks) relative to the other control haplotype (blue).

ligation-dependent probe amplification assay (Fig. 49.2). This method determines whether each exon is present, deleted, or doubled compared with control DNA. Alternatively, microarray-based comparative genomic hybridization can be used for deletion and duplication screening. Sanger sequence analysis is typically performed for the remaining 30% of mutations. However more recently, targeted massive parallel sequencing (MPS) has been used for DMD analysis.

Although no curative treatment for DMD is available, innovative therapies are emerging. Recombinant adeno-associated virus vectors have been used to restore 90% of strength in *mdx* mice by delivery of shortened dystrophin gene constructs. Suppression of nonsense mutations causing premature truncation of the dystrophin protein generated by point mutations in about 10% to 15% of patients can be accomplished with some drugs. Alternatively, for the majority of patients with gene deletions or duplications, exon

skipping using antisense oligonucleotide therapy targeting specific exons has been successful for exon 51. Clinical trials for these and other drugs are ongoing. Alternative therapeutic approaches and new targets linked to the pathogenesis of the disease are being evaluated including use of the patient's stem cells, gene editing by homologous recombination, nonhomologous end joining, and increased expression of dystrophin similar proteins.

MASSIVELY PARALLEL SEQUENCING

Massively parallel sequencing is a high-throughput DNA sequencing technology capable of generating data on a genomic scale in a short period of days. One of the most significant advantages of MPS for diagnostic testing is the ability to target all genes known to be associated with a specific diagnosis (or phenotype) in a single test that is comparable

TABLE 49.3 Commonly Ordered Massively Parallel Sequencing–Based Gene Panels

Panel Name	Included Disorders ^a	Targeted Patient Group
Aortopathy disorders	Ehlers-Danlos syndrome (I, II, and IV), Loeys-Deitz syndrome, Marfan syndrome	Individuals with disease affecting any aortic section
Breast and ovarian hereditary cancer	Hereditary breast and ovarian cancer syndrome	Individuals with a strong family history of breast and ovarian cancer; individuals with early onset of breast or ovarian cancer
Cardiomyopathy disorders	Dilated cardiomyopathy, hypertrophic cardiomyopathy, long QT syndrome	Individuals with a suspected diagnosis of a hereditary cardiomyopathy disorder
Expanded carrier screening	Numerous (>100)	Individuals planning pregnancy or prenatal reproductive partners
Hearing loss	Keratitis–ichthyosis–deafness syndrome, nonsyndromic hearing loss, Usher syndrome	Individuals with a suspected diagnosis of either syndromic or nonsyndromic hearing loss
Hereditary endocrine cancer	Multiple endocrine neoplasia type 1, multiple endocrine neoplasia type 2, Von Hippel-Lindau disease	Individuals with a family history of endocrine cancer; individuals with a personal history of endocrine cancer
Hereditary gastrointestinal cancer	Familial adenomatous polyposis, juvenile polyposis syndrome, Lynch syndrome	Individuals with a personal or family history of gastrointestinal cancer
Noonan spectrum disorders	Cardiofaciocutaneous syndrome, Costello syndrome, Noonan syndrome	Individuals with a suspected diagnosis of Noonan syndrome or a related disorder
Periodic fever syndromes	Familial Mediterranean fever, Majeed syndrome, Muckle-Wells syndrome	Individuals with a suspected diagnosis of a periodic fever syndrome
X-linked intellectual disability	Rett syndrome, Duchenne muscular dystrophy, ornithine transcarbamylase deficiency	Individuals with intellectual disability inherited in an X-linked manner

^aThis is a selected list of commonly included disorders and is not comprehensive.

in price and turnaround time to that of Sanger sequencing for a single-gene analysis. These targeted gene panels are the most commonly ordered clinical tests using MPS technology. Before the development of MPS, testing patients for causative mutations in multiple genes that cause a single syndrome was a very expensive and time-consuming process. Table 49.3 lists some commonly ordered MPS-based gene panels. MPS also enables the sequencing of very large genes at a reasonable cost (e.g., the *DMD* gene). The flexibility of MPS selection and library preparation can provide a comprehensive test of more than 100 genes (e.g., an X-linked intellectual disabilities panel) or a more targeted panel that analyzes a handful of genes associated with a specific phenotype (e.g., a hereditary gastrointestinal cancer panel).

WHOLE-EXOME SEQUENCING

Whole-exome sequencing (WES) refers to an MPS-based DNA sequencing method that specifically targets the coding regions (exons) and directly adjacent intronic regions for the majority of the approximately 20,000 genes known to exist in the human genome. On average, WES is able to identify an underlying genetic alteration in approximately 25% to 50% of patients (depending on the inclusion criteria). This makes WES an effective diagnostic tool for patients with a phenotype that suggests an inherited disorder that does not fit the clinical characteristics of previously described syndromes.

WES has been implemented widely in clinical diagnostic laboratories in the United States, and thousands of patients have been tested by this method. WES should be considered in patients with a phenotype suspected to be caused by a

mutation in a single gene when known single-gene disorders have been eliminated. Careful consideration should always be given to the patient's presentation before determining whether or not WES is the appropriate test for a given phenotype. In many cases, a single gene test or a targeted MPS-based gene panel with multiple genes may be the appropriate first test to order.

Over the past several years, WES has proven to be an invaluable research tool in the discovery of the underlying genetic alterations for many Mendelian disorders. Identification of the underlying molecular alteration (and molecular pathogenesis) that results in a specific disease is the first step in developing treatment modalities. Because of the discoveries made by WES, the next decade will see a vast improvement in the treatment and underlying cause of many inherited disorders.

POINTS TO REMEMBER

- Autosomal dominant, autosomal recessive, and X-linked genetic diseases follow specific modes of inheritance, but imprinting disorders, and mitochondrial and complex diseases do not
- For most genes, pathogenic mutations are located throughout the gene
- For some disease genes, the type of mutation can predict the clinical phenotype and identify targeted therapy
- Diagnostic DNA testing is complicated by genetic and allelic heterogeneity
- Genetic counseling is an important component of patient care and management

GENETICS OF HEMATOPOIETIC MALIGNANCIES

Neoplasia of blood cells is often easier to diagnose and monitor than solid tumors because a simple blood draw usually allows access to tumor cells. Genetic aspects of hematologic malignancies include numerical and structural chromosomal abnormalities and smaller-scale genetic changes found within single genes.

Cytogenetics is very useful in the diagnosis of hematologic disorders. Conventional cytogenetics refers to visual analysis of a karyotype composed of a complete set of metaphase-arrested chromosomes typically stained by Giemsa (G-banding). G-banding highlights light and dark zones corresponding to A-T-rich and G-C-rich regions of chromosomes. This decades-old technique remains very important for the comprehensive bone marrow evaluation of patients with acute leukemia or a myelodysplastic syndrome (MDS). G-banded karyotyping enabled the discovery of many of the recurring translocations characteristic of specific hematologic diseases. Karyotyping provides a genome-scale perspective and is well suited for uncovering large-scale chromosomal aberrations (resolution >5 Mb) including reciprocal translocations, large deletions, and aneuploidy. Cryptic rearrangements and small insertions or deletions are likely to be missed by conventional karyotyping and require more sensitive techniques for detection. Karyotyping is a labor-intensive process that requires considerable expertise for performance and interpretation. In addition, because cell growth in culture is required, turnaround times often range from 3 to 7 days.

NUMERICAL CHROMOSOMAL ABNORMALITIES

Numerical chromosomal abnormalities are found in hematopoietic malignancies. For example, in B-cell acute lymphoblastic leukemia (ALL), the malignant cells can have variable numbers of chromosomes. Cases with greater than 50 chromosomes are referred to as hyperdiploid, while those with less than 45 chromosomes are designated hypodiploid. B-ALL with hyperdiploidy is seen in 25% of childhood disease and decreases in incidence with age. The prognosis is very good, and achievement of cure is highly likely with standard therapy. The number of chromosomes may be less important than the specific chromosomes involved. Patients with three copies of chromosomes 4, 10, and 17, so-called “triple-trisomy ALL,” have an excellent prognosis. Hypodiploid B-ALL is seen in less than 5% of patients overall. Prognosis is generally poor and appears to be correlated to the degree of chromosome loss, with near-diploid (44 chromosomes) and high-hypodiploid (40 to 43 chromosomes) patients faring relatively well. Low-hypodiploid (32 to 39 chromosomes) cases have a high frequency of mutations in the tumor suppressor gene, *TP53*.

Intrachromosomal amplification of parts of chromosome 21 can also occur as a primary genetic event in B-cell ALL and arises from the effect of “gene dosage” due to copy-number alterations of potentially hundreds of linked genes. This abnormality in B-ALL is associated with older age at

presentation and a low white blood cell count. It also fares poorly when treated according to standard-risk protocols and benefits from high-risk ALL therapy.

RECURRENT TRANSLOCATIONS

Many hematopoietic malignancies have structural chromosomal abnormalities, including balanced and unbalanced translocations and large-scale structural changes such as deletions or duplications. Some of these abnormalities are characteristic of certain disease subtypes and are thus repeatedly, or recurrently, found in different individuals with the same disease. Recurrent genetic abnormalities of all types are found across the spectrum of hematopoietic malignancies.

Chromosomal abnormalities may be detectable by conventional cytogenetics or may require more specialized molecular techniques. Fluorescence in situ hybridization (FISH) is a powerful tool that overcomes several limitations of conventional G-banded karyotype. FISH uses fluorescently labeled DNA probes designed to hybridize to specific sequences on metaphase or interphase chromosomal preparations. Resolution is improved to approximately 2 Mb. FISH allows the detection of cryptic chromosomal abnormalities, such as translocations or deletions, which may not be identifiable by routine karyotype. Many FISH probes are commercially available for recurrent abnormalities. Paraffin-embedded formalin-fixed samples can be used because FISH assays do not require viable cells or growth in culture. Break-apart FISH probes allow for identification of gene rearrangements without a priori knowledge of the translocation partner, of which there may be numerous possibilities. Global assessment of copy number changes is not possible by FISH because only a limited number of probes are utilized.

While some genetic lesions are disease defining, many have utility in diagnosis, prognosis, and clinical management. The nomenclature for chromosomal abnormalities is highly developed. Fig. 49.3 details the general format used to represent chromosomal abnormalities. As an example of a hematopoietic

Fig. 49.3 Format used to represent chromosomal abnormalities.

translocation, consider the 9;22 translocation found in some ALL and almost all chronic myeloid leukemias (CML).

B-cell ALL with t(9;22)(q34;q11.2) is a high-risk disease characterized by the production of a fusion protein with constitutively active ABL1 tyrosine kinase activity. This is the most common recurrent genetic abnormality in adult B-cell ALL patients and confers poor prognosis among all age groups. Patients may benefit from tyrosine kinase inhibitor (TKI) therapy in addition to traditional high-dose chemotherapy. While t(9;22)(q34;q11.2) is reliably detected by FISH, the type of *BCR-ABL1* fusions present should be confirmed by quantitative RT-PCR for the purposes of ongoing monitoring during treatment and minimal residual disease detection. The p190 kDa fusion protein is common in pediatric disease, while adult ALL patients typically have either the p190 form or the larger p210 form. The latter is also seen in almost all cases of chronic myelogenous leukemia (CML).

The 9;22 translocation was first discovered in 1960 as a recurrent chromosomal abnormality in patients with CML. This was followed 13 years later by finding a consistent reciprocal translocation between 9q34 and 22q11.2, resulting in a der(22q) (now known as the Philadelphia chromosome) found in virtually all cases of CML. Another 10 years would pass before the precise breakpoints were cloned, and it was shown that the translocation results in juxtaposition of the *ABL1* proto-oncogene on 9q34 to *BCR* on 22q11.2 with formation of a novel *BCR-ABL1* fusion gene. This results in constitutive ABL1 protein tyrosine kinase activity and dysregulated cellular proliferation. Documentation of t(9;22)(q34;q11.2); *BCR-ABL1* fusion is necessary for diagnosis and is readily demonstrated by metaphase cytogenetics, FISH and/or RT-PCR. Distinct *BCR-ABL1* fusion transcripts, which correspond to variably sized fusion proteins, are encountered based on the translocation breakpoints.

Quantitative RT-PCR is important in the clinical diagnosis and management of CML (Fig. 49.4). Routine molecular monitoring of response to TKI therapy in CML is the standard of care. Testing should be performed at diagnosis and periodically throughout the course of treatment. A three-log or greater reduction in *BCR-ABL1* transcript levels within 18 months of initiation of therapy is designated a major molecular response (MMR) and portends a high likelihood of a favorable long-term outcome. Quantitative PCR assays, therefore, should be designed and validated with clinically important levels of sensitivity in mind.

Patients with either CML or Ph+ B-cell ALL are treated with ABL1 TKIs. A subset of patients may develop acquired mutations in the tyrosine kinase domain of ABL1 that impede drug binding. When this occurs, patients will manifest signs of resistance typically evident in rising levels of *BCR-ABL1* transcripts detected by a routine quantitative RT-PCR. Many mutations have been identified, and dozens are recurrent across the spectrum of patients treated with TKIs. The identification of one or more mutations is important for clinical treatment because the sensitivity of *BCR-ABL1* to the available TKIs differs depending on which mutation is present.

In a subset of patients, particularly those who have been treated with multiple sequential TKIs, more than one mutation may arise in the same clone (i.e., on the same *BCR-ABL1* allele). These are commonly referred to as compound mutations, and they may impart resistance profiles that differ substantially from those seen when either mutation alone is present. Compound mutations tend to center around a dozen or so key residues that are frequently found mutated alone. Thus the typical sequence of events in the development of a compound mutation is likely similar in most patients. First, the acquisition and outgrowth of an initial single mutation (X) in a key residue occurs. This is followed by the acquisition of a second mutation (Y) in a clone harboring mutation X, thereby generating a new clone with two mutations (X + Y). At this time, both clone X and clone X + Y coexist in the patient, although clone X + Y may quickly dominate due to enhanced resistance properties. Strategies for analyzing and evaluating the complex clonal architecture in patients with *BCR-ABL1*-positive leukemias who have developed resistance mutations are often imperfect. Sanger sequencing is

Fig. 49.4 An example of quantitative reverse transcription polymerase chain reaction for enumeration of *BCR-ABL1* transcripts. The upper panel shows amplification curves for standards containing serial log dilutions of *BCR-ABL1* fusion transcripts ranging from 10^0 to 10^9 copies (solid lines) and an unknown patient sample (dotted line). The lower panel shows the standard curve for the reaction that plots cycle number versus the log of the template concentration. The quantification cycle is then used to quantitate the *BCR-ABL1* transcript copy number in the patient sample. For normalization purposes, total *ABL1* transcripts can be analyzed separately in an identical fashion to generate a copy number ratio of *BCR-ABL1* to *ABL1* referred to as the *normalized copy number*. The normalized copy number can then be converted to the international standard scale.

not typically useful because the data generated consist of a mixture of sequences and clonal relationships are mostly lost. Other techniques, such as massively parallel sequencing, offer more promise because the sequence data comprises single-molecule sequences and not mixtures, and therefore the clonal architecture is retained. Despite dramatic improvement in long-term survival, treatment of CML patients with TKIs does not typically result in cure.

Although we have focused only on the 9;22 translocation, many other recurrent translocations are found in other hematopoietic malignancies, including T-cell ALL, Burkitt lymphoma, follicular lymphoma, diffuse large B-cell lymphoma, mantle cell lymphoma, extranodal marginal zone lymphoma, multiple myeloma, anaplastic large cell lymphoma, AML, and MDS.

GENE MUTATIONS IN HEMATOPOIETIC MALIGNANCIES

Many different types of genetic abnormalities may be present in a neoplasm that are not detectable by karyotyping or FISH-based assays, but rather by molecular techniques such as PCR and sequencing. In some disorders, such mutations may be the only detectable genetic abnormality and are likely sufficient in and of themselves to promote development of the neoplasm. In other cases multiple single-gene mutations are present and may occur along with structural chromosomal abnormalities and/or translocations detectable by classical karyotyping or FISH and with epigenetic changes that must be queried by yet additional tests. Furthermore, copy number changes may be present and typically require additional, array-based technologies for detection.

Mutations can result from exposure to mutagenic agents (i.e., ionizing radiation or chemotherapeutic agents) or randomly during the process of DNA replication during cell division. Thus mutation rates at any particular nucleotide position depend on a variety of factors, including nucleotide stability due to genome context (e.g., homopolymer tracts or repetitive sequences) or chemical modification (e.g., methylation), the error rate of DNA synthesis, and the accuracy and effectiveness of DNA repair mechanisms. Mutations may therefore leave a signature with clues about the original mechanism that resulted in the error.

Mutations that correlate most closely with aging include C to T transition mutations that arise in CpG dinucleotides due to spontaneous deamination of 5-methylcytosine to thymine. Indeed, there is a positive correlation between the number of such mutations and the age of the patient at the time of cancer diagnosis. Chemotherapeutic alkylating agents such as cyclophosphamide also have a characteristic mutation signature involving C to T mutations. Interestingly, and perhaps not unexpectedly, there is also a positive correlation between the number of divisions of normal tissue stem cells and the rate of malignancies among tissue types. This finding suggests that the majority of malignant processes, including those involving the hematopoietic system, are derived from the evolution of chance mutations that occur during the process of DNA

replication and not from some environmental or toxic insult. Mutations that arise in a stem cell may be noncontributory to the process of malignant transformation. However, they remain a component of the malignant clone and are detectable if queried in an appropriate manner; for example, by whole genome sequencing. These have come to be known as “passenger” mutations and can sometimes be segregated from true disease “driver” mutations that occur in coding regions, at splice sites, or in RNA genes because they are not recurrent over large disease-specific patient cohorts. As more data are generated, the differentiation between passenger and driver will become easier.

Mutations in discrete cellular pathways and regulatory mechanisms are important in hematopoietic malignancies, particularly of myeloid origin. Although many genes may be recurrently mutated, there is a large degree of overlap among the various disease entities and there are few, if any, true disease-defining mutations. Generally the affected pathways may be classified into those involving signal transduction, epigenetic modifiers, RNA splicing, sister chromatid separation during meiosis and mitosis, transcription factors, and chromatin modifiers. The order in which mutations arise also appears to have consequences with respect to the overall clinical and pathophysiologic features of a disease process. There are many important genes in cellular and regulatory pathways with mutations that contribute to malignancy; only *BRAF* and *TP53* are covered here as examples.

Signal Transduction Pathways

Signal transduction pathways mediate cellular communication cell surface receptors. These receptors are often linked to tyrosine and serine/threonine kinases that serve to propagate the message, ultimately to the nucleus where the modulation of gene expression results in some change in cellular activity. Mutations that occur in signaling pathways tend to affect tyrosine kinase mediated signal transduction and often result in constitutively active tyrosine kinases. Activating mutations like these tend to result from recurrent so-called “hot spots” often in regulatory or enzymatic (i.e., tyrosine kinase) domains of these important signaling molecules.

BRAF p.Val600Glu mutations are present in nearly all cases of classic hairy cell leukemia and are absent in other B cell lymphoproliferative disorders, including those that may cause diagnostic confusion with hairy cell leukemia. The mutation promotes constitutive signaling through a multienzyme tyrosine kinase pathway that start at a cell surface receptor and ends with altered mRNA expression. Hairy cell leukemia is an indolent B cell lymphoproliferative disorder typically diagnosed based on immunophenotypic findings assessed by flow cytometry and/or immunohistochemistry along with characteristic neoplastic cells with “hairy” cytoplasmic projections. Although the diagnosis is typically straightforward based on the clinical and laboratory findings, there are occasional cases that can cause diagnostic difficulty. For these cases, identification of the presence of the *BRAF* p.Val600Glu mutation is diagnostically important. *BRAF* inhibitor therapies are available and have been used with some success in other tumors

with BRAF- (p. Val600Glu) activating mutation such as melanoma. In patients with hairy cell leukemia, the inhibition of BRAF and other protein kinases with drugs appears effective at inducing apoptosis.

TP53

The tumor suppressor p53 regulates a variety of critical anticancer functions and is nicknamed the “guardian of the genome.” Its functions include regulation of cell cycle entry and exit at various checkpoints, maintenance of cellular senescence, modulation of autophagy, and control of apoptosis. Patients with germline *TP53* mutations (Li-Fraumeni syndrome) have a very high risk for the development of cancers, often sarcoma or breast cancer. In general, dysregulation of p53-dependent signaling networks is a common feature of aggressive malignancies, including those of the hematopoietic system. Genetic abnormalities that result in loss of p53 activity include chromosomal deletions of the *TP53* gene locus on chromosome 17 (17p), loss of function mutations in the *TP53* gene, and epigenetic suppression of *TP53* expression.

In myeloid malignancies, *TP53* mutations are seen most frequently in patients with AML, MDS, and primary myelofibrosis. *TP53* mutations are loss-of-function variants, including insertions, deletions, nonsense mutations, and splice site mutations that result in the production of truncated protein products. In AML, *TP53* mutations may be associated with complex (three or more) karyotypic abnormalities and have an extremely poor prognosis. *TP53* mutations are commonly seen in a subtype of myeloid cancer that develops following exposure to cytotoxic chemotherapy for another malignancy called therapy-related AML or therapy-related MDS. The myeloid clones that expand following chemotherapy represent rare hematopoietic stem and progenitor cells with age-related *TP53* mutations, rather than newly induced *TP53* mutated clones.

Massively Parallel Sequencing in Hematopoietic Malignancies

Massively parallel sequencing as a testing strategy is becoming more commonplace in the clinical hematology laboratory and offers numerous advantages to traditional techniques. Currently, testing of gene panels, rather than whole exome or whole genome sequencing combine a relatively small number of gene targets, at least compared to the breadth of sequence covered by whole genome or whole exome sequencing. Panels are composed of genes that are recurrently mutated in a particular disease or class of disease. For example, a panel may comprise a few dozen genes frequently mutated in myeloid malignancies. To enhance the representation of specific gene targets for sequencing, PCR- or hybrid capture-based enrichment is commonly employed. The end result is very high coverage (usually greater than 1000×) of a clinically important set of targets. This degree of coverage depth yields test sensitivities that may be as low as 1% to 2% variant allele frequency, far better than what is possible by Sanger sequencing, but not as good as what is achievable by targeted allele-specific PCR assays or digital PCR.

The spectrum of genetic abnormalities present in hematopoietic malignancies requires the use of many complex testing strategies for comprehensive evaluation. These testing strategies include detection of translocations, copy number changes, gene mutations, and epigenetic abnormalities. As the number and type of clinically actionable genetic variants continue to grow, the laboratory evaluation of these patients will continue to be a multidisciplinary effort. Traditional clinical, laboratory, and pathologic methods remain central to patient diagnosis and management and are unlikely to be supplanted in the near future by genetic testing.

CIRCULATING TUMOR CELLS AND CIRCULATING TUMOR CELL FREE DNA

Classic tissue biopsies or surgical resections are invasive procedures that capture only a single snapshot in the evolution of a cancer in a patient. In contrast, a blood-based test or “liquid biopsy” has the potential to characterize the evolution of a solid tumor in real time by extracting molecular information from CTCs or ctDNA. Molecular characterization of CTCs and ctDNA holds considerable promise for the identification of therapeutic targets and resistance mechanisms, and for real-time monitoring of the efficacy of systemic therapies. The major potential advantage of CTC and ctDNA analysis is that they are minimally invasive and can be repeated during patient follow-up. With respect to the clinical laboratory, the development of targeted molecular assays as companion diagnostics, for disease monitoring, and even for early cancer detection are all possibilities at various stages of progression and during treatment regimens.

Cancer genomes are not static but change over the course of therapy. The term *liquid biopsy* refers to blood-based cancer testing and often involves detailed molecular analysis of the tumor from circulating genetic material in the peripheral blood. This genetic information is derived mainly from CTCs and ctDNA (Fig. 49.5). Liquid biopsy offers a simple and noninvasive insight into a patient's cancer using blood samples at any time.

The blood biopsy as a diagnostic, prognostic, and therapeutic tool is appealing because it is minimally invasive and is easily performed in a serial manner. However, there are still several concerns about its routine clinical use: (1) numerous technologies are available for the detection of cancer blood biomarkers, (2) more specific biomarkers are needed to assess treatment response and for evaluation of CTCs and ctDNA at specific stages of the cancer for accuracy, (3) well-designed comparison studies between liquid biopsy (CTCs and/or ctDNA) with conventional tissue biopsy samples are needed for validation, (4) it can be challenging to control the pre-analytical phase to obtain robust and reproducible results in some assay systems, (5) currently available techniques are costly and not easily reimbursable by healthcare, particularly CTCs, (6) multiple ctDNA assays have been developed and are available but none are FDA-cleared, while for CTCs, only one assay (CellSearch, Menarini Inc.) has been FDA-cleared, and (7) the TATs vary depending on the assay and can be longer than a week.

Fig. 49.5 Classic versus liquid biopsy approaches.

Circulating Tumor Cells

CTCs are rare cells that originate from primary or metastatic tumors that have managed to get into the circulation and that may extravasate to different organs. Only a small fraction of CTCs will develop into “true” metastasis. CTCs are a major player in the liquid biopsy cellular approach and may provide real-time information on a patient’s disease status. Cancer metastasis is the main cause of cancer-related death, and dissemination of tumor cells through the blood circulation is an important intermediate step that also exemplifies the switch from localized to systemic disease spread occurring.

The FDA has cleared CTC analysis for breast (2004), colorectal (2008), and prostate (2008) cancer using the CellSearch system based on the critical role that CTCs play in metastasis. However, this system is approved only for prognostic information, not for treatment decisions. CTCs are targets for understanding tumor biology and tumor cell dissemination in humans. Their molecular characterization offers an exciting approach to understanding resistance to established therapies and elucidating the complex biology of metastasis. Further research on the molecular characterization of CTCs should contribute to a better understanding of the biology of metastatic development in cancer patients and the identification of novel therapeutic targets. This approach may provide individualized targeted treatments and spare cancer patients unnecessary and triage into ineffective therapies.

Circulating Tumor Cells: Analytical Techniques

The isolation and further analysis of highly pure CTCs are difficult because these cells are extremely rare in the peripheral

blood, particularly in the early stages of cancer, therefore enumeration-based assays have been inconsistent and not robust. Typically, CTCs are isolated along with a background of peripheral blood mononuclear cells. The combination of high-throughput and automated CTC isolation technologies with generally accepted and validated downstream molecular assays is necessary for the routine use of CTC-based diagnostics.

CTC analysis includes isolation/enrichment, detection, enumeration, and molecular characterization. CTCs are highly heterogeneous, even within the same individual. This has been verified by using reliable single-CTC isolation followed by massively parallel sequencing to clearly reveal differences among CTCs. MPS technologies reveal that intra-tumor heterogeneity may reflect tumor evolution and adaptations that hinder personalized medicine strategies developed from results on single-tumor biopsy samples. CTCs present in blood provide a better picture for individualized treatments because they represent cells that have disseminated from both the primary tumor and cells from secondary metastases.

Circulating Tumor Cells and Breast Cancer

The clinical significance of CTCs has been extensively evaluated in patients with breast cancer. Many clinical studies have shown that CTC detection is associated with overall survival and progression-free survival in both early and metastatic disease. The detection of CTCs is a reliable prognostic factor in patients both with early-stage and metastatic breast cancer. Metastatic breast cancer patients with basal counts of 5 CTCs/7.5 mL of blood or greater have a poor prognosis, and enumeration of CTCs during treatment

predicts the progression of disease earlier than conventional imaging tests. In early breast cancer, CTC numbers are low, and molecular assays are most successful for detection. Quantitative RT-PCR (RT-qPCR) for cytokeratin expression in the peripheral blood of node-negative breast cancer patients is of prognostic value. Elimination of these cytokeratin mRNA-positive CTCs during adjuvant chemotherapy reflects successful treatment.

The main goal of adjuvant therapy is to prevent distant recurrences by targeting residual disseminated tumor cells. However, almost 70% of deaths in patients with early breast cancer occur after 5 years, showing that residual disease can be dormant for very long periods. Differences between primary tumors and CTCs could be of crucial importance for therapeutic decisions. In breast cancer, molecular characterization of CTCs may help identify therapeutic targets and resistance mechanisms and to stratify breast cancer patients.

In breast cancer, anti-HER-2 therapies are prescribed according to the HER-2 status of the primary tumor, as assessed by immunohistochemistry or FISH. However, a continuously growing body of evidence indicates that CTC HER-2 status can be different from that of the corresponding primary tumor. Moreover, CTC HER-2 status can change over time, particularly during disease recurrence or progression.

The HER-2 status of CTCs was correlated to the clinical response of HER-2-targeted therapies in a “liquid biopsy trial” in 2012. Patients who were HER-2 negative in the primary tumor but positive for HER2 in CTCs were randomized into two groups; one group received the anti-HER-2 drug trastuzumab, while the other received a placebo. After trastuzumab administration, the risk of disease recurrence was reduced, and the median disease-free survival was longer.

Endocrine treatment is the preferred systemic treatment in metastatic breast cancer patients who have an estrogen receptor (ER)-positive primary tumor or metastatic lesions. However, 20% of these patients do not benefit from this therapy and demonstrate further metastatic progress. A possible explanation for failure of endocrine therapy might be the heterogeneity of ER expression in CTCs. Similar to the HER-2 story, there is a growing body of evidence that hormone receptor status can change over time, especially during disease recurrence or progression in breast cancer patients. In this context, reevaluation of hormone receptor status by molecular characterization of CTCs is a strategy with potential clinical application. Optimal individualized treatment can be determined by characterizing ER status in CTCs and comparing it to the primary tumor.

Overall, CTC analysis is highly correlative to systemic disease and outcome in breast cancer patients. Monitoring of CTCs can predict early subclinical metastasis in disease-free patients and monitor progression during and after treatment. Many clinical studies support the potential utility of CTC detection in breast cancer. In addition, CTC analysis has been FDA approved for prostate and colon cancer diagnosis only, and shows promise in other cancers, including lung, melanoma, ovarian, pancreatic, head and neck, liver, and bladder.

CTC detection in disease-free post-surgical resection can be used to determine subclinical recurrence during follow-up in early and late stages of melanoma.

CIRCULATING TUMOR CELL FREE DNA

ctDNA isolation, detection, and analysis have significantly improved over the past two decades. ctDNA can be actively or passively released by tumor cells and enter different fluid compartments of the body such as lymphatics, urine, blood, semen, saliva, and cerebral spinal fluid. ctDNA may also be from CTCs that are disrupted in the bloodstream. ctDNA may have physiological functions that influence normal cells, particularly those adjacent to the tumor. The release of ctDNA may have direct effects on tumor microenvironment immune cells, as well as distant organ sites.

Types of ctDNA

Multiple forms of ctDNA exist in the blood of cancer patients (Fig 49.6). The most frequent ctDNA results reported are mutations. Tumor mutations in several cancers have drawn more attention because of the availability of respective targeted therapies that are FDA and CLIA approved in clinical oncology. However, in addition to mutations (single-nucleotide variants, small insertions and small deletions), there are additional types of genomic aberrations in individual cancers with potential utility. These potential targets include methylation of gene promoter regions of coding and noncoding genomic sequences, microsatellite loss of heterozygosity, DNA integrity, gene fusion, copy number variation, and cancer viral DNA.

These different types of ctDNA vary among individual cancer types, although some genomic aberrations can overlap, particularly with cancers of similar embryonic or carcinogenic origin. The clinical utility of one type of ctDNA in a specific cancer may not be the same for other cancers. For example, *BRAF* mutations are found in several cancers, including melanoma, colorectal, and lung, thyroid, and non-small cell lung cancer, but outside of melanoma they are only partially responsive in a subset of patients to anti-*BRAF* small molecule inhibitor therapies. *BRAF* inhibitors in melanoma have the highest response overall but duration is usually less than 2 years at best. Thus ctDNA *BRAF* mutations may potentially be useful for several types of solid tumor cancers. Several epidermal growth factor receptor (EGFR) mutation ctDNA assays have been FDA approved and are used to triage anti-EGFR treatment and monitor non-small cell lung cancer patients during treatment. Of all the ctDNA assays approved to date, EGFR mutation assays have been the most widely used and informative particularly when used with the different EGFR mutation-targeted therapies in carcinomas. This will in the future set precedent to develop new theranostic mutations of specific cancers.

Tumor-Specific ctDNA Mutations

Tumor-specific mutations in ctDNA are most commonly studied in cancer patients. Tumor mutations in ctDNA become

Fig. 49.6 Schematic representation of circulating tumor cell free DNA (ctDNA) in the systemic circulation. ctDNA arises from apoptosis or necrosis of primary and metastatic solid tumors and from degradation of circulating tumor cells (CTC). In the circulation, ctDNA is of variable size, can be quantified by an integrity index, and is often enriched with multiples of 180 bp fragments that wind around nucleosomes. In the circulation, ctDNA may be contained within vesicles, attached to nucleosomes or free in solution. Analysis of ctDNA can identify tumor mutations, microsatellite instability (MSI), loss of heterozygosity (LOH), and methylation patterns. Apoptosis of normal cells also results in circulating DNA that dilutes the variant fraction of abnormal DNA.

increasingly important when the mutations have approved targeted therapies as companion diagnostics and are associated with therapeutic response. ctDNA mutations can easily be assessed with high sensitivity and specificity by qPCR or MPS. Most mutations can now be detected in ctDNA as well as tumor tissue. Although concordance is still a logistic issue.

Assessment of ctDNA mutations in blood during treatment and follow-up provide information to the clinician about new mutations that were not present in the original tumor or start of therapy. New strategies for initiating targeted therapies based on ctDNA analysis (Fig. 49.7) may replace biopsy of metastases for new gene mutations arising during follow-up or use in situations where biopsy is not practical. Currently, clinical trials are underway to validate this logistic.

Methylated ctDNA

Methylated ctDNA is detectable in cancer patients and has utility in both early detection and treatment monitoring. Typically, gene promoter regions contain CpG sites that are hypermethylated or hypomethylated to control gene transcription. In cancer, the promoter regions of tumor suppressor genes may be hypermethylated to limit transcription, and oncogene transcription may be increased by hypomethylation. In the blood of cancer patients, methylated CpG ctDNA can be detected and used for prognosis and as biomarkers of treatment response. During tumor progression, gene promoters in tumor cells typically become hypermethylated. Normal cell regulatory genes can also change in methylation status and be used for methylated ctDNA analysis. Currently, only one assay for methylation of Septin gene is FDA approved for the detection of colon cancer.

Viral ctDNA

Several cancers have an etiology strongly linked to viral DNA integration. In these cancers, ctDNA can be tested for specific cell-free viral DNA. The advantage of assessing viral ctDNA is the high specificity and detection sensitivity because of the unique viral sequences. The most notable and extensive assessment for clinical utility of viral ctDNA is Epstein-Barr virus (EBV) detection in nasopharyngeal cancer, one of the most common malignancies in southern China and Southeast Asia. Patients with metastatic disease have a poor prognosis. EBV ctDNA is associated with treatment outcome prediction. Plasma EBV ctDNA is useful in screening early-stage nasopharyngeal cancer and is relatively low in cost. Radiotherapy and combination chemoradiotherapy are major treatment modalities, whereby in the setting of these treatments, plasma EBV ctDNA levels can help assess treatment response and outcome. Additional examples of viral ctDNA include human papilloma virus for head and neck cancer, and cervical cancer, and hepatitis virus B for hepatocellular carcinoma.

ctDNA Integrity

Another approach to evaluating ctDNA is to examine its size, often referred to as “integrity.” DNA fragment size can be used to determine the origin of cell-free DNA from either apoptotic or necrotic cells. Programmed cell death under normal conditions is accompanied by an organized degradation of the DNA, which results in small and uniform DNA fragments (approximately 140 to 200 bp). In contrast, cell necrosis, which is a frequent event in solid tumors, generates a wide spectrum of DNA fragment lengths, including those greater than 200 bp as a consequence of digestion. The

Fig. 49.7 Examples of circulating tumor cell free DNA analysis in cancer patients with multiple mutations. (A) A melanoma patient presents with a heterogeneous primary tumor with both mutation profile A (*MtA*) and mutation profile B (*MtB*). Initial circulating free DNA (*cfDNA*) assessment indicates a higher level of *MtA* as a consequence of being the predominant tumor subclone. After starting with anti-*MtA* therapy, *MtA* clones decrease, while *MtB* may increase. If the *MtB* burden increases, anti-*mtB* treatment can be initiated, potentially clearing both clones by personalized treatment. (B) A resected tumor of a patient with non-small cell lung carcinoma is analyzed, revealing the targetable mutation L858R in *EGFR* but missing a minor clone harboring *BRAF* V600E. After 1 year of anti-EGFR treatment, the patient relapses with a tumor harboring *BRAF* V600E. (C) Whole genome sequencing of *cfDNA* identifies both L858 *EGFR* and an underrepresented subclone with a V600E *BRAF* mutation. In this diagnostic setting, both targetable mutations could be considered for treatment selection and potential cure.

increased DNA integrity of cell-free DNA in different cancers can be quantified as an integrity index that compares long to short cell-free DNA, such as ALU sequences.

Multimarker ctDNA Assays

The approach of multimarker versus single-marker assays is clearly essential in most cancers. Because of tumor heterogeneity and continual genomic/epigenomic changes during tumor progression, multiple-marker assays are often necessary for diagnosis and monitoring. Furthermore, therapeutics can modify the molecular profile of tumors, particularly when drug resistance develops. Most patients with distant metastasis have inter- and intra-tumor molecular heterogeneity between clinical and subclinical metastasis. Multiple molecular biomarkers and platforms may be necessary to study different genomic/epigenomic aberrations and/or multiple targets efficiently within the tumor load of a cancer patient. Combination drug therapy is often required because monotherapy in many advanced-stage cancers is not sufficient to control long-term

tumor progression as in cutaneous melanoma, breast cancer, and colorectal cancer. Because signal pathways can change during tumor progression and resistance, more complete profiling of specific gene aberrations may be needed. Cancer genomic changes are complex. It is not surprising that multiple biomarkers and assays are needed for adequate patient monitoring and understanding disease progression. As we know, cancer is quite heterogeneous, so in genomic changes it is more important to have a panel of markers for efficient detection. For example, very few cancers have a single mutation at higher than 50% frequency. Other molecular biomarkers, such as circulating microRNA, are on the horizon and may improve the efficiency of circulating nucleic acid assays.

Comparison Between Circulating Tumor Cells and ctDNA

Both CTC and ctDNA technology and applications have greatly advanced in the last decade. Both assays provide some overlapping information as well as unique information for

specific cancers. CTC detection provides real-time information on tumor spread. If CTCs are sampled repetitively over days to weeks and are increasing in number, this may indicate that the tumor is progressing and active metastasis is occurring. Assessing the presence of CTCs in blood may be important before, during, and after therapy because their presence suggests potential metastasis and colonization in distant sites. Continued development of better molecular biomarkers for CTCs that predict survival and establishment of metastasis is important. Molecular characterization of CTCs in addition to quantification will provide more guidance for treatment decisions, particularly for targeted therapies. For example, the analysis of gene expression in a blood biopsy is only feasible in CTCs and not in ctDNA; this may be important for the detection of crucial therapy response biomarkers, such as androgen receptor splice variants and biomarkers indicating response to immunotherapy with checkpoint inhibitors.

ctDNA detection indicates there may be tumor present, but unlike CTCs, it does not indicate that metastasis is occurring. Consistent detection or increasing concentrations over time suggest that the tumor is active (progressing or rapidly renewing cell turnover). ctDNA assays require less blood, typically less than 2 mL, whereas most CTC assays require 7 to 10 mL. When the demand for other blood tests is high, the additional volume required by CTC assays can be a concern. Assays that require less blood will have better patient compliance, particularly for repetitive phlebotomy during treatment and follow-up. Table 49.4 compares the relative merits of CTC and ctDNA analyses.

The development of both CTC and ctDNA liquid biopsies provides many new opportunities for implementation over

the next 5 years. These assays, upon validation, may provide better clinical management in treatment monitoring and understanding of tumor progression for many different types of cancers. As new biosensors, molecular procedures, and molecular devices develop in both CTC and ctDNA analysis, the sensitivity and specificity, as well as logistics, will improve. With the resource of the cancer gene atlas (TCGA NIH USA: <http://cancergenome.nih.gov/>), there is a significant amount of sequencing data of multiple cancer types that can be translated into new CTC and ctRNA/DNA targets in the future.

CIRCULATING NUCLEIC ACIDS FOR PRENATAL DIAGNOSTICS

Traditional methods of sampling fetal genetic material for a definitive diagnosis, such as chorionic villus sampling and amniocentesis, are invasive and expose the fetus to the risk of spontaneous miscarriage. The discovery of cell-free fetal DNA (cffDNA) in the circulation of pregnant women has led to noninvasive genetic and chromosomal assessment of the fetus through the sampling of maternal peripheral blood. The clinical introduction of cffDNA tests has substantially reduced the number of invasive procedures performed worldwide.

The risk for Down syndrome, with an incidence rate of 1 in 800 pregnancies, is the predominant reason for women seeking prenatal diagnosis. Strategies have been devised to identify high-risk pregnancies without invasive procedures by combining maternal age, serum biochemical markers, and ultrasonographic findings. However, false-positive rates are high. To improve the sensitivity and specificity of prenatal screening, methods for direct detection of the core pathology of the condition were needed; for example, trisomy 21 for Down syndrome. To this end, noninvasive methods have been developed to provide access to fetal DNA for analysis.

Cell-Free Fetal DNA in Maternal Plasma

Although it is hard to capture the rare, intact fetal cells in the maternal circulation, fetal DNA in the cell-free portion of maternal blood; namely, plasma and serum is more prevalent. Chromosome Y DNA was first detected in the plasma and serum of women who were pregnant with male fetuses, but not in women with female fetuses, in 1997. Many properties and uses of circulating cffDNA have now been investigated. cffDNA analysis is currently used for routine prenatal testing.

BIOLOGY OF CIRCULATING CELL-FREE FETAL NUCLEIC ACIDS IN MATERNAL PLASMA

Every milliliter of maternal plasma contains thousands of genome-equivalents of cell-free DNA, with the fetus contributing a minor proportion. In other words, the majority of the cell-free DNA in maternal plasma is derived from the mother. The median amount of cffDNA as a proportion of the total DNA in maternal plasma, termed the “fetal fraction,” is around 10% in the first and second trimesters and around 20% during the third trimester. The absolute concentration of

TABLE 49.4 Comparison Between Circulating Tumor Cell Free DNA and Circulating Tumor Cells

ctDNA	CTCs
Minimal amount of blood (<2 mL)	Larger blood draw (>7 mL)
Logistically easier to assay due to purity of ctDNA	Logistically difficult to assay due to small number of cells and purity
More informative	Less informative for the sample used
Easily quantifiable due to high-sensitivity molecular assays	Difficult to quantify due to heterogeneity and cell recovery
Easier to assess tumor heterogeneity	Tumor heterogeneity is difficult to assess
Identifies presence of tumor	Identifies presence of tumor
Cannot identify metastasis occurring	Can identify metastasis occurring
Highly diagnostic	Diagnosis not dependable clinically
Prognostic	Prognostic
Can identify tumor resistance during therapy	Poor in identifying tumor resistance during therapy

CTC, Circulating tumor cells; ctDNA, circulating tumor cell free DNA.

cffDNA increases with gestational age, probably as a consequence of the increase in placental tissue mass.

Fetal DNA molecules are first detectable in maternal plasma around the 10th week of gestation. cffDNA is cleared from maternal plasma very rapidly after delivery with a half-life of about an hour, revealing that fetal DNA molecules in maternal plasma have a high turnover rate with efficient clearance. Renal clearance studies show that renal excretion is only a minor component of fetal DNA clearance. Despite the rapid clearance kinetics, cffDNA amounts to some 10% to 20% of the total DNA in maternal plasma, suggesting that substantial amounts of fetal DNA may be released continuously.

Cell-free DNA is a metabolic by-product of cell death and is therefore present in the circulation as short fragments in a “cell-free” form. The size profile of cell-free DNA molecules indicates that fragments are generally shorter than 200 bp (Fig 49.8). The most frequently represented size in plasma is 166 bp in length, and 166 bp corresponds to the length of DNA that is wound around a histone core with a linker. This characteristic size suggests that cell-free DNA is mainly derived from mononucleosomes. Interestingly, cffDNA molecules are somewhat shorter, and the most frequently represented size is 142 bp in length. This shorter length corresponds to the length of DNA wound around a histone core without a linker. This implies that the fetal DNA molecules may have undergone further steps of degradation compared to maternal DNA in maternal plasma. In addition to these dominant peaks, there are smaller amounts of cell-free DNA

that are successively shorter in 10-bp increments. This observation suggests that DNase participates in the degradation of cell-free DNA because DNase cutting sites are located every 10 bases around the nucleosomal DNA.

Fetal Chromosomal Aneuploidy Screening

Down syndrome is one of the key reasons for couples to consider prenatal diagnosis. Therefore the key to achieving non-invasive prenatal detection of Down syndrome is to provide evidence that increased copies of chromosome 21 are present in maternal plasma. The majority of the DNA in maternal plasma, including DNA from chromosome 21, originates from the mother who has a normal amount of chromosome 21. If the fetus has trisomy 21, it would contribute additional amounts of chromosome 21 into maternal plasma. Therefore the additional amount of cell-free chromosome 21 DNA molecules in maternal plasma is dependent on the fetal fraction (i.e., the percent of fetal DNA in the background of maternal DNA in the plasma). The higher the fetal fraction, the easier the identification of trisomy 21–associated changes in maternal plasma.

Methodological Approaches

To precisely quantify and detect this small additional amount of chromosome 21 DNA, most protocols utilize massively parallel sequencing. One approach is based on random or shotgun sequencing of maternal plasma DNA. If a random fraction of all cell-free DNA fragments are sequenced, the relative amount of

Fig. 49.8 Size distribution of fetal, mitochondrial, and total DNA. Numbers denote the DNA size in bps at the peaks. Schematic illustrations of the structural organization of a nucleosome are shown above the graph. From left to right, DNA double helix wound around a nucleosomal core unit with the sites for nuclease cleavage shown; a nucleosome core unit with approximately 146 bp of DNA wound around it; and a nucleosomal core unit with an approximately 20-bp linker intact.

DNA obtained from each segment across the genome should reflect the relative DNA contribution of that segment in the genome. To determine the relative amount of DNA from each segment—say, each chromosome—one determines the number of DNA molecules sequenced from that chromosome as a proportion of all molecules sequenced from the sample. The relative amount, or genomic representation, is then compared

with the expected amount for the same chromosome among a control group of samples representing euploid pregnancies (Fig. 49.9). If a sample shows a genomic representation of chromosome 21 that is significantly different (e.g., more than three standard deviations) from the control group, the amount of chromosome 21 is considered elevated and therefore suggestive of trisomy 21.

Fig. 49.9 Schematic illustration of the procedural framework for using massively parallel genomic sequencing for the noninvasive prenatal detection of fetal chromosomal aneuploidy. Fetal DNA (*thick blue fragments*) circulates in maternal plasma as a minor population among a high background of maternal DNA (*black fragments*). A sample containing representative DNA molecules in maternal plasma is obtained. Plasma DNA molecules are sequenced, and the chromosomal origin of each molecule is identified through mapping to the human reference genome by bioinformatic analysis. The number of sequences mapped to each chromosome is counted and then expressed as a percentage of all unique sequences generated for the sample, termed $\% \text{chrN}$ for chromosome N. Z-scores for each chromosome and each test sample are calculated using the formula shown. The z-score of a potentially aneuploid chromosome is expected to be higher for pregnancies with an aneuploid fetus (cases E to H) than those with a euploid fetus (cases A to D). (From Chiu, R. W. K., Allen Chan, K. C., Gao, Y., Lau, V. Y. M., Zheng, W., Leung, T. Y., et al. [2008]. Noninvasive prenatal diagnosis of fetal chromosomal aneuploidy by massively parallel genomic sequencing of DNA in maternal plasma. *Proc Natl Acad Sci U S A*, 105, 20458–20463.)

Because this approach is based on random whole-genome sequencing, it could in principle be applied to other chromosomal aneuploidies, such as trisomy 18 and trisomy 13, and the sex chromosome aneuploidies, such as Turner syndrome, 45 X0, and Klinefelter syndrome, 47 XXY. The protocol could also be repurposed for the detection of microdeletion and microduplication syndromes.

Clinical Implementation

cffDNA-based noninvasive prenatal screening for fetal chromosomal aneuploidy became clinically available in 2011. Within 3 years, service availability extended to over 60 countries. In general, cffDNA-based noninvasive prenatal screening achieved detection rates of about 99% for Down syndrome with less than 1% false-positive rates. Depending on the specific protocol used, the detection rates for trisomy 18 and trisomy 13 are about 90% or greater with less than 1% false-positive rates. cffDNA-based prenatal screening has achieved better detection sensitivities and specificities than screening by maternal serum biochemistry and/or fetal ultrasonography. However, false-positive cases still occur, and therefore cffDNA assessment is still a screening procedure and not a definitive diagnosis. All clinical guidelines recommend that cffDNA tests with positive findings suggestive of chromosomal aneuploidy should be confirmed by tests on fetal genetic material collected by conventional invasive methods such as chorionic villus sampling or amniocentesis.

ANALYTICAL ASPECTS

Cell-free nucleic acids exist in plasma in the form of short fragments and are present in low abundance. The key to successful analysis of cffDNA lies in the preservation and maximization of the fetal fraction in the maternal blood sample. Thus attention to a number of preanalytical and analytical details is important to ensure the quality of the analysis.

Maternal Blood Sample Collection and Processing

One advantage of cffDNA analysis for prenatal screening is that, unlike maternal serum biochemistry testing, the use of the cffDNA tests is not restricted to a specific gestational period. This is because the cffDNA tests target the detection of the core pathologies of the fetus that exist throughout the pregnancy. However, during the earliest stage of pregnancy, there may not be a sufficient amount of fetal DNA in the maternal circulation. While cffDNA has been detected in maternal plasma in individual pregnant women from as early as 18 days of pregnancy, they become quantitatively sufficient for most testing purposes from about the 11th week of pregnancy. Between 9 to 13 weeks of gestation, 2% of pregnancies show fetal DNA fractions that are below 5% and are prone to potential false-negativity.

Maximizing the fetal DNA fraction in the maternal sample is a key factor to many cffDNA tests. With such a consideration, maternal plasma is preferred over maternal serum.

Clotting of the maternal blood cells results in the release of more maternal DNA into serum as compared to plasma. While the absolute fetal DNA amounts in plasma and serum are similar, the fetal DNA fraction is significantly reduced in serum.

After the maternal peripheral blood samples are collected, plasma is harvested via centrifugation. The goal of centrifugation is to minimize the residual maternal blood cells in the sample. Reduction in maternal DNA contamination results in maximization of the fetal fraction. Therefore two-step centrifugation protocols are recommended. The plasma supernatant is carefully harvested after the first centrifugation with care not to disturb the underlying maternal blood cell layer. With the second centrifugation, the remaining cells in the form of a cell pellet are separated from the final supernatant. The resultant plasma can be stored frozen until further analysis.

Circulating Cell-Free Fetal DNA Analysis

A significant amount of cffDNA has a length shorter than 100 bp. For plasma DNA extraction, a protocol that is efficient in preserving the small DNA molecules is advantageous. Researchers have used size-selection methods to increase the proportional representation of short DNA within the sample to improve the detection of fetal DNA. In addition, the detection of short DNA from maternal plasma can be used to detect fetal disorders. The rationale is that when the fetus has an aneuploidy, such as trisomy 21, there should be an additional dose of short DNA from chromosome 21. Therefore the overall size profile of the chromosome 21 DNA molecules is shorter than that of other nonaneuploid chromosomes.

Measuring the Fetal DNA Fraction

Analysis of the fetal DNA fraction is an important quality control parameter for cffDNA analysis. The statistics developed to determine the presence or absence of a significant difference in chromosome dosage or allelic ratio is dependent on the sample containing at least a certain amount of fetal DNA. Therefore, for the tests based on massively parallel sequencing, the proportion of chromosome Y sequences is often used as a fetal fraction measurement for chromosome-Y-positive samples. A panel of placenta-specific DNA methylation markers has also been developed to quantify the fetal DNA. The proportion of short DNA in a sample is also a reasonable measure of the fetal DNA fraction.

Massively Parallel Maternal Plasma DNA Sequencing

The advantage of massively parallel sequencing-based cffDNA assessment is that many maternal plasma DNA molecules can be analyzed per sample, regardless of whether the DNA fragment is originating from the fetus or the mother. For quantitative sequencing applications, such as for fetal chromosomal aneuploidy detection, the key to success is to maximize the signal-to-noise ratio of the sequencing data covering the genetic abnormality of interest. Trying to maximize the fetal

fraction improves the chance of detecting the fetal abnormality. Increasing the sequencing depth either for random or targeted sequencing improves the precision, and thus reduces the noise, for genomic representation or allelic ratio assessments. The size of the genomic locus of interest also matters. At the same sequencing depth, larger loci, such as whole chromosome aneuploidies, are much easier to detect than subchromosomal aneuploidies. Thus protocols for the detection of subchromosomal aneuploidies require higher sequencing depths. The current massively parallel sequencing protocols also suffer from a certain extent of GC bias. To reduce the imprecision surrounding the quantitative measurement of cfDNA by sequencing, GC normalization steps are typically included in the bioinformatics analysis of the data. This is especially important for the detection of aneuploidies in GC-rich chromosomes, such as chromosomes 13 and 18.

On the other hand, current massively parallel sequencing protocols have a sequencing error rate that cannot be ignored. This has an impact on the detection of single-nucleotide

variants of the fetus, such as point mutations, polymorphic alleles, and de novo mutations. Because cfDNA is the minor species of DNA in maternal plasma, high-depth sequencing is needed to detect fetal single-nucleotide variants. Yet, the higher the total number of bases sequenced, the higher the chance for sequencing errors. Thus extra care is needed in designing protocols for the detection of fetal single-nucleotide variants by sequencing. For example, targeted capture of loci of interest followed by sequencing is one feasible option. Targeted sequencing allows a high depth to be achieved without sequencing a high total number of bases, thereby reducing the number of sequencing errors detected and improving the signal-to-noise ratio.

ACKNOWLEDGMENT

The authors wish to acknowledge the original contributions of Aaron D. Bossler and Angela M. Caliendo, on which portions of the Infectious Disease section of this chapter are based.

REVIEW QUESTIONS

- What is generally considered a significant change in a patient's HIV-1 viral load?
 - 0.2 log₁₀ copies/mL
 - 0.3 log₁₀ copies/mL
 - 0.5 log₁₀ copies/mL
 - 1.0 log₁₀ copies/mL
- For nucleic acid testing of CT and NG, how long do NAATs remain positive after successful treatment of patients?
 - 1 day
 - 1 week
 - 3 weeks
 - 3 months
- Which is a gene target used extensively in taxonomic metagenomics studies?
 - 5S rRNA
 - 16S rRNA
 - 23S rRNA
 - 30S rRNA
- Which of the following is the most common mutation identified in the *CFTR* gene?
 - p.Arg68Cys
 - p.Arg117His
 - p.Ile507del
 - p.Phe508del
- Which of the following *HTT* genotypes would be diagnostic for Huntington disease? CAG repeats of:
 - 17 and 34
 - 19 and 45
 - 12 and 15
 - 14 and 27
- Whole exome sequencing is most useful in patients:
 - with a constellation of findings associated with a known microdeletion syndrome
 - with a phenotype suspected to be the result of a balanced translocation
 - with a constellation of findings that are not associated with any known disorder
 - with a phenotype suspected to be related to a mutation in a single gene
- What is the most common ctDNA used for clinical tests in cancer patients?
 - methyated DNA
 - integrated DNA
 - amplified genomic DNA
 - mutation in DNA of gene exons
 - viral DNA
- In nasopharyngeal carcinoma patients, what viral ctDNA is of clinical utility?
 - Herpes virus
 - Papilloma virus
 - EB virus
 - HIV virus
- In non-small cell lung cancer patients, what cancer mutation and detection method is most frequent and FDA approved for ctDNA monitoring of the respective targeted therapy?
 - BRAF
 - EGFR
 - KRAS
 - P53
- What are the main benefits of CTCs analysis?
 - It is easy, standardized, and high throughput
 - It can give valuable prognostic and predictive information for the presence of active metastasis in cancer patients both at the DNA, and at the gene expression level
 - CTCs are directly comparable with the primary tumor
 - CTCs are all identical and thus easy to detect at very low levels

11. Cell free-fetal DNA
 - a. is predominantly cleared via the maternal kidneys
 - b. is predominantly shorter than the maternally derived cell-free DNA in maternal plasma
 - c. shows a peak size of 246 bp
 - d. is the predominant species of cell-free DNA in maternal plasma
 - e. is predominantly derived from the fetal liver
12. Analysis of cell-free fetal DNA
 - a. using maternal serum is preferred over maternal plasma
 - b. is only applicable during the second trimester of pregnancy
 - c. could only be achieved by the detection of chromosome Y
 - d. is important to assess the fetal fraction
 - e. cannot be based on massively parallel sequencing due to its scarce quantity
13. Noninvasive fetal chromosomal aneuploidy assessment by circulating cell-free fetal DNA analysis
 - a. is only applicable to trisomy 13
 - b. could be preceded by conventional maternal serum biochemistry screening
 - c. shows equal performance for chromosome 21 and the sex chromosomes
 - d. is not applicable to the deletion of fetal microdeletion
 - e. is restricted to the third trimester of pregnancy
14. The most sensitive method for routine molecular monitoring of response to TKI therapy in chronic myelogenous leukemia patients is
 - a. fluorescence in situ hybridization
 - b. massively parallel sequencing
 - c. RT-qPCR
 - d. karyotyping
15. *TP53* loss of function mutations confer a poor prognosis in hematopoietic malignancies as *TP53* generally plays the role of
 - a. receptor tyrosine kinase
 - b. tumor suppressor
 - c. RNA splicing molecule
 - d. chromatin modifier
16. *BRAF* V600E mutation is an example of a mutation which affects signal transduction pathways and is commonly detected in
 - a. Acute myeloid leukemia
 - b. Chronic myelogenous leukemia
 - c. Myelodysplastic syndrome
 - d. Hairy cell leukemia

Reference Information for the Clinical Laboratory

Khosrow Adeli, Ferruccio Ceriotti, Victoria Higgins

OVERVIEW

Laboratory tests are ubiquitously used in clinical practice to screen, diagnose, and monitor patients for several medical conditions. To correctly interpret laboratory test results, physicians often use reference intervals (i.e., normal ranges) as a health-associated benchmark by which to compare patient test results. If a laboratory test result falls within the reference interval, the patient is considered to be within a healthy range for that particular test. On the other hand, if a laboratory test result falls outside the reference interval, the patient may require follow-up testing to confirm the presence of a particular medical condition. Therefore, population-based reference intervals are a fundamental tool in laboratory medicine to assess health status.

Although the concept and utility of reference intervals appear straightforward, their establishment can be challenging and complex, particularly for the pediatric population. Determining robust reference intervals requires a sufficiently large reference population (120 individuals per partition according to CLSI EP28-A3c) comprised of representative, healthy individuals. Recruiting a healthy pediatric population can pose additional challenges due to parental consent, small blood sample volume, and the large number of healthy subjects required. Due to the profound stages of growth and development throughout childhood and adolescence, these populations often additionally require several age and sex partitions.

Given the complexity of reference interval establishment, it is difficult for most laboratories to undertake this task, and instead, they often use reference intervals established from other laboratories, textbooks, or manufacturer product inserts. Unfortunately, several of these sources often do not use appropriate sampling methods (e.g., sample from patient populations) and/or statistical procedures to establish reference intervals, leading to inaccurate test result interpretation. In addition to the lack of evidence-based reference intervals in clinical use, many laboratories use reference intervals that were established using a different analytical instrument or population. Prior to adopting a reference interval, each clinical laboratory must ensure that the analytical method used to establish the reference interval is comparable to the method used for patient testing. Moreover, it is not yet clear to what extent ethnicity and/or local environmental factors influence reference intervals for specific analytes, and therefore reference intervals

developed based on one reference population may not be applicable to a laboratory serving a different population.

It is important to note that despite the application of exclusion criteria to reference populations (i.e., populations used to establish reference intervals), they may still include individuals with subclinical conditions. Therefore, although reference intervals are a useful tool for clinicians, they should not be used as definitive limits of health and disease.

The reference intervals presented in the following tables are for general informational purposes only. Each individual laboratory should generate its own set of reference intervals or validate published reference intervals based on the CLSI EP28-A3c guidelines (CLSI document EP28-A3c. Wayne, P. A.: Clinical and Laboratory Standards Institute, 2010; p. 30-34).

Reference Interval and Critical Value Tables

- **Table A1.** Pediatric and Adult Reference Intervals for Biochemical Markers (Serum, Plasma, Urine, and Whole Blood)
- **Table A2.** Pediatric and Adult Critical Values (Risk Thresholds) for Biochemical Markers

CHAPTER OUTLINE

Tables A1 and A2 include up-to-date reference intervals and critical values obtained from recent studies of pediatric and adult reference values for several biochemical markers. Wherever possible, data from recent, large a priori reference interval studies based on healthy populations have been used to update each table with robust reference information. Where no new data were available, reference intervals from the *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics*, 6th edition tables are presented.

Table A1 provides pediatric and adult reference intervals for several biochemical markers. The majority of pediatric reference intervals presented in this table are based on recent data published by the Canadian Laboratory Initiative on Pediatric Reference Intervals (CALIPER), a national research project that has established age- and sex-specific pediatric reference intervals based on thousands of healthy community children and adolescents. As noted in the table, the majority of CALIPER reference intervals were determined on Abbott Architect assays. For specific biochemical and endocrine markers, both pediatric and adult reference

values were obtained through the recent Canadian Health Measures Survey (CHMS), a study of approximately 12,000 children, adults, and the elderly. CHMS reference intervals were determined based on numerous platforms, including Ortho Clinical Diagnostics and Siemens, as noted in the table. Other reference intervals were adopted primarily from reference tables in *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics*, sixth edition.

Table A2 provides a table of pediatric and adult critical risk values. Notifying clinical staff of critical results is an important post-analytical process in all acute care clinical laboratories. Data from numerous sources (including CLSI Guideline GP47. Wayne, P. A.: Clinical and Laboratory Standards Institute, 2015; p. 100) are included in this table of critical risk values to assist laboratories in establishing and updating their critical risk result management policy.

TABLE A1 Pediatric and Adult Reference Intervals for Biochemical Markers

Analyte	Specimen	Condition	REFERENCE INTERVALS		
			Conventional Units	Conversion Factor	SI Units
α 1-Acid glycoprotein Pediatric values (0–19 years) based on Abbott Architect method	S	0–<6 months	mg/dL	0.01	g/L

Acid-citrate-dextrose (ACD), 963

Acidemia, 688, 885–887

Acidosis, 663

lactic, 383, 694

metabolic, 663

anion gap, 693–694, 693f, 693b

bicarbonate for, 692–695

characteristics of, 692t

compensatory mechanisms in, 695

renal tubular, 669, 695

respiratory, 692t, 696, 696b–697b

compensatory mechanisms in, 696

Acinus, of liver, 702, 703f

Acrodermatitis enteropathica, 493

Acromegaly, 778

ACS. *see* Acute coronary syndrome

Activation energy barrier, 222f

Activator, 226

Active center, 217

Active transport, 682

Activity, 146

Acute abdomen, 741, 741b

Acute coronary syndrome (ACS), 633

atherosclerosis, 633

causes of, 633

clinical history in diagnosis of, 633–634

definition of, 630

Acute hepatitis, 711–712, 711t

Acute intermittent porphyria (AIP), 530t

Acute kidney injury (AKI), 660, 664–666, 665t, 666b

Acute myocardial infarction (AMI), 630

definition of, 634b

diagnosis of, 634, 634b

electrocardiogram for, 633f

guidelines and, 640, 642f

precipitating factors, 633

Acute pancreatitis, 323, 324f, 741–742, 742b

Acute phase response, 305, 306b

Acute photosensitivity, without skin

fragility, 534

Acute porphyrias, 525, 531, 532b

clinical features of, 531, 531t

differentiation between, 534

genetic testing in, 538b

management of, 531

patient presenting with suspected, 533–534

Acute renal failure (ARF), 660

Acute respiratory viral infection, 965

Acute rhabdomyolysis, 316

Acute tubular necrosis (ATN), 664

Acute viral hepatitis, 712

Acute-phase response, 467

Acylcarnitine, 891

Acylcholesterol acyltransferase, 393, 395f

Acylglycerols, 396–399, 398f

Adalimumab (ADA), for inflammatory bowel disease, 735

Adapter, 956

Addison disease, 793–794, 795f–796f, 795b, 797t

Adenohypophysis

description of, 774–776, 775t

hormones produced by, 774

Adenomas, toxic, 827

Adenosine triphosphate

hydrolysis, 656

production of, 395

Adiponectin, 442t–444t

Adrenal carcinoma, 802

Adrenal cortex, 787–810, 808b

hormones secreted by, 788

laboratory evaluation of

aldosterone, 806–807

cortisol, 805–806

11-deoxycortisol, 807

specimens for, 804

suppression tests, 796–798

Adrenal cortex disorders

congenital adrenal hyperplasia, 801–802

Cushing syndrome. *see* Cushing syndrome

description of, 791–803

hypoadosteronism, 794–795

Adrenal glands

anatomy of, 788–789, 789t

steroid hormones secreted by. *see* Steroid hormones

Adrenal insufficiency, 793–794, 795f–796f, 795b, 797t

Adrenal medullary system, 456

Adrenal tumors, 802

Adrenarche, 844

Adrenocortical steroids

circulation of, 791

glucocorticoids. *see* Glucocorticoids

regulation of, 789–791

Adrenocorticotrophic hormone (ACTH)

in adrenal insufficiency, 793

biochemistry of, 780

in Cushing syndrome, 795–796

deficiency, 796b

definition of, 774, 780

reference intervals for, 989t–1025t

stimulation tests, 793, 794b

Adsorption chromatography, 191f

Adult-onset diabetes, 605

Advanced glycation end products, 624–625

Advanced Medical Technology

Association, 5

Adverse drug reactions (ADR), 898–899

Affinity, 238
